### LIST OF CONTRIBUTORS

### TO VOLUME II.

- Dr. E. F. ARMSTRONG, FIC, F.RS. [CARBOHYDRATES; DEXTRINS, DIASTASE; EMULSIN.]
- HARRY BAKER, Esq., F.I.C. (The Castner Kellner Company, Weston Point). [Chlorine.]
- Professor C. O. BANNISTER, The University of Liverpool [Copper, Metallurgy of.]
- Dr. GEORGE BARGER, M.A., F.R.S., Professor of Chemisty in relation to Medicine in the University of Edinburgh. [Calumba; Cascara Sagrada; Cascarilla Bark, Cheiroline; Choline and Related Substances; Chrysarobin, Colchicum; Colocynth; Conine and the Alkaloids of Hemlock, Curara; Cusparia Bark; Dandelion Root; Digitalis, Dulcamara; Elaterium; Ergot of Rye; Eriodiamine, Erythrophleine; Eserine; Euonymus.]
- G. S. BLAKE, Esq, ARSM, B.Sc, M.IMM. [CHROMIUM.]
- BERTRAM BLOUNT, Esq., F.I.C. [CEMENT.]
- Professor W A BONE, D.Sc, F.R.S, Imperial College of Science and Technology, South Kensington, and ERNEST BURY, Esq, M.Sc, O B.E., The Skinningrove Iron Co, Ltd. [Coke Manufacture and the Recovery of By-Products]
- Professor W. A. BONE, D.Sc., F.R.S., and Professor R. V. Wheeler, D.Sc. [Gaseous Explosion.]
- Professor J S. S BRAME, FIC. [PROTECTION OF METALS FROM CORROSION.]
- JOSEPH BURTON, Esq. (Pilkington Tile and Pottery Co., Clifton Junction, Manchester).
  [Clay]
- Dr. J. C. CAIN, F.I.C, Editor of the Journal of the Chemical Society, London. [Disazo- and Tetrazo- Colouring Matters]
- Sir DUGALD CLERK, K B.E , LL D., F.R.S. [EVAPORATION.]
- Dr. JULIUS B COHEN, FR.S., Professor of Organic Chemistry in the University of Leeds. [Diphenylamine, Diphenylmethane.]
- W. H. COLEMAN, Esq. [CARBOLIC ACID, CREOSOTE.]
- JAMES CONNAH, Esq., B.A., B.Sc., FI.C., Deputy Principal, The Government Laboratory, London [Chartreuse, Chocolate; Cocoa, Coffee, Cordials and Liqueurs, Denaturants.]
- C. F. CROSS, Esq., B.Sc, F.I.C., F.R.S. [CELLULOSE]
- Sir JAMES J. DOBBIE, M.A., D Sc, LL D, F.R S, late Principal of the Government Laboratory. [Corydaline and the Corydalis Alkaloiis.]
- Dr. THOMAS EWAN, M Sc. (Cassel Cyanide Co., Ltd., Glasgow). [Cyanides ]
- Dr. ARTHUR J EWINS (Messrs. May & Baker, London). [CHLOROFORM; CYTISINE; DAMASCENINE.]
- SAMUEL FIELD, Esq, Northampton Polytechnic Institute, Clerkenwell, London. [Electrodeposition and Electroplating.]
- Dr. J. A. NEWTON FRIEND, F.I.C [CORROSION OF METALS.]
- W. M. GARDNER, Esq., M.Sc., Dyeing Department, Technical College, Bradford. [Dyeing; Dye-stuffs, Identification of, on Fabrics.]
- JOHN GOLDING, Esq., D.S.O., F.I.C., University College, Reading. [Cheese.]
- Dr. J. N. GOLDSMITH, M.Sc., F.I.C. [CELLULOID.]
- Dr. ERNEST GOULDING, F.I.C., Imperial Institute, South Kensington. [Cotton.]
- SIR ALFRED D. HALL, K C.B, F R S., Board of Agriculture. [Cereals; Crops]
- Professor G. G. HENDERSON, M.A., D.Sc., LL.D., F.R.S., The University, Glasgow. [Catalysis in Industrial Chemistry.]
- T. H. P HERIOT, Esq , F.I.C., Ronal Technical College, Glasgow. [Decolourising Carbons]
- J. W. HINCHLEY, Esq., A R.S M, Professor of Chemical Engineering, Imperial College of Science and Technology South Kinsington. [CRYSTALLISATION.]

- GEORGE T. HOLLOWAY, Esq., A.R C.S., F.I.C. [COLUMBIUM.]
- BERNARD F. HOWARD, Esq., and OLIVER CHICK, Esq. (Messrs. Howard & Sons, Ilford). [CINCHONA ALKALOIDS.]
- Dr. HARRY INGLE. [CORK.]
- HERBERT INGLE, Eq., B.Sc., FI.C., late Chief Chemist to the Transvaal Agricultural Department. [Carrot; Cassava; Castor Seeds; Celery; Cherry; Chestnut, Chick Pea; Chicory; Clover; Cranberry; Cucumber; Date; Egg Fruit; Elderberry]
- HAROLD KING, Esq., M.Sc. [CAMPHOR.]
- VIVIAN B. LEWES, Esq , F.I.C. [CORROSION AND FOULING OF STEEL AND IRON SHIPS AND THEIR PREVENTION.]
- Dr. JULIUS LEWKOWITSCH, M.A, FI.C. (Revised by C. A. Mitchell, Esq., M.A., F.I.C.) [Cameline Oil; Candles, Candle-nut Oil, Castor Oil, Chaulmoogra Oil Group, Chinese Vegetable Tallow; Chocolate Fats, Coco-nut Oil Group; Cod Liver Oil; Cotton Seed Oil; Curcas Oil, Dégras or Sod Oil; Dika Fat Group; Driers, Edible Oils and Fats.]
- WILLIAM D. McCREATH, Esq (The Quantock Vale Cider Co., Ltd., North Petherton, Bridgwater). [Cider.]
- CHARLES A. MITCHELL, Esq., M.A , F.I.C. [CANDELILLA WAX; COPYING OR INDELIBLE INK PENCILS.]
- PROFESSOR GILBERT T. MORGAN, O B.E., D.Sc, F.R.S, Professor of Chemistry in the University of Birmingham. [Cerium; Cerium Metals and Earths; Diazo-Compounds; Dysprosium; Erbium, Europium.]
- L. MYDDELTON NASH, Esq , F.I.C. [CASEIN.]
- Professor A. G. PERKIN, F.R.S., F.I.C., Department of Color r Chemistry in the University of Leeds. [Camwood; Catechu, Catellagic Acid; Cedrela Toona, Chamomile Flowers, Chay Root; Chestnut Extract, Chica Red and Carajura, Chromone; Clover Flowers; Coprosma; Coto Bark; Cotton Flowers; Cotton Seed, Colouring Matter of, Courmaranone Group, Cyanellagic Acid; Daphnetin, Datisca Cannabina; Delphinium Consolida, Diphenyl-dimethylolid, Divi-Divi, Drosera Whittakeri; Dyer's Broom; Ellagic Acid, Ellagitannic Acid, Eriococcus Coriaceus; Erythrin; Evodia Meliafolia]
- Professor A. G. PERKIN, F.R.S., and Dr. ARTHUR E. EVEREST. [Cochineal, Evernic Acid and Everninic Acid.]
- Professor J. C. PHILIP, O.B E., D Sc , F.R.S., Imperial College of Science and Technology. [Chemical Affinity; Colloids; Cryoscopy, Diffusion.]
- Dr. SAMUEL RIDEAL, FI.C., and Dr. ERIC K RIDEAL, M.B.E., M.A., F.I.C. [DISINFECTANTS.]
- Dr. F. W. RUDLER, I.SO. [ENAMELS.]
- Dr. SYDNEY SMITH, B Sc , F.I.C. (Wellcome Chemical Works, Dartford). [Cocaine and the Coca Alkaloids]
- L. J. SPENCER, Esq., M.A, F.G.S, Mineral Department, British Museum. [Carbonite, Carclazite, Carnallite, Carnotite, Cassiterite, Catapleite, Celestite; Cerargyrite, Cerite, Cerussite, Chalcanthite; Chalcedony, Chalk, Chalmersite, Chalveite; China-Stone; Chiolite, Chloanthite, Chronite, Chrysoberyl, Chrysocolla; Chucchite; Cinnabar; Cinnamon Stone; Clayite; Cobaltite; Colemanite; Collophanite; Columbite; Copper-glance; Copper Pyrites; Cordylite; Crudum; Covellite; Cristobalite; Crocidolite; Crocoite, Crookesite; Cryolite; Cryolithionite, Cuprite, Cylindrite, Danalite; Datolite, Descloizite, Diabase; Diallage; Diamond; Diaspore, Diatomite; Dietzeite, Diopside, Dioptase; Diorite; Dolerite; Dolomite; Domeykite; Dysanalyte; Dyscrasite; Emboyite, Emery; Enstatite; Epidorite; Epidote, Epsomite; Erythrite; Eucairite; Euclase; Eucryptite; Euclalyte; Euxenite.]
- Dr. J. SUDBOROUGH, F.I.C., Professor of Chemistry in the Indian Institute of Science. [Esterification.]
- Professor JOCELYN F. THORPE, C B.E., F.R.S., Imperial College of Science and Technology, South Kensington. [Diphenyl.]
- Professor EDWIN R. WATSON, M.A., D.Sc., Dacca College, East Bengal. [COLOUR AND CHEMICAL CONSTITUTION]
- Dr. M. A. WHITELEY, O.B.E., F.I.C., A.R.C.S., Assistant Professor of Organic Chemistry, Imperial College of Science and Technology, South Kensington. [Carnine; Carnitine; Carnosine; Creatine; Creatine; Cystine; Dialuric Acid; Dilituric Acid]
- Dr. SYDNEY YOUNG, Sc.D., F.R.S, F.I.C., Professor of Chemistry, Trinity College, Dublin [Distillation.]

### DICTIONARY

OF

### APPLIED CHEMISTRY.

CALAFATITE v. ALUNITE.

CALCULI v. URINE.

CALCUSOL. Trade name for a preparation of acid potassium carbonate and piperidine-p-

sulphamine benzoate

CALIATURWOOD. This wood, the botanical origin of which appears to be unknown, is very similar to though somewhat darker in colour than sanderswood It was imported from the East Indies and is stated to have been chiefly employed on the Continent According to Franchimont and Sicherer it contains santalin but in larger amount than sanderswood.

CALICHE. The term by which the impure native sodium nitrate or Chile saltpetre is known throughout South America. Also applied to a limestone hardpan found in Arizona and else-

where (v Sodium)

CALLISTEPPIN v ANTHOCYANINS. CALLUTANNIC ACID v TANNINS. CALMATAMBIN v. GLUCOSIDES.

CALMONAL. Calcium methylbromide. CALOMEL. Mercurous chloride (v. MERCURY).

CALOMELOL. A colloidal preparation of

CALOPHYLLUM INOPHYLLUM (Linn.). A tree (ord Gutisferæ), Alexandrian laurel, dilo of Fiji, tamarınd of E. Polynesia, and sultana champa (Hind.) of India), the seeds of which yield 60 p c. of a fragrant green oil, fluid at ordinary temperatures, solidifying when cooled below 10°. The tree bears fragrant white flowers. The oil, the woondel or bitter oil of Indian commerce, used in medicine and for lamp oil, is of a greenish tint, and a very little imparts its colour to a whole cask of coco-nut oil (Pharm. J. [3] 8, 363).

CALOTYPE v. PHOTOGRAPHY.

Vol. II.—Т.

transversely and dried. It was introduced into Europe in the 17th century as an antidote for poison, and found a place in the London Pharmacopæia of 1788. It possesses mild bitter tonic properties, for which purpose it is now chiefly employed in medicine.

The drug contains 30-35 p c. of starch, some mucilage, traces of a volatile oil, but no tannin; the root gives 4-7 p.c., the rhizome 12-17 p.c of ash. There are further present two bitter

principles and three alkaloids

Columbia  $C_{28}H_{32}O_{9}$  (according to Ulrich, Annalen, 1907, 351, 363; but cp Feist, lc.), the best-known bitter principle, occurs to the extent of 08 pc., and is extracted by hot ether and recrystallised from the same solvent. It forms colourless prisms, mp 182°, hardly soluble in hot or cold water, little in cold alcohol or ether, readily in hot ether, chloroform, and alcohol. Columbin adds directly 8 bromine atoms. A crystalline diacetyl derivative melts at 218°. Bolling 5 pc potassium hydroxide yields columbic acid C<sub>28</sub>H<sub>32</sub>O<sub>10</sub>, crystals, m.p 220° (Frey, Annalen, 1907, 351, 372), bolling 15 pc. hydrochloric acid gives an amorphous yellow substance and yellowish green fluorescence. A second bitter principle, m.p. 246°, almost insoluble in most solvents, was isolated by Feist (Arch. Pharm 1907, 245, 586).

The alkaloids were at first mistaken for berberine, to which they are closely related (Gordin, Arch. Pharm. 1902, 240, 146; Gunzel, ibid. 1906, 244, 257; Gadamer, ibid. 1902, 240, 450; and particularly Feist, ibid. 1907, 245, 586). All three yield yellow quaternary salts The aqueous solution of an alcoholic extract of the drug is extracted with ether to remove columbin (see above), and concentrated potassium iodide then precipitates the iodides, which CALUMBA. Calumbæ radæ, B.P.; Calumba,
U.S.P. Colombo, Columbo. (Racene de Colombo,
Fr.; Kalumba or Columbowurzel, Ger.)
The root of the Jateorrhiza Columba (Miers),
a • herbaceous climbing plant, inhabiting the
forests of Eastern Africa (Fluck. a. Hanb. 23;
Bentl. a. Trim. 13). The fleshy root is sliced

2 CALUMBA

groups and one hydroxyl group; it is a methyl ether of the second, which contains three methoxy and two hydroxyl groups, for methylcolumbamine and dimethyljateorrhizine are Palmatine iodide contains four methoxyl groups, but no hydroxyl, and hence remains undissolved on treating the mixed iodides with sodium hydroxide. Its exact relationship to the other two is unknown Reduction of the corresponding nitrates leads in all three cases to colourless tetrahydio derivatives. Methylcolumbamine is oxidised by permanganate to corydaldine (an oxydation product of corydaline, qv), a trimethoxy-o-phthalic acid (gallo-earboxylic acid?), mp 200°, and a nitrogenous acid, mp 200°-202° The free bases corresponding to the above salts are unknown, so that it is doubtful whether the alkaloids are ammonium hydroxides or the corresponding anhydrides

For the identification of columbin and the alkaloids under the microscope, see Tunmann, Pharm Zentr H. 1914, 55, 775 G B

CALYCANTHINE C<sub>11</sub>H<sub>14</sub>N<sub>2</sub>, crystals, mp 243°-244° (dry), occurs with isocalycanthine, prisms, mp 235°-236° (dry), in the seeds of Calycanthus glaucus (Wild), 2 p.e. One mitrogen is secondary, the other tertiary. Toxic (Gordin, J. Amer. Chem Soc 1905, 27, 144, 1418; 1909, 31, 1305; 1911, 33, 1626)

CAMELINE OIL, Dodder oil, or German

CAMELINE OIL, Dodder oil, or German Sesamé oil, is prepared from the seeds of Myagrum sativum (Crz.), Camelina sativa (Linn), ('gold of pleasure') Several centuries ago the seed was grown all over Germany as a crop, but at present it is only cultivated on a small scale in some part of South Germany, Belgium, Holland, Hungary, the Balkan States, and South Russia. The seed is occasionally expressed in Hull, but, as a rule, the press cakes arrive in this country from Odessa, and are used (in Liverpool) in the manufacture of 'compound cakes' The average composition of cameline seed is stated as follows.—

Oil			-294 рс
Water			75,
Proteins			25 9 ,,
Carbohyd	rates		173,
Crude fib	e		105,
$\mathbf{A}\mathbf{s}\mathbf{h}$			92,

The oil has a golden-yellow colour and a pungent taste and smell. On exposure to the air it dries slowly. It is a semi-drying oil, and therefore yields, on boiling with litharge or manganese, a slowly drying varnish. The low saponification value of the oil points to the presence of crucic acid

The 'cold-drawn' oil is used for edible purposes in Russia. The oil expressed in this country, as also the oil expressed by heat in Hungary and the south of Russia, is used for soap making

It has the following analytical characters sp gr 0 9224-0 9260 at 15°; solidification point, -15°-19°; saponification value, 185-188; iodine value, 133-136; and mp. of fatty acids, 18°-20°; molecular equivalent of fatty acids, 296 A sample examined by Grimme (Chem Rev. Fett Ind 1912, 19, 102) contained 1 16 pc of unsaponifiable matter According to van Ketel and Antusch (Zettsch.

angew Chem 1896, 581), linseed is liable to be contaminated with cameline seed, and so may yield an oil with a low iodine value. J. L

CAMPHOID. A preparation of one part of guncotton dissolved in 20 parts each of absolute alcohol and camphor.

alcohol and camphor.

CAMPEACHY WOOD v. LOGWOOD
CAMPHANIC ACID v. LACTONES.
CAMPHENE, CAMPHINE v. TERPENES.
CAMPHOL v. CAMPHORS.

CAMPHOPHORONE v. KETONES.

CAMPHOR. The term camphor was applied exclusively, in the sixth century, by Arabian and Chinese writers, to Borneo or Malayan Camphor (Borneol), but in the sixteenth century it included Laurel or Common Camphor, for Garcia d'Orta mentions the latter as well known in Europe in 1563, and points out what indeed is true at the present day, that the much more costly Borneo or Sumatra ('amphor is entirely consumed in the East (cf Fluck a Hanb 510) The similarity in properties between laurel camphor and the crystalline separations from the volatile oils of plants, led, in the eighteenth century to an extension of the term camphor so as to include these solids. An attempt by Berzelius (Lehrbuch VI 580) to simplify the nomenclature, by calling all solid portions of volatile oils, 'stearoptenes,' and the liquid portions 'clæoptens' has only resulted in the ' continued use, almost synonymously, of the words stearontene and camphor. The discovery that laurel camphor contains oxygen has still further amplified the meaning of the word, which in its most comprehensive sense now includes most of the oxygenated products, both liquid and solid, of volatile oils.

Camphors are volatile oxygenated hydrocarbons, usually possessing a peculiar characteristic odour. They are mostly crystalline solids insoluble in water, but soluble in alcohol Except in the case of a few which are produced artificially they are obtained from plants where they occur associated with hydrocarbons from which they are probably derived. Most plants when distilled in steam yield volatile oils composed of heavier oxidised compounds held in solution more or less by lighter hydrocarbons. The former often separate in crystals during the condensation of the oil or afterwards on standing.

or they may be obtained by fractional distillation. The more important camphors, using the term in its larger signification, may be considered, for convenience, in 4 groups, as isomerides or homologues of: (1) Peppermint camphor, menthol  $C_{10}H_{20}O$ ; (2) Borneo camphoi, borneol  $C_{10}H_{18}O$ ; (3) laurel camphor  $C_{10}H_{16}O$ ; and (4) thyme camphor, thymol  $C_{10}H_{16}O$  For the most part camphors behave like alcohols or phenols, but laurel camphor and menthone are ketones, cineol is an ether and alant camphor The majority of camphors belong to a lactone saturated or unsaturated cyclic systems, but in 1891 Semmler (Ber 24, 210) introduced the expression 'olefinic camphors' for certain substances which possess an open chain structure, are closely related to the cyclic camphors, and are responsible for the aroma of many essential oils. The chief members of this group are citronellol C<sub>10</sub>H<sub>20</sub>O, geraniol, nerol and citronellas C10H18O, and citral C10H16O. (See l also Perfumes.)

Peppermint camphor. Menthol C<sub>10</sub>H<sub>19</sub>OH. le-6-180propyl-1-cyclohexanol. The lævo 3-Me-6-isopropyl-1-cyclohexanol. modification of this camphor is the chief con stituent of peppermint oil, the product of distillation of the herbs Mentha piperita (Linn) and M. arvensis (Linn), varieties piperascens and glabrata. It is also a minor constituent of a few other volatile oils. A menthol of unrecorded rotatory sign predominates in the oil from Hyptis suaveolens (Linn) (Bacon, Phillipine J. Sc. 1909, 4, A, 130). The proportion of menthol n normal Japanese oil of peppermint varies between 69 and 91 pc, whilst English and American oils contain 48 to 68 pc A portion, about 10 p c., of the menthol is present in ester form combined with acetic and isovalerianic acids The camphor is extracted by freezing oils rich in menthol, whereby the crystals separate and are recovered either by pressure or by centrifugal treatment. The more important papers dealing with menthol in its bearing on oil of peppermint are: Beckett and Wright (Chem. Soc Trans. 1876, 29, 1), Atkinson and Yoshida (ibid. 1882, 41, 50), Moriya (ibid. 1881, 39, 77), Power and Kleber (Arch. Pharm. 1894, 232, 639), Power and Fluckiger (Pharm J 1880 [3] 11, 220), Andres and Andred (Ber 1892, 25, 609), Schindelmeiser (Apoth Zeit 1906, 21, 927), and the semi-annual reports of Schimmel and Co, and of Roure Bertrand Fils.

Menthol crystallises in prisms belonging to the hexagonal system, and in appearance resembles magnesium sulphate It has a strong peppermint odour and taste, and produces a sensation of warmth on the tongue which is replaced by a sensation of cold when air is replaced by a sensation of cold when all is inhaled M p 42°-43°, 43 5°-44 5° (Gildemeister and Hoffmann, Die Atherischen Ole, 1910, i. 405), b p 215 5° at 758 mm (P. a K.), sp gr. 0 88 at 20° (Long, J Amer Chem. Soc 1892, 14, 151),  $[\alpha]_{\rm D}^{20^{\circ}} -50$  7° in 10 p c alcoholic solution (Beckmann, J. pr Chem 1897, [2] 55, 15). Menthol is very slightly soluble in water, but soluble in the usual organic solvents and in concentrated hydrochloric acid. It rotates on the surface of water in a similar manner to laurel camphor Mixed with chloral, thymol, or laurel camphor, menthol reacts forming a liquid (Kyle, Amer J Pharm 1885, 429; Becker, bul. 1886, 283) When menthol is boiled with sulphuric acid diluted with half its volume of water it acquires an indigo-blue or ultramarine colour, the acid becoming brown (Brit. Pharm

Menthol is a saturated secondary alcohol which under the influence of dehydrating agents, e.g. phosphorus pentoxide, zinc chloride, potassium bisulphate, passes into the hydrocarbon menthene, C<sub>10</sub>H<sub>18</sub>. A very large number of esters of menthol are known, of which the acetate C<sub>10</sub>H<sub>19</sub>OAc, b p 227°-228°, [a]<sub>D</sub>-79 26°, (cf. Kishner, J. Russ Phys. Chem Soc. 1895, 27, 480), and isovalerianate, C<sub>10</sub>H<sub>19</sub>OOC C<sub>4</sub>H<sub>9</sub>, occur in oil of peppermint (P. a. K.). For the identification of l-menthol by means of derivatives, the phenylcarbamate C<sub>10</sub>H<sub>19</sub>OCONHPh, m.p. 111°-112° (Leuckart, Ber 1887, 20, 115), the hydrogen phthalate C<sub>10</sub>H<sub>19</sub>OCC C<sub>7</sub>H<sub>5</sub>O<sub>3</sub>, m.p. 122° (Pickard and Littlebury, Chem. Soc. Trans. 1912, 101, 118), and benzoate C<sub>10</sub>H<sub>9</sub>OBz, m.p. 55°-56° (P. a. L.) are characteristic.

Two atoms of hydrogen are removed from 1-menthol by treatment with chromic acid mixture (Beckmann, Annalen, 1889, 250, 325) with formation of 1-menthone, a liquid ketone which occurs to the extent of about 20 pc. in oil of peppermint (B a W.), and with an isomeride, d-isomenthone, forms 50 pc of American pennyroyal oil obtained from Hedeoma pulegoides (Linn) (Barrowcliff, Chem. Soc. Trans. 1907, 91, 875). Menthol has been obtained synthetically from menthone and pulegone (Beckmann and Pleissner, Annalen, 1891, 262, 32, Haller and Martine, Compt. 1end 1905, 140, 1298), also from thymol by use of the Sabatier and Senderens method of reduction By this latter method the four possible menthols corresponding to menthone, namely, d- and l-menthol and dand l-neomenthol, have been prepared (Pickard and Littlebury, Chem Soc Trans. 1912, 101, A small proportion of d-neomenthol was isolated at the same time from Japanese oil of peppermint.

In its medicinal action menthol resembles phenol—Its chief uses are as a local anæsthetic for relief of superficial pains of various kinds, also dissolved in oil as a spray for influenza, hay fever, &c., and as a local application in

certain cutaneous diseases.

Camphors isomeric with menthol Citronellol  $C_{10}H_{20}O$ , a liquid isometide of menthol occurs as l-citronellol in rose oil, Rosa damascena (Mill) (Tiemann and Schmidt, Ber 1896, 29, 922), and as d-citronellol in Java citronella oil, Andropogon Nardus Java de Jong (Schimmel's Rept 1902, 114), and in the oil from Barosma pulchella (Linn) (ibid 1910, 117), whilst both forms occur in geramium oil, Pelargonium graveolens (Ait.) (Tiemann and Schmidt, Ber 1896, 29, 924).

Borneo and Allied Camphors. Malayan, Barus or Dryobalanops camphor; Borneol, camphol C<sub>10</sub>H<sub>1.7</sub>OH, 1, 7, 7,-trimethyl [1, 2, 2]-bicyclo 2-heptanol This camphor occurs in nature in the dextro- and levorotatory varieties, esterified chiefly in the lavorotatory modification Common borneol, which is dextrorotatory, is the product of Dryobalanops aromatica (Gartn), a majestic tree indigenous to Sumatia, Borneo, and Labuan. The camphor is deposited in fissures in the old wood, and to obtain it the The tree is cut down trees have to be sacrificed and the wood is examined by a laborious process of splitting The collected camphor averages 3 to 11 lbs from each tree Owing to the reck-less manner in which the trees have been destroyed without the planting of others, the forests of Sumatra now contain few that are worth working (Pharm. J. 1881, [3] 12, 83). The states of Sarawak and Brunei are much richer in trees, and at the present time produce borneol by similar methods (cf Hanb. and Fluck 516; Kremers, Pharm Review, 1905, 23, 7; Gildemeister and Hoffmann, Die atherischen Öle, 1916, iii 178) The crude camphor is best purified by sublimation (Pelouze, Annalen, 1841, 40, 326).

d-Borneol is also a constituent of the following volatile oils: Rosemary, Rosmarinus officinalis (Linn.) (Gildemeister and Stephan, Arch. Pharm. 1897, 235, 586); Siam Cardamom Amomum cardamomum (Linn.) (Schimmel's Rept. 1897, ii. 9), Nutmeg, Myristica fragrans (Houtt.) (Power and Salway, Chem. Soc. Trans.

1907, 91, 2037); Lavender, Lavandula vera (D.C.) (Bruylants, J. Pharm. Chim. 1879, [4] 30, 139; cf. Charabot, Bull. Soc. Chim. 1897, [3] 17, 380); Spike Lavender, Lavandula Spica (Linn.) (Bouchardat, Compt rend 1893, 117, 53 and 1094), and Virginian Snake-root, Aristolochia serpentaria (Linn.) (Spica, Gazz. chim. ital. 1887, 17, 314). In addition to these natural sources d-borneol may be obtained, by the action of reducing agents on laurel camphor when borneol, of the same sign of rotation as the camphor used, is obtained mixed with a small proportion of tsoborneol of opposite sign (Haller, Compt. rend. 1887, 105, 227; Beckmann, J. pr. Chem. 1897, [2] 55, 31), and in small proportion with l-borneol it is found among the products of the distillation of amber with potash (Berthelot and Buignet, Annalen, 1860, 115, 245)

Borneol is harder and less volatile than laurel camphor, and does not sublime in the bottles in which it is kept. It has a peppery camphoraceous odour and burning taste M p. 203°-204° (preparations containing isoborneol melt 206°-208°), b p. 212°, sp. gr. I 011 (Plowman, Pharm. J. 1874, [3] 4, 711). It crystallises in the hexagonal system (Traube, J. pr. Chem. 1894, [2] 49, 3); [a]<sub>D</sub> +37.7° (Beckman, Appeler, 1899, 250, 252; Heller, Competer, 253, 254; Heller, Competer, 254, 254; Heller, Competer, 254, 254; Heller, Competer, 255, 255; Heller, Competer, 255, 255; Heller, Competer, 255; Heller, 255; Hell mann, Annalen, 1889, 250, 353; Haller, Compt rend 1891, 112, 143; Pickard and Littlebury, Chem Soc. Trans. 1907, 91, 1973). Borneol is a saturated secondary alcohol, and on oxidation yields camphor,  $C_{10}H_{16}O$  of the same rotatory sign. Powerful exidising agents produce camphoric acid C<sub>10</sub>H<sub>18</sub>O<sub>4</sub>, and further degradation products (Laurent, Annalen, 1837, 22, 135, Pelouze, *ibid.* 1841, 40, 328; Kachler, *ibid.* 1878, 191, 143) Removal of a molecule of water by phosphoric anhydride gives rise to a solid terpene, camphene, C<sub>10</sub>H<sub>16</sub> (Wallach, *ibid*. 1885, 230, 239); for the mechanism of this change, see Meerwein, ibid. 1914, 405, 129) Concentrated hydrochloric acid (Berthelot, ibid 1859, 112, 366), or phosphorus pentachloride (Kachler, *ibid* 1879, 197, 89) reacts with borneol producing *bornyl chloride* C<sub>10</sub>H<sub>17</sub>Cl, a product identical with pinene hydrochloride or 'artificial camphor.' For the characterization of borneol the phenylcarbamate, C<sub>10</sub>H<sub>1</sub>,0CONHPh, mp 138°-139° (Bertram and Walbaum, J pr Chem 1894, [2] 49, 5), the acetate C<sub>10</sub>H<sub>17</sub>OAc, m p. 29° (B. and W. Arch Pharm. 1893, 231, 304), and the addition products with bromal, mp 105°-108° (Minguin, Compt rend 1893, 116, 889), and chloral, mp 55°-56° (Haller, ibid 1891, 112, 145), are employed

l-Borneol is a constituent of the following oils Valenan, Valeriana officinalis (Linn) (Bruylants, Ber. 1878, 11, 452, Ohiviero, Bull, Soc Chim 1895, [3] 13, 917), Canadian Snakeroot, Asarum canadense (Linn) (Power and Lees, Chem Soc Trans 1902, 81, 63), Arborvitæ, Thuja occidentalis (Linn) (Wallach, Annalen, 1907, 353, 213), Citronella, Andropogon nardus (Linn) (Schimmels, Rept. 1912, 1, 43), Pinus maritima (Mill) (Belloni, Chem Zentr 1906, 1, 1552), Yellow Pine, Pinus palustris (Mill.) (Schimmels, Rept. 1910, 1, 106), and Feverfew, Matricaria Parthenium (Linn.) (ibid. 1894, 1, 71). It is also contained in the fusel oil of the crude spirit obtained by the fermentation of the sugar of madder, and formerly known

as madder camphor (Jeanjean, Annalen, 1857, 101, 95), and in Ngai camphor, the name given to the solid part of the essential oil of Blumea balsamifera (D. C.) (Plowman, Pharm. J. 1874, [3] 4, 712; Fluckiger, ibid. 828; Schimmels, Rept 1910, 1, 149). From this latter source the l-borneol had a higher rotatory power  $[\alpha]_{\rm D}$  — 39° 25′, than is usually observed (Schimmels Rept 1895, 1, 74). On oxidation with intricacid l-borneol yields levorotatory camphor.

Numerous esters of borneol are known. Those of l-borneol, which occur in nature, are bornyl acetale, in oil of valerian (Bruylants), Siberian fir oil, Abies sibirica; Ledeb (Hirschsohn, Chem Zentr 1892, 11 793), hemlock spruce oil, Abies canadensis; Michx. (Hunkel, Pharm. Review, 1896, 14, 35), and coriander oil, Coriandrum sativum (Linn) (Walbaum and Muller, Wallach Festchrift, 1909, 654), bornyl formate, butyrate and isovalerianate in oil of valerian (Bruylants).

Inactive borneol, the racemic mixture of d- and l-borneol has been obtained by the distillation of the crude product of the action of sulphuric acid on turpentine (Armstrong and Tilden, Chem. Soc Trans 1879, 35, 752); an ester of i-borneol is also obtained by treating pinene with oxalic acid (Schindelmeiser, J Rus. Phys Chem Soc 1902, 34, 954).

Isoborneol, a stereoisomeride of borneol and an intermediate product in the manufacture of synthetic camphor, was first obtained by Bertram and Walbaum (J pr Chem 1894, [2] 49, 1) from camphene obtained by the action of sodium acetate and glacial acetic acid on pinene hydrochloride at 200°. Camphene is warmed with glacial acetic acid and a little, 50 pc, sulphuric acid, and the resulting acctate is decomposed by alcoholic potash. Isoborneol can now be prepared from pinene hydrochloride directly, by the action of boiling glacial acetic acid in the presence of a small quantity of a metallic salt such as anhydrous zinc chloride (Weizmann and Clayton Aniline Co, Eng Pat. 8266, 1906) It is also formed to a small extent in the reduction of laurel camphor (Beckmann, J pr Chem 1897, [2] 55, 35) It differs from borneol, physically, in its greater volatility, its higher m p 212° (in sealed tube), and its greater solubility in benzene and light petroleum, chemically in its greater stability towards oxidising agents, and in the ease with which it loses water forming camphene. Its bromal addition compound melts at 71°-72°. The optically active isoborneols melt at 214°, and have [α]<sub>n</sub>±34 3° (Pickard and Littlebury, Chem Soc. Trans. 1907, 91, 1979).

Camphors isomeric with borneol. Cineol, Cajeputol or Eucalyptol C<sub>10</sub>H<sub>10</sub>O, anhydro 1-Me 4 (a-Me a-oxyethyl) 1-oxyeyclohexane, is a constituent of a great number of volatile oils of Eucalyptus globulus (Labill.) (Jahne, Ber. 1884. 17, 2941), Wormseed, Artemisia maritima (Linn.) var. Stechmann (Wallach and Brass, Annalen) 1884, 225, 291, Hell and Sturcke, Ber. 1884, 17, 1970); Cajeput, Melaleuca Cajeputi (Roxb.) (Wallach and Gildemeister, ibid. 1888, 246, 276); M. viriaflora de Brogn. et Gris (Bertrand, Bull. 820. Chim. 1893, [3] 9, 432). Cincol melts at 1°-15° (Scnimmel & Co.); bp. 1/6°

(Wallach, Annalen, 1888, 245, 195) It has a camphor-like odour and is optically inactive. It is characterised by its addition compounds. with the halogens, with hydrobromic acid m.p. 56°, which also serves for the isolation of small quantities (Wallach, Annalen, 1888, 246, 280), with phosphoric acid (Scammell, D. R. P. 80118), with arsenic acid (US Pat. 705545, Thoms and Molle, Arch Pharm 1904, 242, 172), with iodole (tetraiodopyirol), m.p 112° (Bertram and Walbaum, Arch. Pharm. 1897, 235, 178), by means of which very small quantities can be detected (Hirschsohn, Chem Zentr. 1893, 1. 503), and with resorcinol (Baeyer and Villiger, Ber 1902, 35, 1209). The compounds with hydrobromic acid, phosphoric acid, arsenic acid, and resoremol are used for its quantitative estimation (cf Turner and Holmes, Amer J Pharm. 1915, 87, 101), the question as to their relative efficiency being still a matter of dispute. Dehydrating agents convert cineol into dipentene C<sub>10</sub>H<sub>16</sub> (Wallach and Brass, Hell and Sturcke). Oxidation by permanganate gives cincolic acid C<sub>10</sub>H<sub>16</sub>O<sub>5</sub>, m p 197 (Wallach and Gildemeister), but towards reducing agents it is very stable The oxygen atom in cincol is present as an oxide or ether linking. The aitificial production of cincol has been effected by the action of dilute acids on terpineol or terpin hydrite (Wallach, Annalen, 1887, 239, 18).

Cincol is used in medicine as a local antiseptic diessing, and for catarrhal conditions of

the respiratory mucous membranes.

The volatile oils of the following contain other isomerides of borneol; Citionella, Andropogon Nardus (Linn.) (Semmler, Ber 1893, 26, 2254) and Eucalyptus cutrodora (Hook) (Schimmels, Rept 1907, 2, 35) contain d-Citronellal, whilst 1-Citronellal is contained in 'Java lemon oil' (ibid 1903, 1, 21). Linaloe, Ocotea caudata (Mez.) (Barbier, Compt 1end 1895, 121, 168), Lavender, Lavandula vera (D.C.) (Bertram and Walbaum, J. pr. Chem. 1892, [2] 45, 590); Bergamot, Citrus Aurantium (Linn) (Bertram and Walbaum, ibul 602) contain l-linalol, whilst d-linalol ('corundrol') is contained in oil of coriander, Coriandrum sativum (Linn) (Barbier, Compt. rend. 1893, 116, 1460). Geranium, Pelargonium graveolens (Ait.) (Bertram and Gildemeister, J. pr Chem. 1894, [2] 49, 191), Citronella, Andropogon Nardus (Linn) (Schimmels, Rept. 1893, 2, 12); Lemon grass, Cymbopogon flexuosus (Stapf) (Tie-mann and Semmler Ber 1893, 26, 2721), contain geraniol ('rhodinol') Neroli oil from Citrus Aurantium (Linn), subspec. amara (Linn) (Hesse and Zeitschel, J. pr. Chem. 1902, [2] 66, 481) contains nerol. d-a-Terpineol, m p. 37°-38°, is a constituent of oil of sweet orange, Citrus Aurantium (var) dulce (Linn.) (Stephan, J. pr. Chem. 1900, [2] 62, 523) of neroli and petit-grain oils; 1-a-terpineol of oil of camphor, Cinnamomum Camphora (Nees et Eberm.) (Schimmels, Rept. 1903, 2, 39); 1-Terpineol, m p. 35°, of caleput oil, Melaleuca cajeput (Roxb) (Voiry, Bull. Soc. Chim. 1888, [2] 50, 108)

Common and allied camphors. Laurel Camphor; Dertro Camphor. (Camphre, Fr; Campher, Ger.) C<sub>10</sub>H<sub>10</sub>O 1.7.7-Trimethyl [1-2]-bicyclo 2-heptanone. Common camphor is contained in all pa ts of the camphor la rel, Ci immomum

Camphora (Nees et Eberm), a tree inhabiting Japan, Formosa and Southern China It occurs also as a constituent of the volatile oils of Spike, Lavandula spica (D.C.) (Lallemand, Annalen, 1860, 114, 198); Rosemary, Rosmarinus officinalis (Linn) (ibid. 197); Sage, Salvia officinalis (Linn) (Mur, Chem Soc. Trans. 1880, 37, 678); Siam Cardamom, Amomum Cardamomim (Linn) (Schimmels, Rept. 1897, 2, 9); American Wormseed, Chenopodium ambrosoides (Linn.) var anthelminthuum (Gray) (ibid. 1908, 1, 112), and Sassafras, Sassafras officinalis (Nees) (Power and Kleber, Pharm Review, 1896, 14, 101)

Although camphor is at the present time still manufactured artificially, most of the camphor of commerce is obtained from the camphor laurel, the chief industry being confined to Japan. Formosa and China The fined to Japan, Formosa and China experimental plantations which were undertaken for the production of natural camphor m Florida, California, Jamaica, East Africa, Malay States, Algeria and Ceylon have at least in one case, that of Florida, begun to furnish camphor on the commercial scale (Oil, Paint and Drug Rep., March 29, 1915) In Formosa the camphor industry before the China-Japanese war was nominally in the hands of the Chinese, but owing to the savage state of the interior of the island, and the unscrupulous methods of the dealers, it had declined to small and unimportant proportions Afterwards Japan assumed the control of the industry, and it was made a government monopoly in 1899, and this was extended to Japanese camphor in Since the establishment of the monopoly the old crude methods of obtaining the camphor (Fluck. and Hanb 513) have been replaced by more modern ones. The camphor wood in the form of chips is steamed in roughly built furnaces, and the camphor which is driven off is condensed in cooled wooden vessels, and freed from most of the oil by draining, crude of 'grade B' camphor being thus obtained. For the production of refined or 'grade A' camphor, the crude material is heated in large non retorts, through which a current of air is passed the first 48 hours only sufficient heat is applied to drive off the water and oil. The retoits are then connected with a condensing chamber, the roof of which is cooled by running water, and are heated to a high temperature in order to volatilise the camphor. It is then formed into blocks in wooden moulds and pressed, first by steam power and finally by a very high hydraulic pressure (Collins, J. Soc. Chem. Ind. 1904, 75) The yield of camphor is greater in winter than in summer, while the reverse is true of the oil. In summer a charge of 120 kilos, of wood gives 2.4 kilos, or 2 p c. of camphor, and 18 litres of oil; in winter, 3 kilos., or 2.4 p.c. of camphor and 0 5-0.7 litre of oil.

Crude camphor appears in commerce as a coarse wet powder of a greyish-white colour Chinese crude camphor is packed in round wooden pots of about 150 lbs net content, Japanese in lead-lined wooden boxes containing about 130 lbs. net. The principal impurities of crude camphor are water, camphor oil, iron, sand, wood, &c. Light oil of camphor has a sp gr. of 0.895-0.920; b.p. 170°-180°, and contains pinene, camphene, dipentene, phellandrene and

fenchene. Heavy oil of cumphor, having a sp.gr. of 0 960-0 970, and b p. 240°-300°, contains cadinene, safrol, eugenol, cincol, fenchone, terpincol, &c. Besides these compounds, both of the oils contain a large amount of camphor in solution Before refining crude camphor, the oil and water must be got rid of, as the oil gives the refined camphor a fatty touch, and the water renders it opaque. The elimination of water and oil is often effected by washing in a centrifugal machine with small quantities of water; the liquid diaming off contains both oil and water. The separation is also done by hydraulic pressure, or by crystallisation from boiling benzene or light Resublimation in Europe is done principally in glass retorts, yielding a round concave cake weighing 6-8 lbs, having an opening in the centre In America the camphor is sublimed from flat iron pans with iron covers, yielding plates of about 18 inches square and 1 inch thick, weighing from 8 to 10 lbs. The process consists in mixing the camphor with a little lime, charcoal or iron filings, according to the quality, and charging each pan with about 12 lbs of material, the subliming pans are heated slowly for 2 hours, and then fired rapidly up to 190° this temperature being kept for from 12 to 16 After cooling, the refined product is removed from the cover by slightly heating, and is then cut into the desired shape (Drobegg, J. Soc Chem Ind. 1907, 381)

Purified camphor comes on to the market in three forms, 'bells,' 'blocks' and 'flowers.' Block camphor consists of colourless translucent masses traversed by numerous cracks. It can be broken but is too tough to admit of being powdered by trituration. This may, however, be readily effected if a little alcohol be added, which escapes again during the operation. Camphor finds very extensive commercial application in the preparation of celluloid, in medicine where it is used externally as a mild rubefacient and to destroy parasites, internally, as a carminative and intestinal disinfectant, and to a minor extent in the manufacture of explosives Sp gr 0 986-0 996; mp. 178.75° corr. (Lenz. Arch. Pharm. 1911, 249, 289); b p 204° It sublimes to some extent at ordinary temperatures and condenses in hexagonal crystals (cf. Folger, Y.B. Pharm 1886, 232);  $[\alpha]_{\rm D}$  44·22° in 20 p.c. alcoholic solution (Beckmann, Annalen, 1889, 250, 353). Refraction coefficient (Kanonnikof, J. pr. Chem 1885, [2] 31, 348) Camphor in common with chloral hydrate and some other substances rotates in a peculiar manner on the surface of water (lowering of surface tension by solution), (Tomlinson, Phil Mag. 1873, [4] 46, 376, Pharm. J. 1874, [3] 4, 654, 672; Chem. News, 1885, 52, 50). It is very sparingly soluble in water (1:700), readily in 90 pc. alcohol (1·1), also in chloroform and ether. Mixed with chloral hydrate, it forms an oily liquid  $C_{10}H_{16}O$ ,  $CCl_{3}CHO,H_{2}O$ , which has been employed in CCI<sub>3</sub>CHO,H<sub>2</sub>O, which has been employed in medicine as an anodyne pigment (Brown, Pharm. J. 1873, [3] 4, 729; Saunders, *ibid.* 1876, [3] 7, 89; Cazeneuve and Imbert, Bull Soc. Chim 1880, [2] 34, 209; Zeidler, J. 1878, 645; Albright, Amer. J. Pharm. 1886, 282) Similar combinations take place between camphor and chloral alcoholate (Zeidler), phenol camphor and chloral alcoholate (Zeidler), phenol (Léger, Bull Soc Chim 1890, [3] 4, 725); menthol (Kyle, Amer J. Pharm. 1885, 429), and thymol (Symes, Pharm. J 1879, [3] 9, 598).

thymol (Symes, Pharm. J 1879, [3] 9, 598).

Camphor is a saturated hydroaromatic ketone, but does not combine with sodium bisulphite For identification purposes use is made of the oxime  $\rm C_{10}H_{16}NOH,~m.p.~118^\circ-119^\circ$  (Auwers, Ber. 1889, 22, 605), the semicarbazone (Auwers, Ber. 1889, 22, 605), the semicarouzone  $C_{10}H_{16}=N$  NHCONH<sub>2</sub>, m.p. 236°-238° (Themann, Ber 1895, 28, 2191), the oxymethylene compound  $C_{10}H_{14}O=CHOH$ , mp 80°-81°, and the benzylidene compound  $C_{10}H_{14}O=CHC_6H_5$ , mp 96° Of its substitution products, one, a-bromocamphor  $C_{10}H_{15}OBr$  has been employed in medicine as a sedative in nervous excitement, and is an article of trade It is best prepared by treating powdered camphor with biomine at 100°, pouring the liquefied product into water and recrystallising from spirit (Armstrong and Matthews, Chem News, 1878, 37, 4) It has a weak camphoraceous odour and taste, mp 76°; bp 274° It is insoluble in water, but soluble in the common organic solvents, in fixed oils, and in sulphuric acid By the action of reducing agents camphor is converted into a mixture of borneol and isoborneol, the former predominating (Beckmann, J pr Chem. 1897, [2] 55, 35, Haller, Compt rend 1887, 105, 227). On oxidation with nitric acid (Kachler, Annalen, 1878, 191, 143) or hot alkaline permanganate (Grossei, Ber. 1881, 14, 2507), camphor yields camphoric acid C<sub>8</sub>H<sub>14</sub>(COOH)<sub>2</sub>.

Synthetic Camphor, Inactive Camphor Camphor can be manufactured from turpentine oil, and has from time to time appeared on the market. It is termed 'synthetic' camphor to distinguish it from the so-called 'artificial camphor,'which consists of pinene hydrochloride, and is unsuitable for the chief purposes to which camphor is applied. Only when the prices of the natural product are abnormally high has synthetic camphor been able to compete with it During the war, in Germany, owing to the failure of supplies of d-camphor, the Schering interests and probably other firms (Houseman, Amer. J. Pharm. 1915, 87, 58) produced synthetic camphor in quantity, whilst the American Camphor Corporation contend that they can supply the requirements of the celluloid trade with synthetic camphor (Oil, Paint and Drug Rep, March 29, 1915) Natural camphor and synthetic camphor only differ in their action on polarised light, the latter being either mactive or showing only a slight activity; in their physiological action they are identical (Joachimoglu, Ber deut Pharm Ges 1916, 26, 427). By working at low temperaturer, however, Darmois (Compt rend 1910, 150, 925) has obtained synthetic camphor with the rotati n of natural camphor, French oil of turpentine yielding l-camphor, whilst turpentine from the Aleppo pine, *Pinus halepenis* (Mill) yielded d-camphor The various routes taken by patented processes for the manufacture of synthetic camphor are shown by Fig. 1.

The first commercial process consisted essentially in converting oil of turpentine into pmene hydrochloride, which compound by elimination of hydrogen chloride yields camphene. Camphene is then converted into isoborneol, which, like natural borneol, yields camphor on oxidation. For the preparation of pmene

hydrochloude, oil of turpentine, which contains 70-90 p.c. of punene, depending on its origin, is treated with dry hydrogen chloride, whereby a solid hydrochloride is obtained together with a

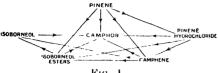

Fig 1.

liquid hydrochloride which is not suitable for the manufacture of camphene. This liquid hydrochloride contains a considerable proportion of the solid hydrochloride in solution, which may be recovered by oxidising the only product with dilute nitric acid, or by extraction with petroleum after treatment with sulphune acid at 40°, which polymerises the oil (Eng. Pat. 7319, 1908) The preparation of camphene by the removal of hydrogen chloride from pinene hydrochloride (Wallach, Annalen, 1887, 239, 6, Bruhl, Ber 1892, 25, 147; Reychler, Bull Soc Chim 1896, [3] 15, 371) was at first attended with difficulty. the yield was small and the product was liable During the last two to contain chloride decades the following methods have been patented for the production of camphene in farge quantities, many of which are claimed to give almost theoretical yields and a product free from chloride. Heating the hydrochloride with bases of the aliphatic series such as methylamine, or with piperazine or piperidine (US Pat 707270, 1902), or with tertiary bases of the pyridine and quinoline group (Eng. Pat. 5032, 1906); by heating with alcoholic, aqueous, or gaseous ammoma (U.S. Pat. 707271, 1902), or ammonia in presence of a phenol (D. R' P 264246, 1912), by heating with aqueous sodium hydroxide or ammonia in presence of a soap (US Pat 725890, 1903); by heating with lead acetate in glacial acetic acid solution (Fi Pat 349896, 1904); by heating with glacial phosphoric acid in glacial acetic acid solution (D R P 207888, 1908), by heating with a metallic salt of a higher fatty acid (Eng. Pat. 19960, 1906; 1948, 1907), or with a mixture of metallic salts of the fatty acids (Eng. Pat. 2488, 1913); by heating with a metal and an oxidising agent, such as zinc and barium peroxide in molecular proportions (Fr. Pat 361333, 1905); by heating with salts of phenols or naphthols either anhydrous or in presence of water (Eng Pat 16429, 1906; 21180, 1906; 5674, 1908) by herting with lime or other similar oxide (Fr Pat 375897, 1907; Eng Pat. 25453, 1907), in the presence of phenol at 180° (Eng. Pat. 22810, 1906), in the presence of polyvalent alcohols or carbohydrates (Eng. Pat 10784, 1907), by heating with alkali, and alkali or alkaline earth salt of a sulphonic acid of the benzene or naphthalene series (Eng. Pat. 10783, 1907); by heating with alkali or alkaline earth salts of organic sulphamides or with phenolsulphonic acids (D. R. P. 197346, 197805, 1907); by heating with alkali or alkaline earth hydroxides in presence of compounds which combine with water such as alkalı or alkalıne earth oxides (Fr Pat. 413282, 1909); by heating with zinc oxide in presence of alkalı nydroxide (Eng. Pat. 11029, 1911); by

heating with  $\alpha$  or  $\beta$  -naphthylamine (D. R. P. 206386, 1907), or with aniline (D. R. P. 205850, 1907); by heating with a meta- or pyro-borate, silicate, phosphate or arsenate in aqueous solution (D. R. P. 205295, 1908); by heating with phenol, cresol or naphthol and the carbonate of an alkalı or alkalıne earth metal (Eng Pat. 13902, 1909); by heating under reflux until the hydrochloric acid has gone (US Pat. 923967, 1909); by the Grignard reaction (Hesse, Ber 1906, 39, 1127) According to Eng. Pat. 10227, 1910, pinene vapour when passed over a catalyst at 200°–300° is converted into camphene

Beitram and Walbaum (J pr. Chem 1894, [2] 49, 1) made the discovery that camphene is converted into isoborneol by warming with a mixture of acetic acid and a little sulphuric acid, and decomposing the resulting isobornyl acetate by alcoholic potash. This method is employed on the manufacturing scale variant of the method is described in Eng. Pat 19961, 1906, where camphene is heated with oxalic acid in a suitable solvent with a condensing agent such as sulphune or phosphoric acids with formation of normal and acid esters of isoborneol. Camphene has also been directly converted into isoborneol by boiling in acctone with half its weight of 20 pc H<sub>2</sub>SO<sub>4</sub> for 10 hours, or in an autoclave at 100° for a shorter time (Fr. Pat The isoborneol purified by 385341, 1907) crystallisation from light petroleum or benzene is then oxidised to camphor. For this purpose various oxidising agents are employed, many of which have been patented Amongst these are . potassium permanganate in glacial acetic acid (Ber. 1900, 33, 3430); aqueous solution of permanganate employed with a benzene solution of isoborneol (F1. Pat 341513, 1904), potassium permanganate in alkaline solution (D. R. P. Anm. 38311, 1904), chlorine, either gaseous or in solution (Eng. Pat. 28035, 1904, U.S. Pat. 802792, 1905), hypochlorite, either alone (US Pat 864162, 1907), or in presence of copper and ferric chlorides (Eng. Pat. 20050, 1908); chromic acid or chromates (Eng. Pat. 26779, 1904, 14550, 1907); in acetone solution (Eng. Pat. 21946, 1907); or in presence of an indifferent solvent (Eng. Pat. 5513, 1908; 24779, 1912); nitric acid in which the presence of nitrous acid is essential (Eng. Pat. 9857, 1907); nitric acid in presence of vanadic acid and oxygen (Eng. Pat. 18047, 1908); nitric acid in presence of a halogen (U.S. Pat. 1313661, 1919), oxygen (U.S. Pat. 801485, 1905); oxygon, oxides of heavy metals or peroxides (Fr. Pat. 385352, 1907); basic oxidising substances, e.g. CuO, HgO (Eng Pat. 3750, 1908), metals or oxides which can liberate hydrogen from isoborneol (Eng Pat 26708, 1908); electrolytic methods (U.S. Pat. 875062, 1907; Fr. Pat. 387539, 1907); ozone (US Pat. 801483, 1905), nitrous anhydride (U.S. Pat. 802793, 1905); metallic copper at 300° in absence of air (Eng. Pat. 17573, 1906). According to US Pat. 790601, 1905, and Eng. Pat 21171, 1906, 180bornyl acetate and other isobornyl esters can be directly oxidised to camphor without previous saponification.

Camphene can also be directly oxidised to camphor (Armstrong and Tilden, Ber 1879, 12, 1756), and the following processes have been patented: Treatment with ozone at 80° (Eng Pat. 21294, 1890); treatment with hot air or

oxygen (Eng. Pat 3555, 1896), oxidation by potassium permanganate in acetone solution (addition to Fr Pat 349896, 1904); treatment of camphene at 180° with an oxidising agent, such as chromic acid, converts it into oxonide C<sub>10</sub>H<sub>16</sub>O<sub>2</sub>, which loses oxygen on treatment with water, and is converted into a lactone, camphenolide, which yields camphor on heating in presence of water (Fr. Pat 361333, 1905), oxidation with a per-salt of potassium and sulphuric acid (Fr. Pat 389092, 1908)

Another method of obtaining synthetic camphor depends on the formation of bornyl and isobornyl esters by the direct action of various acids on pinene or turpentine oil following processes have been patented: Treatment of anhydrous turpentine at 120°-130° with anhydrous oxalic acid (US Pat 698761, 1902, cf. Pond, J Soc Chem Ind 1907, 385), by heating pinene with anhydrous oxalic acid in presence of anhydrous chlorides, eg. AlCl<sub>8</sub> with the addition of a diluent (Eng. Pat. 14408, 1908); by heating turpentine with an alcohol and an acid anhydride, e g B<sub>2</sub>O<sub>3</sub> at 120°-140° (Eng Pat. 11248, 1908); by heating pinene with an aromatic polysubstituted acid (Eng Pat 18049, 1908); terpenes or oils containing terpenes heated at 160° with propionic or butyric acid (Fr Pat. 408106, 1909) Similar methods, based on the direct formation of bornyl or isobornyl esters from pinene hydrochloride, have been patented. by heating with an alkaline formate or oxalate in alcohol and water for 10 hours to 120° (Eng. Pat 5549, 1904); by heating with metallic formates and formic acid (Eng Pat 14379, 1907), solid pinene hydrochloride is heated with an alkaline earth oxide in presence of excess of a lower member of the fatty acids (Fr Pat. 393504, 1908); turpentine treated with dry hydrochlone acid gas is boiled with an alkali, alkaline earth or metallic butyrate or propionate in presence of excess of the corresponding fatty acid (Fr Pat 408065, 1909), by heating pinene hydrochloride in acetic acid solution with lead acetate (Fr Pat 349896 1904); by heating in acctic acid solution with an acetate and fused CaCl2 or KHSO4 (Eng. Pat. 1936, 1908); by heating with acetic acid in presence of zinc chloride (Eng. Pat. 8266, 1906), or some other zinc salt (Eng. Pat. 10798, 1900), and with addition of an alkali or alkaline earth salt of a formate, acetate or butyrate (Eng Pat. 18280, 1906); by heating with the acetate of an alkaline earth for 20 hours at 180° (Fr Pat 375590, 1907), by heating with a fatty acid in presence of metallic zinc (Eng. Pat. 16605, 1907), or by heating with organic acids in presence of zinc (Eng. Pat. 14752, 1908); by heating with fatty acids and zinc chloride in presence of cobaltous chloride or other suitable inorganic salt (Eng. Pat. 22129, 1907); solid pinene hydrochloride is shaken with a salt of acetic or stearic acid or phenol with an excess of either acetic, stearic acid or phenol in presence of a dehydrant (Fr Pat 382790, 1906)

The direct conversion of pinene hydro-chloride into camphor is claimed in Eng Pat 27317, 1913, by heating with nitric acid or its salts in presence of a catalyst, whilst two processes for the conversion of turpentine into camphor have been patented. They are: turpeutine is treated with a halogen at a low

temperature,  $-25^{\circ}$ , until the increase in weight is 25-50 p.c., and the product, still at a low temperature, is mixed with one-eighth to onefifth its weight of NaOH, when it is converted into camphor (Fr Pat. 392182, 1907); turpentine in a neutral solvent is treated with nascent oxygen (Fr Pat 406005, 1908)

(For analyses and points of difference between natural and commercial synthetic camphor, see Crane and Joyce (J. Soc. Chem Ind. 1907, 386), Lohmann (Ber. deut Pharm. Ges. 1909, 19, 222), and Lenz (Aich. Pharm. 1911, 249, 289).)

L $\alpha vo$ camphor; Matricaria camphor This camphor occurs naturally in the volatile oils of Feverfew, Matricana Parthenium (Linn) (Chautard, J. pr. Chem 1848, 45, 45; Compt rend 1853, 37, 166); Tansy, Tanacctum vulgure (Linn.) (Schimmels, Rep 1895, ii. 35), and Artemisia Nana (Pursh) (Whittelsey, Chem Zentr. 1909, 11 2160). It is also a constituent of Ngai camphor, the solid portion of the oil of Blumea balsamifera (D.C.) (Schimmels Rep. 1910, 1 149). It can be prepared by oxidation of camphene obtained from lavorotatory pinene (Riban, Bull, Soc Chim. 1900, 24, 19, Darmois, Compt. rend 1910, 150, 925), and by oxidation of l-borneol with nitric acid (Pope and Harvey, Chem Soc Trans 1901, 79, 76). It differs from common camphor only in its behaviour towards polarised light.

Inactive camphor is a constituent of the oil of Chrysanthemum sinense (var.) japonicum (Keimatsu, J. pharm Soc. Japan, 1909,

236, 1)

The following are the more important isomerides of camphor which occur naturally in volatile oils:  $Pulegone \ C_{10}H_{16}O$ , is only found in oils of the Labiate, chiefly in European Pennyroyal, Mentha pulegium (Linn) (Beckmann and Pleissner, Annalen, 1891, 262, 1); Fenchone in its dextro modification is a constituent of oil of Fennel, Foeniculum vulgare (G) (Wallach, Annalen, 1891, 263, 129), whilst the laro variety is found in oil of Thuja, Thuja occidentalis (Linn) (Wallach, Annalen, 1892, 272, 99), Thujone occurs in three forms, as d-a-thujone in Thuja oil (Paolini and Divizia, Atti. R. Accad dei Lincei, 1912, 21, [1] 570), as 1-a-thujone in the same oil (Wallach, Annalen, 1893, 272, 99); and as d-\$\textit{d-\textit{\textit{d-b-thu}}}\textit{one in oil of Tansy, Tanacetum vulgare} (Linn) (Semmler, Bei. 1892, 25, 3343), and oil of Wormwood Artemisia Absinthium (Junn) (ibid); Citral is a frequent constituent of volatile oils and a major ingredient of the oil from Backhousia citriodora (F v M) (Bertram, Schimmels, Rep. 1888, ii. 17), and of Lemon-gr ss oil, Cymbopogon flexuosus (Stapf.) (ibid.); Sabinol is the most important constituent of oil of Sav.n, Juniperus Sabina (Linn.) (Fromm, Ber. 1898, 31, 2025).

The more important homologues of common camphor belong to the sesquiterpene alcohols (see Terrenes) Owing to their capacity for crystallising from volatile oils some of them have long been known

Matico camphor C<sub>15</sub>H<sub>26</sub>O, was formerly a constituent of oil of matico, Piper angustifolium (Ruiz et Pavon), but appears to be absent from present day oils. M.p.  $94^{\circ}$ ,  $[a]_{D}$ -28  $7^{\circ}$  (in chloroform). Boiling with 25 p.c. sulphuric acid converts it into a blue sesquiterpene

C<sub>15</sub>H<sub>24</sub> (Kugler, Ber 1883, 16, 2841, Thoms, Arbeit Pharm. Inst. Berlin, 1905, 2, 125).

Cedar camphor, Cypress camphor, Cedrol  $C_{1b}H_{2d}O_{,}$  is a frequent constituent of the volatile oil of  $Juniperus\ virginiana\ (Linn\ ),\ m\ p\ 86°-87°, <math>[a]_{D}\ 9.5\ (in\ chloroform).$  It yields cedrene  $C_{1b}H_{2d}$ when treated with phosphoric anhydride (Walter, Annalen, 1841, 39, 247, cf also Semmler and Mayer, Ber. 1912, 45, 1384)

Cubebs camphor C<sub>15</sub>H<sub>26</sub>O, is a constituent of the volatile oil of Piper Cubeba (Linn), when it has been exposed to the air for some time M.p. 68°-70°, bp 148°, with loss of water, a change which very readily takes place under various conditions of treatment forming a sesquiterpene (Schmidt, Ber 1877, 10, 188. Schaer and Wyss, Arch Pharm 1875, 206, 316)

Ledum camphor C<sub>15</sub>H<sub>26</sub>O, obtained from the volatile oil of Marsh Tea, Ledum palustre (Linn ). Needles, m p  $104^{\circ}$ - $105^{\circ}$ , b p.  $282^{\circ}$ - $283^{\circ}$  The sesquiterpene, ledene C<sub>15</sub>H<sub>24</sub>, is readily produced by the action of dehydrating agents (Rizza, Chem. Zenti 1887, 1257; Hjelt, Ber 1895, 28, 3087; Lomidse, Chem. Zeit Repert, 1903, 27, 284)

Patchouli camphor, patchouli alcohol  $C_{15}H_{26}O,\ crystallises$  out from patchouli oil, the product of *Pogostemon Patchouli* (Pell), m p 56°, [a]<sub>p</sub>-977° (in chloroform) It readily loses the elements of water forming patchoulene  $C_{15}H_{24}$  (Montgolfier, Compt rend 1877, 84, 88, Wallach, Annalen, 1894, 279, 394, Schimmels, Rep 1905, 1 62)

Eudesmol C<sub>15</sub>H<sub>26</sub>O, is a constituent of the oils of various species of Eucalyptus, but especially of E macrorhyncha (F v M) (Baker and Smith, J. Linn Soc. N S W. 1899, 33, 86) M p 84°, [a], 31 3° (in chloroform) (Semmler and Tobias; Ber 1913, 46, 2026, Semmler and Risse, ibid 2303).

Thyme and allied camphors. Thymol  $C_{10}H_{14}O$ ,

Isopropyl m-cresol
Thymol is a constituent of the volatile oils of Ajowan, Carum cophicum (Benth) (Haines, Chem Soc Trans 1856, 8, 289; Stenhouse, Annalen, 1855, 93, 269, ibid 1856, 98, 309, Muller, Ber 1869, 2, 130), Thyme, Thymus vulgaris (Linn) (Doveri, Annalen, 1848, 64, 374; Lallemand, *ibid* 1857, 102, 119); Wild Thyme, T. Serpyllum (Linn) (Jahns, Ber 1882, 15, 819, Ocimum viride (Willd) (Goulding and Pelly, Proc Chem Soc 1908, 24, 63); Horsemint, Monarda punctata (Linn) (Arppe, Annalen, 1846, 58, 41), Satureia Thymbra (Linn) (Schrmels, Rep 1889, n 55), Origanum hirtum, (Link.) (Holmes and Umney, Perf. and Essent. Dir Rec., 1913, 4, 73) On the manufacturing scale it is prepared from Ajowan and Horsemint Oils (cf. Holmes, Perf and Essent, Oil Rec, 1916, 7, 311; also U S Dept. Agric. Bull. 372, 1916), by extraction with caustic soda solution, when the thymol forms a water soluble sodium salt, and is thus separated from the hydrocarbons alkaline solution is acidified with hydrochloric acid, which precipitates the crude camphor. may then be purified by crystallisation from glacial acetic acid or alcohol. Another plan is to submit the oil to fractional distillation and to freeze out the thymol from the heavier portions of the distillate. A possible source for syn-

thetic thymol is cymene (U.S. Pat. 1306512,

Thymol has the odour of thyme and a warm pungent taste; m.p. 50·5°-51 5°; b p. 232° at 752 mm. It is sparingly soluble in water (1:1200) and glycerine (1:1000), but readily in the usual organic solvents and alkaline solutions. It forms a liquid with menthol (Kyle, Amer J. Pharm. 1885, 429); camphor (Symes, Pharm. J. 1879, [3] 9, 598), berberne (Lloyd, New Remedies, 1881, 195), but not with chloral hydrate (Symes, cf. Mazzaia, Gazz chim ital. 1883, 13, 272) If a solution containing thymol be warmed with half its volume of glacial acetic acid, together with more than its volume of sulphuric acid, a deep red-violet colour is developed. This reaction is obtained even in very dilute solutions For the further identification of thymol use is made of the phenyl carbamate  $\rm C_{10}H_{13}OCONHPh$ , mp 107° (McKenzie and Semmler, Ber 1906, 39, 1158), and nitrosothymol C<sub>10</sub>II<sub>13</sub>O(NO), m p 160°-162° (Schuff, Ber 1875, 8, 1500) The methyl ether of thymol C10H13OMe occurs naturally in the essential oil of sea-samphire, Crithmum maritinum (Linn) (Delépine and Belsunce, Bull Soc Chim. 1918 [ıv ] 23, 24)

For estimation of thymol in essential oils, Kremers and Schremer (Chem Zentr. 1897, n 147, cf Messinger and Voitmann, Ber. 1890, 23, 2753) recommend the following process known weight of the sample is mixed with an equal volume of light petroleum in a stoppered burette, and agitated with 5 p c aqueous caustic soda till no further diminution of the oily layer takes place, and a drop of the oil dissolved in 20 drops of chloroform, on gently warming with a small piece of sodium hydroxide, does not turn red The decrease in volume is observed or the alkaline liquor can be titrated with rodine, but it appears the results obtained by titration are about 3 pc lower (For iodometric estimation, see also Messinger (J pr Chem 1900,

[2], 61, 247)

(For the estimation of the purity of thymol, see Seidell (Amer Chem J 1912, 47, 508), Ehon (J Amer Chem Soc 1917, 39, 1513), Redman, Weith and Brock (J Ind Eng Chem

1913, 5, 831))

Thymol is extensively used in medicine on account of its strong antiseptic properties. In its general behaviour it resembles carbolic acid It has also been used internally as a vermicide Of its derivatives a great number have been tried in medicine, but only three have been used to any extent: Thymol volude (Messinger and Vortmann, Ber 1890, 23, 2754; Carswell, Chem. News, 1893, 68, 181, DRP. 49739, 1889) obtained by condensation of two molecules and the introduction of two atoms of iodine is used as a substitute for iodoform; thymoform  $[C_{10}H_{13}O]_2CH_2$  (D R P. 99610, 1898) used as an antiseptic dusting powder; thymol carbonate (C<sub>10</sub>H<sub>13</sub>O)<sub>2</sub>CO (Richter, J. pr Chem 1883, [2] 27, 505) is used as an anthelminthic

Camphors isomeric or homologous with thyme camphor. Carvone, formerly carvol C<sub>10</sub>H<sub>14</sub>O, b.p 230°, is a liquid isomeride contained in the following volatile oils Caraway seed, Carum carvi (Linn.) (Wallach, Annalen, 1893, 277, 107), and Dill-fruit Anethum graveolens (Linn) (Gladstone, Chem. Soc. Trans. 1872, 25, 1), both

containing 50 to 60 p.c. d-carvone, whilst 1-carvone is contained in the volatile oils of Spearmint, Mentha viridis (Linn) (Gladstone, ibid. Fluckiger, Ber. 1876, 9, 473); Kuromoji, Lindera sericea (Bl.) (Kwasnik, Arch. Pharm 1892, 230, 265). 1-Carvone has been found in Ginger-grass oil, Cymbopogon Martini (Stapf) (var) Sofia (Walbaum and Huthig, Schimmels, Rep. 1905, i. 34). For the isolation of carvone, its power of combining with sulphuretted hydrogen to form a crystalline hydrosulphide (C<sub>10</sub>H<sub>14</sub>O)<sub>2</sub>H<sub>2</sub>S, mp. 210°-211°, is employed (Fluckiger, Ber, 1875, 9, 468, Wallach, Annalen, 1899, 305, 224), but a simpler process is to form the water soluble compound with neutral sodium bisulphite (cf Sadtler, J Soc Chem. Ind 1904. 23, 303) On reduction carvone yields dihydrocarveol C<sub>10</sub>H<sub>1</sub>,O, a constituent of Caraway Oil (Schimmels, Rep. 1905, i 50)

Carvacrol, cymophenol C<sub>10</sub>H<sub>14</sub>O, Isopropyl o-cresol is a thick oil, solidifying at 0°, b p 236°-237°, closely related to thymol It is formed by distilling carvone in presence of sulphune acid, phosphoric acid, or caustic potash, and occurs mainly in various thyme, origanum and monarda oils. It may also be obtained by chemical means from Spruce Turpentine (US) Pat. 1265800, 1918, cf also J Ind Eng Chem 1918, 10, 982) For its identification the phenylcarbamate C<sub>10</sub>H<sub>13</sub>OCO-NHPh, mp. 140° (Gildemeister, Arch. Pharm. 1895, 233, 188) and its nitroso-derivative C<sub>10</sub>H<sub>13</sub>O(NO), m.p. 153° (Klages, Ber. 1899, 32, 1518), are especially suitable

Irone  $C_{1,3}H_{20}O$  is a constituent of oil of orris, the product of distillation of Iris germanica florentina (Linn), I pallida (Lam), and I (Linn) (Tiemann and Kruger, Ber 1893, 26, In the diluted state it has an odour of Bp 111°-112° at 2 mm, 144° at 2675) violets 16 mm. It has been synthesized from acetone and A4-cyclocitral (Merling and Welde, Annalen, 1909, 366, 119), see Perfumes.

Santalol C15H24O is a liquid camphor obtained from the volatile oil of sandalwood, Santalum album (Linn) The commercial product known under various trade names is prepared by steam distillation of the finely divided sandalwood The bulk of the world's supply comes from Mysore, where it was being distilled locally (Perf and Essent Oil Rec 1917, 8, 359) The physiological action of the oil is attributed to its alcoholic constituent, santalol, which is present to the extent of about 90 pc., and has been separated into a-santalol, a thick colourless liquid with a faint odour of sandalwood, bp 301°-302°, [a]<sub>D</sub>+1° 13′, and  $\beta$ -santalol, b p. 158° at 5 mm.,  $[\alpha]_D$  -41°47′ (von Soden, Arch Pharm 1900, 238, 353, Schimmels, Rep 1910, n. 107).

The oxygen content of the foregoing camphors is one atom. The following contain two atoms of oxygen: Diosphenol, Buchu camphor C<sub>10</sub>H<sub>16</sub>O<sub>2</sub>, a crystalline separation from oil of Buchu leaves, *Barosma betulina* (Bartl), *B. crenulata* (Hook), B. serratifolia (Willd.) (Fluckiger, Pharm. J. 1880, [3] 11, 174, 219), is closely related to thymol and carvacrol, into which it passes quantitatively by the action of concentrated hydrochloric acid at 150°-180° M p. 83°-84°, b.p. 109°-110° at 10 mm. It is characterised by its reduction of ammoniacal silver solution and Fehling's solution (Semmler and McKenzie, Ber. 1906, 39, 1158; Konda-koff and Bachtscheef, J. pr. Chem. 1901, [2] 63, 61)

Inula or Alant camphor, alantolactone  $C_{15}H_{20}O_2$  is the chief constituent of oil of Dissert. Rostock, 1895). Mp. 76°, bp. 275°, with partial decomposition (Bredt. and Posth, Annalen, 1895, 285, 349). It dissolves in alkalis with formation of the corresponding hydroxy acid, which melts at 94°. The lactone has been used in medicine, under the name 'helenin,' as an antiseptic for internal use. (See also Sprinz, Arch. Pharm 1901, 239, 201)

H. K. CAMPHORAL. Trade name for the camphoric acid ester of santalol.

CAMPHOSAN. A solution of camphoric acid methyl ester in santalol.

CAMWOOD. Camwood or 'cambe wood,' stated to be derived from a variety of Baphia nutida (cf banwood), is very similar in general properties to the other 'insoluble red' dyewoods It is, however, more expensive, yields deeper shades on dyeing, and its colouring matter is said to be more soluble than that present in the other woods

It has been examined by O'Neill and Perkin (Chem Soc. Trans. 1918, 113, 126), who employed for this purpose similar methods to those found

serviceable with sanderswood (lc)

Iso-santalin, the main colouring matter, forms a chocolate-coloured powder, which on grinding becomes redder in appearance, and is readily soluble in boiling methylated spirit When heated, it shows no sign of melting, darkens at 280°, and is fully decomposed at 290°-300°, being then a carbonaceous powder. It possesses the formula  $C_{22}H_{16}O_6(OCH_3)_2$ , gives with alcoholic potassium acetate the salt C<sub>96</sub>H,<sub>3</sub>O<sub>32</sub>K or C<sub>72</sub>H<sub>65</sub>O<sub>24</sub>K, shows evidence of the formation of soluble oxonium salts, and in general properties closely resembles its isomer santalin. The colour reactions and also the dyeing properties of the two compounds indicate, however, that they are distinct substances .-

Santalın Iso-santalin Alcoholic hydrobromic acid Crimson Reddish-violet Dilute sodium Dull red. Dull violet. hydroxide. ferric Alcoholic chloride Violet Bluish-violet

For dyeing the colouring matter in alcoholic solution was added to the water in the dye-beth and the dyeings were carried out (a) employing wool alone, (b) employing wool alone and subsequently saddening with bichrome, (c) employing wool mordanted with bichrome and cream of tartar, and (d) employing wool mordanted with bichrome and sulphuric acid.

Acetyl-180-santalin  $\mathrm{C_{24}H_{18}O_8(C_2H_3O)_4}$ , consists of a deep salmon-coloured powder, and does not possess a definite melting-point, being gradually decomposed without fusion between 250°–280°. A molecular weight determination employing naphthalene gave the high figure 2344, a result very similar to that given in these circumstances by acetyl-santalin itself, and which may possibly be due to the production of a colloidal solution

Deoxy-iso-santalin C<sub>24</sub>H<sub>18</sub>O<sub>2</sub>(OCH<sub>3</sub>)<sub>2</sub>, corresponding to the deoxysantalin of sanderswood, is a scarlet amorphous powder which has not yet been obtained in a definitely crystalline condition. When heated, it did not show a distinct melting-point, but decomposed at 160°–165° with evolution of gas. A solution of this substance in absolute alcohol gives no immediate precipitate with potassium acetate, as happens in the case of 130-santalin, and only when excess of the reagent is employed is a gelatinous deposit formed.

A comparison of the colour reactions and dyeing properties of deoxy-iso-santalin (a) and deoxy-santalin (b) is given in the following table—

(a)**(b)** Alcoholic solution\* . Orange Orango-brown Alcoholic hydrobiomic acid . Bught crimson Scarlet. Dilute sodium hydroxide . Crimson-scarlet Scarlet Alcoholic ferric . Violet. chloride Maroon.

The dyeing experiments were carried out by the same methods as those described above.

Deoxy-iso-santalin	(a) Pale red- violet	$^{(b)}_{ m Red}$ puce.
Deoxy-180- santalın	(c) Dull red- violet	(d) Pale dull red-violet.
Deoxy-santalın	$\stackrel{(a)}{\mathrm{Red}}$	(b) Dull bluish- red
Deoxy-santalın	. Dull crimson	(d) Red.

 $Acetyl-deoxy\text{-}iso\text{-}santalin \quad C_{24}H_{20}O_7(C_2H_3O)_4, \\ \text{when heated, fused and decomposed at }170^\circ\text{-}175^\circ\text{-}15$  It consists of an almost colourless powder differing considerably in appearance from acetyl-iso-santalin. A molecular weight determination, employing naphthalene as solvent, gave the figure 1324, which is approximately half that found in the same circumstances for acetyl-iso-santalin.}

By exhaustion with alcohol the sample of camwood employed by these authors gave 16 p.c. Camwood does not appear to contain either ptero-carpin of homopteio-carpin. A. G. P

CANADA BALSAM v BALSAMS, and OLEO-RESINS.

CANADA PITCH or HEMLOCK SPRUCE RESIN v RESINS.

CANADINE. A member of the isoquinoline group of alkaloids, occurring together with hydrastine and berbeijne in *Hydrastis Canadensis Sec* under Hydrastine

CANADIUM. A term formerly applied to a supposed new element, now used to denote an alloy of 1 part palladium, 2 parts of platinum, and 6 parts of mckel, used as a substitute for platinum. It has similar resisting powers, and melts at about 1570° Its cost is about half that of platinum (Heath, Met. and Chem. Eng. 1917, 17, 666)

CANADOL. Petioleum ether or ligioin That portion of refined petroleum which boils at about 60° and has sp gr of 0 65 to 0 70, consists mainly of noimal hexane (v Paraffin, and Petroleum).

### CANANGA OIL v OILS, ESSENTIAL.

**CANARIN.** A yellow colouring matter obtained by the action of bromine or a mixture of potassium chlorate and hydrochloric acid or ammonium persulphate upon potassium or ammonium throcyanate, it probably consists of  $C_8H_6ON_8S_7$  (Goldberg, J pr Chem 1901, ii, 63, 465, 64, 439, cf H Schmid, Dingl poly J 251, 41) (For details of mode of preparation, v. ibid. 253, 130, also J. Soc. Chem. Ind. 3, 476). Cloth dyed with canaim resists light and soap. Neither concentrated acids not alkalis destroy it or dissolve it out of the fibre. Bleaching powder has no action upon it. Acts as a moddant for basic aniline dyes.

CANDELILLA WAX. Candelilla occurs as a deposit on the surface of the candelilla plant (probably Euphorbia antisyphilitica), which grows wild in Mexico and Texas ally the wax was separated by boiling the parts of the plant with water, but of recent years a method of extraction with chloroform has been introduced, some of the works being capable of dealing with 5 tons a day From 2 5 to 6 p c of crude wax is obtained, and is purified by straining and melting in water containing 0.5 to 1 p c of sulphuric acid. The crude grey product contains up to 65 pc of water, 3 to 15 pc of dirt, and 0 5 to 1 5 p c of mineral matter purer red or brown variety is probably obtained by the extraction method (Berg, Chem Zeit 1914, 38, 1162)

Several methods of extraction have been patented In Sharp's process (US Pat. 1018589, 1912) the wax plant is boiled with petroleum spirit in the presence of fuller's earth, the extract clarified, and the solvent evaporated In Watson's patent the plants are heated to 149°, and subjected to the action of a downward current of steam (US Pats 1042992, 1912, and 1058648, 1913). A special form of extractor devised by Thatcher (US Pat 1056378, 1913) comprises a digesting compartment, reservoir for the solvent, and vaporisers to evaporate the solvent

The crude greenish-grey wax melts at 67°-68°, and has sp gr. at 15°, 0 9825-0 9850; acid value 12.4-14.39; sapomification value,

46'1-64'9; nodine value, 16'6-36'8; unsapomfiable matter, 77-91'2 p.c., largely consisting of hydrocarbons. The constituents identified include hentriacontane, dotriocontane (m.p. 71°), myricyl alcohol, two cholesterols, an oxylactone (m.p. 88°), and resmous constituents giving the Liebermann-Storch reaction (Fraps and Rather, J Ind Eng. Chem. 1910, 2, 454, Hare and Bjerregaard, ibid. 1910, 2, 203, Sanders, Chem. Soc. Proc. 1911, 250; Meyer and Soyka, Monatsh. Chem. 1913, 34, 1159; Berg. Lc.)

A difficulty attending the use of the pure blown or red wax, is that it can only be bleached after the addition of a considerable quantity of paraffin wax, and is therefore only suitable for the manufacture of inferior kinds of varnish, for insulating telephone wires, and especially for boot polishes, for which its low m p is an advantage. For other purposes, such as candlemaking, it is inferior to carnauba wax (m p 83-91°) (\* WALES)

CANDLES. Candles represent some of the most ancient and most useful forms of illuminants. The excellence of a candle depends on the nature of the wick and of the combustible matter, and on the manner and extent in which these are apportioned. The prototype of the candle was undoubtedly the torch, which must be regarded as a huge wick with the minimum amount of combustible matter, this proportion being gradually altered until the ratio used at present, viz. about 1 part wick to 50 parts of combustible matter, is reached.

The following table shows the stages in the development of candles.

Torch Pine branches or slips (Lat. tæda), saturated, naturally or artificially, with resinous or fatty matter

Link Rope-strands steeped in iosin, tar, or pitch; in olden times, doubtless, in asphalt or bitumen.

Flambeau. A core of hemp, soaked in rosin and coated with crude beeswax. Later, the outer coat was made of bleached wax

Dips. Wicks of rush-pith (rush-lights), clude flax or cotton, and subsequently of twisted cotton yarn, coated with beeswax or tallow by repeated dippings.

Mould's (Introduced about the 15th century by the Sieur de Brez.) Hard tallow, spermaceti, stearine, or parafiin wax, cast round the wick in a mould.

In addition to these varieties may be mentioned rolled, poured, and drawn candles

Dips, the cheapest, as well as the oldest form of candle, were made until comparatively lately of tallow or household grease. Beeswax candles were usually poured, drawn, or rolled. The great advantage of the 'dip' lies in the ease with which it can be made. The thrifty house-keeper was wont to set aside the superfluous kitchen fat for melting day, when part went to make soap, whilst the harder portions were formed into candles. The fat was thrown into boiling water and boiled three or four times with a little salt to 'render' it. The dirt and impurities being removed by subsidence, the clean liquid fat was run through a strainer into the candle pan. Some skill and experience were required to regulate the temperature of the melted fat. If too hot, the liquid fat would run

off the wicks; if too cold, the material would congeal too quickly and adhere to the wicks irregularly and in lumps. In households these would be rushes, divested of their piel with the exception of a thin strip which was left to give strength to the pith. These were usually tied in bunches of four, so that one wick could be held between each pair of fingers, and thus be immersed in the liquid fat. A short time was allowed for each dipping to cool the last coat Four dippings mostly sufficed, when the finished candles were hung up in an airy loft to harden and whiten

In dips as manufactured on a large scale, the wicks are of twisted cotton, and are strung on rods, each rod holding eight. The workman, holding an end of the rod in either hand, first immerses the wicks in very hot tallow, in order that their fibres may be thoroughly saturated, and then, as each rod is ready, it is slid on to a cross frame to cool; the wicks are then redipped in tallow at a temperature little above its solidifying point, till the desired weight is obtained. As a rule four 'dispures' are required

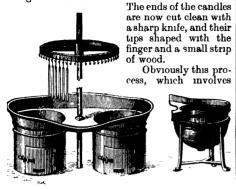

obtained As a rule four 'dippings' are required.

Many devices exist for reducing labour and ensuring uniformity of result in manufacturing Of these contrivances, the 'Edinburgh wheel' is the best known It consists of a long pole, pivoted vertically, and having mortises cut about its centre through which pass long wooden bars, each pivoted at its centre on an These bars carry frames at their exiron pin tremities, each of which, in its turn, holds about eight wick-rods. The post revolves, and as each bar with its frame passes over the melting pan, it is pulled down, so as to immerse the wicks. The opposite frame restores equilibrium, and the rotating and dipping are con-tinued until the proper weight is obtained, which is signalled by some continuance on the post, itself the object of much inventive in-The most perfect apparatus of this kind was patented by Price's Candle Company and worked at the Inventions Exhibition in London in 1885.

Rolled, poured, and drawn candles. Rolled candles are now almost obsolete. Formerly, the larger sizes of church candles were made by 'rolling' a cake of warm wax, kneaded until it was plastic, round a wick, and imparting the necessary smoothness and uniformity by means of a rolling-pin. This process has now been entirely superseded by that of 'pouring.' 'Drawing' is resorted to only in the case of 'cables' of small sizes, and tapers.

In pouring, an apparatus similar to that used in dipping is employed, but instead of the wicks being dipped, the melted beeswax is poured over them while the frame is kept in rotation (Fig. 1). In the larger sizes, the wicks have to be reversed from time to time to ensure a uniform thickness. The workman ascertains the correct dimensions by measuring with a piece of tape. After every two or three pourings, according to the weather, the hoops are hung in a current of air to cool. When the candles are of the requisite thickness, they are severed from the frame and placed on a smooth marble slab The operator then rolls them to and fro under a board, on which he leans with his full weight. By this process, which requires much skill and practice, the irregularities are smoothed away,

and the candles, in the hands of a skilful workman, assume the evenness of outline of moulded candles, with a peculiar softness, indescribable, though unmistakable when once identified.

his 1

much skilled labour, must render beeswax candles very expensive. They are, indeed, the most costly form of illuminant. Their use is confined to churches and, to a small extent, to carriage lamps, in which formerly no other candle could be employed, by reason of the strong spring, although now several efficient substitutes exist and are in use.

To understand the favour which beeswax continued to enjoy long after the introduction of stearine and paraffin wax candles, which are not only much cheaper, but give a better light, we must take several circumstances into account The first and, doubtless, the most cogent fact lies in the sharp contrast which formerly obtained between beesway and tallow, a contrast which finds mention in many a tale of social life. even as far back as the times of Haroun Alras-The candle at one period was absolutely the only means of illumination available, and formed a very considerable item in the household expenses As only the rich could afford this luxury, the beeswax candle became intimately associated with the other signs of wealth, as introduction of spermaceti, in the middle of the 18th century, greatly affected the use of beeswax, and this was quickly followed by the adoption of gas in houses. Within the last decades, the electric light has replaced both beeswax and spermaceti candles in houses where for centuries no other light was known

Tc adapt the beeswax as it comes from the hive to the requirements of the chandler, but Lttie is needed beyond the ordinary cleansing; processes. The clean beeswax is run from the 'copper' over a rapidly rotating drum into cold water, by which means it becomes divided into fine shavings. These are exposed to the influences of sun and air for several weeks, with occasional re-meltings and pourings, after which the now cream-white wax is ready for use.

Drawn candles are made by drawing a considerable length of wick through a pan of beeswax (Fig. 2), maintained at a regulated temperature by (fire or) steam. The wick is wound from one drum on to another. As it leaves the pan, it traverses a plate perforated with holes in-

creasing from one sixteenth of an inch to half an inch in diameter, whereby the superfluous wax is stripped off, the coated wick as it emerges being of the diameter of the hole. When the wick is all wound off, the drums are reversed, the end of the coated cotton passed through the

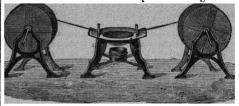

Fig. 2.

hole next in size, and the operation continued till the requisite thickness is obtained. This is seldom over half an inch, as the risk of cracking increases considerably with the diameter of the cable. In fact, this process is resorted to mainly for manufacturing 'spills' or lighting-wicks and the little tapers used for decorating Christmastrees, but here also stearine in the former and paraffin wax in the latter have gradually displaced beeswax.

Mould Candles -The chief variety of candles now made are mould candles. In order to ensure the proper burning of a candle, great attention must be bestowed upon the preparation of the wick, which is to the candle what the burner is to the gas. Till about 1820 the only wicks used were made of twisted cotton yarn, still to be seen in tallow dips No means for consuming the wick being employed, snuffers had to be used to remove the charred and glowing end Several expedients were devised to bring the wick automatically into contact with the air, and thus cause it to be consumed as the candle burnt The best of these consisted in twisting the wick round a rod, and while in a state of tension, coating one side with rize or other stiffening. This imparted a tendency to turn outwards and curl over, which to a great extent obviated the use of snuffers. Palmer, in 1852, invented a simple means for achieving the same result more thoroughly by introducing a fine thread coated with metallic bismuth into the substance of the wick, which thread he called the 'doctor' When ignited, the easily fusible metal formed a globule on the end of the cotton, which by its weight bent the wick out of the flame into the air, when the oxygen could combine with the incandescent carbon, whilst the bismuth was volatilised. So successful was this device, that Palmer's 'metallic wick' candles achieved great popularity, especially for burning in candle lamps, for which large candles, some-times weighing two pounds, were employed. The same device was again patented in Germany, by Varenkamp, as late as 1899

But the introduction of 'braided' or 'planted' wicks by Cambacères (in 1825) rendered such precautions unnecessary, the flat form of the wick, as now made, imparting a sufficient tendency to curve and bend outside the flame, where the cotton can burn completely. Now all except tallow dip candles are provided with these cores.

Before the wick can be used by the candle maker, it has to be 'pickled,' i.e. soaked in a

solution of certain chemicals, which vary with cated apparatus, consists of a cluster of pewter the nature and purpose of the cotton. The moulds, introduced in 1724 by Freitag, held preparation of these solutions forms one of the chief items in the manufacture of a good candle, and to carry it out thoroughly demands considerable practical experience; for the wick itself varies much in its composition, especially as regards the percentage of mineral matter The plait, too, will vary in tightness, however carefully woven Then again, a paraffin candle requires a thin wick to check a too-rapid supply of the liquid fuel. A beeswax or sperm candle, on the other hand, the melted material of which is less mobile, or has less tendency to smoke, needs a thicker wick. The nature of the combustible, its melting-point, viscosity, and burning powers; the compounding of a suitable material by mixing candle materials from several sources; the selection of a wick that in number of threads, structure, and substance is adapted to the special material chosen; the subsequent treatment of this with such salts as will correct or enhance its tendencies, -these are some of the points which must be considered before proceeding with the more mechanical operations involved in candle making

The wicks, which arrive at the factory from the cotton spinner in hanks, are placed two or three days before being wanted in the appropriate pickling solution. The object of 'pickor 'smoking,' two great defects to which the candle is liable. The 'pickling' retards the too rapid combustion of the cotton, and vitrifies it slightly, so that when the wick protrudes from the flame any ash can drop off readily In order to ensure the ready lighting of a candle, it has been proposed (Haase, Fr Pat 342527) to impregnate the protruding end of the wick with a solution of celluloid in acetone nitre, sal ammoniac, potassium chloride or chlorate, and ammonium phosphate, are the principal salts employed for pickling; though almost every manufacturer has his own recipe. The proportion of the salt to water is usually about 2 oz to 1 quart The wicks are steeped in the solution for about 24 hours, after which they are placed on a perforated shelf, to allow the bulk of the liquid to drain off, and then transferred to a centrifugal machine rotating at a speed of nearly 1000 revolutions a minute, where the residual water is expelled without the slightest torsion or other disturbance in the structure of the threads, which would be almost inevitable in any other process. The hanks, still slightly damp, are placed in a cupboard heated by steam, and finally hung up in an airy room until required. The amount of salt remaining in the fibre must, of course, be very small, but it is quite sufficient to influence materially the burning of the candle The wick is next transferred to the spools, from which it passes to the moulding machine. This task is performed by boys, who wind the wick off the This task is hank previously stretched on a circular rotating frame, on to 'spools' or bobbins on spindles (Fig 3) As they wind, they let the wick run through their fingers, to detect any knots or other irregularities, which might interfere with the burning of the candle. The spools are now ready for transport to the machine, invented by Cahouet in 1850. The old 'hand-frame,' the forerunner and prototype of the present complimoulds, introduced in 1724 by Freitag, held

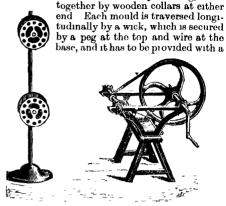

Fig. 3

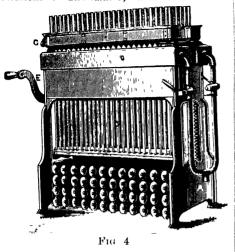

little loop of cotton, through which a wire is passed

The butt ends of the moulds open into a trough about 1 inch deep. Into this the hot material is poured until it is quite filled, and the whole frame is then placed in a tank of water, the temperature of which varies with the quality of candle, as will be explained presently When quite cold, the candles are removed from the pipes by simply inverting the frame, the cake of superfluous candle material having been previously scraped off, and the wires and pegs withdrawn As the pipes are made slightly conical and as the substance shrinks in cooling, there is seldom any difficulty in emptying the frame; if one or two of the candles should refuse to leave the moulds, a slight tap with a mallet speedily loosens them This method is obviously slow and cumbrous, and were it not that some buyers will have hand-made goods, also that a few odd sizes for which it would not be worth while to keep special machines can only be made in hand-frames, these frames would have been abandoned long since hand-frame can be filled and emptied once an hour, whilst a modern machine will do thice the amount of work in the same time

Fig 4 represents a candle machine of modern manufacture, for making candles with oidinary, i.e. not self-fitting, ends. It embodies the conbined inventions and improvements made successively by Sampson (Eng. Pat 1796); Binns (Eng. Pat. 2488, 1801); Morgan (Eng. Pat. 6610, 1834); Tuck (Eng. Pat. 7409, 1837); Palmer (Eng. Pat. 12077, 1848); Cowper (Eng. Pat. 1988, 1856); Humiston (Eng. Pat., in the name of Newton, 2641, 1857); Stainthorp (Eng. Pat, in the name of Pitman, 2556, 1857); Stainthorp (Eng. Pat. 740, 1860) The machine consists mainly of a metal tank, G, in which the pipes are fixed with their butts opening in a trough and their tips emerging below. The tips are not of one piece with the moulds, but can slide up and down, fitting water-tight when drawn home. The motion is communicated by pistons, D, to which the tips are soldered, and which are perforated longitudinally.

The wicks wound on the above-mentioned spools, which rotate on a series of spindles at

the base of the machine, pass up these perforations D. The tank G, which surrounds the

pipes, is preferably connected with hot and cold water cisterns, or with cold water and steam. The moulds are made of pewter (an alloy of tin

and lead), other materials, such as tin, brass, glass, &c, not having been found suitable in practice Porcelain moulds have been patented for paraffin candles (Ger Pat 195702), but it is very unlikely that they will be adopted in candle works, as they are too costly; moreover properly cleaned pewter moulds impart the same lustre to a candle that the porcelain mould gives. To begin the operation of casting, the wicks are drawn through the pistons, tips, and pipes, and temporarily secured in the troughs. These, and the moulds opening into them, are now filled roughly, merely to afford a startingpoint for the wick, and emptied as soon as the material is cold. To effect this, the trough is scraped clear with a 'spud' (a blunt kinfe of the width of the trough), after which the handle E is slowly turned. This imparts, by means of rack-and-pinion gear, a vertical motion to the pistons, which mount up the pipes, carrying the dummy candles with them, and unwinding the wick from the spools As the candles emerge from the pipes, they are received in a clamp frame c, which is held open by a spring handle When the tips are clear of the trough, the clamp is closed, gripping the candles firmly handle is now turned the leverse way, causing the pistons to descend in the moulds till the tips close the ends securely. Thus the wicks

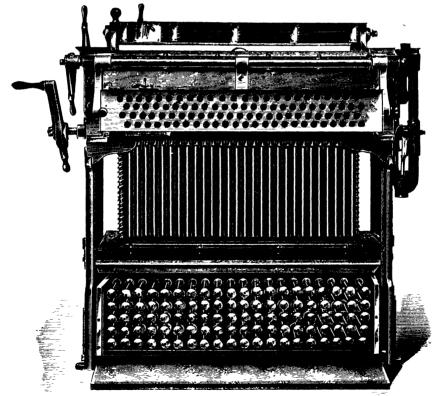

Fig. 5.-Multiple moulding machine.

are left in the centre of the pipes, held by the most recent type of this machine is shown in dummies above and the spools below. The Fig. 5. The next step depends on the nature of

the material used. If stearine candles are to be made, the tanks are charged with tepid water, the temperature of which the operator determines by his hand in preference to other methods. The reason for this precaution depends upon the highly crystalline structure of 'stearic' acid ('stearme'), which renders it hable to crack if chilled too suddenly, or to crystallise if cooled too slowly, whereby the appearance if not the structure of the candle would be impaired Therefore the melted stearine is stirred, with the aid of simple machinery, while in the melting pans, till it assumes the consistency and appearance of gruel, in which state it is transferred to the 'jacks,' cans having a flat, wide spout. and thence to the moulds. When these are full, they are allowed to rest about 25 minutes until they are sufficiently hard to permit of their being withdrawn without fracture. The troughs are not scraped in this case, as the tops are hard enough if the candles are raised 2 inches. As soon as the pipes are filled again and the material set sufficiently to hold the wick without extraneous acid, the upper row of candles, often while still warm, is removed into trays where they cool and bleach. This tendency of stearine to crack was a great obstacle to the success of these candles when they were first introduced. Among the various devices employed to overcome the defect was that of stirring a small proportion of arsenic into the melted steamne This certainly broke the grain, but it was of course diffused into the air on burning the candles When this generally known, the prejudice against stearine candles was such as to affect injuriously the success of the new substitute for tallow, and to this day stearine candles enjoy but a comparatively limited popularity in this country

In a patent process for preparing the fatty acids for stearine candles (Reuter Process Co, Eng Pats 9393 and 9394, 1915), the glycerides are fractionally saponified by boiling with sulphonic acids, such as Twitchell's reagent (Eng Pat. 4741, 1908). It is claimed that candles made from the resulting fatty acids are not decolourised by an exposure of several

days to the sun and air.

Paraffin Candles - At present, stearine candles are replaced in this country by candles made of a mixture of stearine and paraffin wax, except in the case of hollow candles (see below) In France, however, the stearine candle, being protected by customs duties on paraffin wax, holds its own against paraffin candles; and in that country, as also in Italy, stearine candles are manufactured in considerable quantities In Germany and Austro-Hungary, the stearine candle is gradually being ousted by the paraffin candle When, in 1854, James Young obtained from shale oil a pure white paraffin, which was subsequently made into candles under a patent of J K. Field, the immediate popularity of the novel illuminant left little doubt as to what would be the material of the candle of the future. Even the most enthusiastic optimist of that day would have hesitated before accepting the prophecy that paraffin candles would be sold at half the price of tallow dips, as is the case to-day.

The main difficulty experienced in the early stages of the manufacture of paraffin candles arose from want of precaution in regulating the

temperature while casting. The same machine can be employed for either paraffin or stearing candles, but when paraffin wax is to be used. the water in the tanks is raised to a temperature of nearly 200° F., by passing steam through the pipe. Also the paraffin wax itself is heated to about 170°-180° F., and poured in a highly mobile state. When the pipes are filled, the hot water is discharged from the tanks and cold water immediately introduced, thus suddenly chilling the fluid material. If the exact point be missed, failure will result. Thus, if the pipes are colder than the inflowing paraffin wax, it will congeal as it touches the metal, assuming a dull. striated aspect. On the other hand, if the moulds are allowed to cool slowly, the candles will shrink on to, instead of from, the walls, and will be injured in removal from the moulds, if indeed they can be withdrawn at all in the solid When the operation is properly carried out, and the pipes are not worn by usage, and further, if the paraffin is highly refined and of a high melting point, the candles leave the moulds with a lustre which hardly suffers by ordinary handling. This lustre, combined with the translucency, snowy whiteness, and ready adaptability to ornament in shape and colour, gives paraffin wax the pre-eminence over all other materials for candle making It has, however, its disadvantages. The readiness with which it liquefies by heat, gives to even the best paraffin candles a tendency to 'gutter' Moreover, the paraffin wax has the peculiar property, which is independent of the melting-point, of becoming plastic after exposure to a moderate degree of heat. The time required to develop this tendency varies, it is true, with the hardness or fusibility of the paraffin wax, which ranges from 105° F to 140° F; but even ceresin, of a melting-point of 142°-143° F, is affected by pro-The inferior varieties of paraffin tracted heat candles, from the ease with which their substance melts, are very prone to smoke, the wick is apt to be too abundantly supplied with combustible, and is consequently chilled below the point at which complete combustion can take place

By judiciously mixing stearin and paraffin wax, the candle maker is able to obviate many of the defects of the substances, whilst retaining their advantages Such candles as 'petrostearine,' 'palmitine,' and other popular varieties and especially the paraffin candles of the Saxo-Thuringian paraffin-wax industry, are made on

this principle.

In the United States the method of preparing such composite candles is to melt the paraffin wax by means of steam, to add a small proportion of stearine, and to clarify the naxture by the addition of oxalic acid, which precipitates calcium salts. The clear upper layer of wax is then drawn off into a steam-jacketed pan, where it is heated, and impurities are detected and separated, after which it is transferred by means of a 'swimmer' to a 'jack' or bucket, which delivers it in a regulated stream to the moulding machine (Campbell, J. Inst. Petrol. Techn. 1916, 2, 274)

In Laursen-Schjodt's process (Fr. Pat. 466027, 1913), oleine or stearme is dissolved in turpentine or other solvent, the solution treated with the calculated amount of alkali for sapomification, and the resulting mass incorporated with paraffin wax.

The use of tilmethylamine in the manufacture of composite candles has been patented by Herzmann (D. .R P 275344, 1911), the trimethylamine being treated first at the ordinary temperature, and then under pressure at 150° with chlorohydroxy fatty acids or sulphuric esters of hydroxy fatty acids such as Turkey-red oil. The resulting product can be saponified

In Burke's patent (Eng. Pat. 14975, 1914) about 0.25 p.c. of a heavy metal salt of an organic acid (e.g. lead oleate or palmitate) is added to

the parafhn wax

FIG. 6

The transparency of stearine and paraffin candles may be reduced by adding from 1 to 6 p.c of 'denatured' ethyl or methyl alcohol,

the amount depending upon the degree of opacity desired (Moretti, Fr. Pat

431490, 1911)

One of the greatest improvements in candle making is the self-fitting end, by which simple device a candle will fit any normally constitueted sconce without being sciaped or using paper or any other expedient to enlarge or diminish the butt. The self-fitting end patented by J. L. Field (Eng. Pat 3032, 1861), is now in universal use

Fig. 6 gives an example of the conical butt, whilst Fig. 7 represents the machine patented by E. Cowles for its manufacture. The difficulty to be overcome lies in the butt projecting beyond the stem of the candle, which renders the ordinary method of withdrawal impracticable. To meet this, the butts are cast

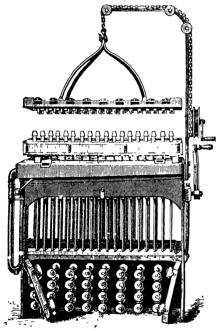

Fig. 7.

in a separate frame, which can be fitted to or removed from the pipes at will. When the machine is to be filled, the butt frame is lowered by the chain till the butts rest upon Vol. II.—T.

and fit tightly into their respective pipes. The wicks are then drawn through the butt moulds with a wire and clamped in a centric position. after which the filling is proceeded with in the usual manner. When cold the wicks are east loose, the tops scraped off, and the upper frame hoisted off the butts, as shown in the illustration, the operation being concluded as before. It will be noticed that this apparatus precludes running a continuous wick, as is done in the making of candles having plain ends; and in a large factory, a serious loss is incurred in the course of the year by the meh or two of wick snipped off at each operation. A very ingenious machine for saving this waste is due to E Cowles, who invented a split bed-plate holding the butts When ready for withdrawal, the butt

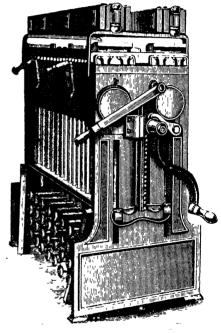

Fig. 8

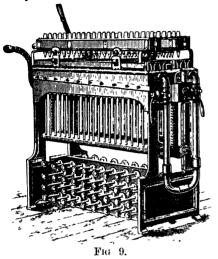

moulds are raised and opened out by a simple lever motion, and the candles can thus be passed through without further trouble (Figs. 8 and 9)

Numerous improvements have been made in the construction of candle machines by the makers in this country, in France, the United States, and Germany, but all these improvements affecting the principle All these machines work discontinuously. A continuous candle machine, for a description of which the reader must be referred to Engineering, 1901, Feb. 1st, has been constructed by Fournier et Cie, Marseille. The machine is very complicated, and would seem only to commend itself to works where a very large output can be relied upon, and where, at the same time, the works suffer from a shortage of cooling water.

An improvement, which has found more favour on the Continent than in this country, consists in perforating the stem of the candle

0

longitudinally so as to afford an internal escape for any combustible which would otherwise have

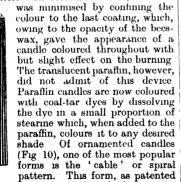

guttered down the outside The up-draught of air which takes place in the tubes has a tendency to ensure more perfect combustion. By reason of the hardness required in their manufacture, these candles must be made with stearine.

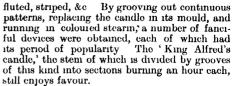

A more recent process to prevent guttering is that devised by Powell and Bush (Eng. Pat 110579, 1916), according to which the candles are varnished with a colour varnish or with paraffin wax stiffened with a combustible powder such as cellulose

('andles made for ordinary purposes are ready for packing immediately after leaving the Better-class candles are subcandle machine jected to polishing and finishing processes in special machines, which are much more used on the Continent than in this country

Much art has been expended on the ornamentation of candles Before the introduction of aniline dyes, candles were coloured with such pigments as vermilion, ultramarine, and verdigus, these, besides causing a dull, heavy appearance, rumed the wick by choking it with meom-bustible matter. In beeswax candles, this evil

by Field, was made by turning the plain candle in a lathe of complicated structure, which could fashion over thirty different sizes and patterns of candles, e.g. cabled, spiral,

The demand for cabled candles is now so large that they are made in moulds, the pistons while ascending being caused to rotate, so as to screw the candles out of their spiral moulds

Candles burning with coloured flames have been patented by Scheurer (D R P 216338, 1907), the candle material being impregnated with nitrates or other salts readily decomposing when heated, and metallic salts or wires capable of imparting a colour to the flame

Night lights are short thick cylinders of a fat or wax, furnished with small wicks, their object being to give a constant and lasting rather than a bright light They are usually cast direct in paper cases, and are recommended to be placed on water Price's Candle Co have adopted the plan of casting the cylinders in a machine similar to a candle frame, and employing a material so hard (pressed coco-nut stearine) as to retain its torm in hot weather without external support These lights are burnt in glass cups, thus shedding their full light and rendering the precaution of water unnecessary Another very popular form of this illuminant is Clark's 'pyramid' night light, which, as its name indicates, is coniform. In this, the material employed is pressed tallow of great purity, and the wick is a rush-pith with two lateral strips of the peel left adhering These turn outwards in burning, giving a neat and shapely flame. The base of the cone is a disc of plaster of Pans, which holds the wick upright till the whole of the fat is consumed; a result achieved less surely in the other kinds, where the wick is of 'inkle' (flax), held by a little strip of tin, into which the base of the fibre is fixed

Candles intended for heating purposes, and so burning with a hot smokeless flame, and giving only a feeble light, are prepared from esters of amino or imino acids melting between 50° and 130°, and decomposing between 200° and 300° Ammonium nitrate or similar substance is also added (Scheuble, D. R. P. 234340, 1909)

The use of viscose filaments as a material for candle wicks has been patented by Wilson (Eng Pat 5170, 1913).

The strides made in gas and electric illumination have not materially affected the prosperity of candle manufacture. On the contrary, every year sees a considerable increase in the number of candles made This is especially due to the increasing consumption of candles in mines (Transvaal, India, Australia, &c). An inquiry made by the writer, in 1903, as to the consumption of candle material in this country, led to an estimated quantity of 45,600 tons, which may be distributed over the different materials mentioned above, as follows tallow (for dips), 1000 tons; stearine, 2190 tons, paraffin wax, 42,200 tons, ceresin, 100 tons. France produces about 30,000 tons of candles, chiefly stearine candles; Germany, about 11,000 tons, chiefly paraffin candles; Holland, about 6000 tons, chiefly stearine candles; Belgium, about 4000 tons, chiefly stearine candles. Austro-Hungary,

Italy, and Russia produce much smaller quantities than the last-named countries.

Candles were exported from Germany to the value of £56,000 in 1912, principally to Russia, Mexico, Biazil and the Mediterranean countries. In 1912 the exports from Austria-Hungary, chiefly to the Balkan States, Russia, Turkey, and Egypt, were valued at £14,000; whilst the total exports from the United Kingdom (1913) were of the value of £435,000 (Board of Trade, Bull. No 89)

CANDLE-NUT OIL is obtained from the fruits of the candleberry tree, Aleurites moluccana (Willd), belonging to the family of spurgeworts (Euphorbiacca) The tree attains the height of 30 or 40 feet, is a native of the Moluceas and South Pacific Islands, and is widely distributed over the tropics of the eastern hemisphere, it also occurs in the Cameroons In India it is known as 'Indian akhrout.' The fruits resemble walnuts in their appearance, but the shell of the candle-nuts is far thicker. The name 'candle-nut' is derived from the practice of the South Sea Islanders to dry the kernels, thread them on reeds, forming a candle, several of these candles being wrapped in a leaf of pandanus (screw-pine) so as to make a torch

The average composition of the kernels is as follows

JW5					Per cent.
Oıl					. 610
Water					. 50
Proteins					. 230
Ash					. 34
Carbohyo	irates	and	crude	fibre	76
_					
					100 0

The cold-drawn oil is limpid, colourless, or yellowish, has a pleasant odour and bland taste, but cannot be used for edible purposes on account of its purging properties

The oil extracted from a typical sample of the nuts had the following characters sp gr at 155°, 0 9276; refractive index (25°), 1 4970, acid value, 08, saponification value, 1882, and rodine value, 1516 (Tests for Candle-nut American Soc for Testing Materials, 1914)

The oil is obtainable in enormous quantities, but hitherto it has not been used to such an extent as its drying properties would warrant

The fruit of A titloba (Forst) is two-celled, fleshy, ohve-coloured, and about two and a half inches in diameter. Each cell contains one nut, resembling in appearance and taste a walnut, the shell of which is very hard The seeds yield about 50 pc of an oil known as 'kekuna oil' Seeds from Hong Kong, where the tree is cultivated as one of the best shade trees, were found to contain 60 p c. of an edible oil very similar to that obtained from A. moluccana; whilst Mauritius seeds yielded 68 l p c. of oil with the following characters. sp gr. at 15°, 0 927, saponification value, 1937; and iodine value, 151. The nuts are worth about £28 per ton in Europe (Bull Imp. Inst 1912, 10, 44). CANELLA BARK. The dued

The dued bark of Canella alba (Murr), obtained from Florida and the West Indies in large buff-coloured quills or pieces of about an inch broad. Has a bitter pungent acrid taste and odour of a mixture of cloves and cinnamon, due to a volatile oil con-

The bark contains a bitter principle, cloves canellin, together with resin, mannite, and starch. Used in medicine as an aromatic bitter and tonic, and in rheumatism and gout

CANELLE or BISMARCK BROWN v. Azo-COLOURING MATTERS.

CANFIELDITE v. ARGYRODITE

CANNABIN or INDIAN HEMP RESIN v.

CANNABINENE v. RESINS.

CANNABINOL. The active constituent of Indian hemp resin or 'hashish' (v Resins).

CANNABIS INDICA v. RESINS. CANNONITE v EXPLOSIVES

CANTHARIDES. Spanish flies (Lytta vesicatoria) Dried coleopterous insects used in medieme, in the form of plasters, tineture, limments, &c, on account of their vesicating properties, due to a peculiar acrid principle, cantharidin.

Employed also as a stimulant diuretic, as an aphrodisiac, and as an emmenagogue Obtained principally from Hungary, Russia, and the South of France

(Gadamer, Arch Pharm 1914, 252, 609, 1917, 255, 277, 1917, 255, 315) is obtained by treating the powdered insects with chloroform, ether, or ethyl acetate, acidined with sulphure acid, evaporating the extract and treating the residue with carbon disulphide or light petroleum, to remove fat, or by mixing the canthandes with water and magnesia, drying, treating with dilute sulphuric acid, and extracting with ether. The yield varies from 03 to 103 pc of the insects taken Crystallises in trimetric plates, melts at 218°, but begins to sublime at 85° It is tasteless and modorous, blisters the skin strongly, especially when in solution or mixed with fat Yields the alkaline solution or mixed with fat salts of cantharie acid C10H11O5, by heating with aqueous solution of potash or soda For other derivatives of canthandin, see Rudolph, Arch. Pharm 1916, 254, 423. Gadamer has shown that the isocantharidin and isocantharidic acid of Andeilini and Ghira are in reality acetyl hydrato cantharic anhydride and acetyl hydrato

canthanc acid respectively
CANTON'S PHOSPHORUS v. CALCIUM CAOUTCHOUC v RUBBER; also TERPENIS CAOUTCHOUC OIL. An oil which has proved efficient in preventing rust - It is spread with a piece of flannel in a very thin layer over the metallic surface which is to be preserved, and allowed to dry. To remove it, the article taining eugenic acid which is also found in oil of has simply to be treated with caoutchouc oil again, and washed after 12 to 24 hours (J. Soc. Chem Ind 1, 315)

CAP COMPOSITIONS v EXPLOSIVES. CAPE BERRY WAX & WAXES CAPRIC ACID or DECOIC ACID v DECATOIC ACLD

CAPROIC OF HEXOIC ACIDS C'5H11 COOH

Seven isomerides are known

1 n-Caproic acid CH3(CH2)4COOH occurs in the fats, in cheese, and, possibly, mixed with certain of its isomerides, in cocoa-nut oil, in St John's bread, in the fruit of Heracleum sphondylium and in the flowers of Satyrium hircinum, and in the fusel-oil from the fermented molasses of mangel wurzel best prepared by fractionating crude fermentation butyric acid (Lieben, Rossi, Annakn, 159,
75, 165, 118), b p 204 5°. sp gi 0 9446 at 0°
2 Isobatyl acetic acid, or γ-methylicaleric acid

### (CH,),CHCH,CH,COOH

is present in butter, may be obtained by the action of hydroide acid upon hydroxyisocaproic acid (Mick & Annalen, 180, 57). Fittig Ruhlmann, ibid 226, 347), or by the distillation of isobutylmalome acid (Konig, Monatsh 15, 20 , Bentley and Perkin, Chem. Soc. Trans  $1898,\,487)$  , b p  $200^\circ\text{--}201^\circ$  , sp gi. 0.925 at 0°

3 Diethylaectic acid, pseudocaproic acid, or a-ethylbutynic acid (C<sub>2</sub>H<sub>3</sub>)<sub>2</sub>CH COOH, may be obtained by the action of sodium upon acetic ester, and treatment of the product by othyl iodide (Frankland and Duppa, Annalen, 138, 221), by boiling diethylcarbinol eyanide with potassium cyanide (Saytzeff, ibid 193, 349), by reduction of dichlorethyl acetic ester by sodium amalgam (Markownikow, Ber 1873, 1175), by heating sodium ethylate and sodium acetate in a stream of carbon monoxide (Geuther and Frohlich, Annalen, 202, 308), by heating diethylmalonic acid at 170°-180° (Conrad, ibid 204, 141), by heating α-diethyl-β-hydroxy-butyric acid (Schnapp, ibid 201, 70), by heating diethyleyanacctic acid with concentrated hydrochloric acid at 160° (Hesse, ibid 18, 749), bp  $190^{\circ}$  (756.5 mm), sp gr 0.9196 at  $20^{\circ}/0^{\circ}$ 

4 Methylpropylactic acid or a-methylcalcic acid CH<sub>3</sub> CH<sub>2</sub> CH<sub>2</sub> CH<sub>2</sub> CH<sub>3</sub> CO<sub>2</sub>H is obtained by the oxidation of its aldehyde, and by the reduction of methylacitylic acid (Licben and Zeisel, Monatsh 4, 37, 63), by heating a-methyl valerolactone or isosacchain with hydrodic acid and red phosphorus (Liebermann and Scheibler, Ber 1883, 1823, Kiliani, *ibid* 185, 632), by heating  $\alpha$ -methylpropyl- $\beta$ -hydroxybutyric acid (Jones, Annalen, 226, 292), and by the distillation of turpentine, bp 193°-194°, sp gi 0 9279 at 18°/0°, 1 part water dissolves 0 5693 part at 17°

5 Methylisopropyl acetic acid, isocaprone

acid, or ab-dimethylbutyric acid

### $(CH_3)_2CH$ $CH(CH_3)CO_2H$

may be formed from methylasopropylearbinol cyanide (Markownikow, Zeitsch Chem 1860, 1 205), by the oxidation of the corresponding hexylalcohol from Roman camomile oil (Kobig, Annalen, 195, 102), or by melting camphoric and with caustic alkali (Crossley and Perkin,

Chem. Soc Trans 1898, 16), bp 189°-191°.
6 Dimethylethylacetic acid or aa-dimethylpromonic acid (CH<sub>3</sub>)<sub>2</sub>C(C<sub>2</sub>H<sub>5</sub>)CO<sub>2</sub>H is formed by

the action of hydrochloric acid upon dimethylethylearbinol cyanide (Wischnegradsky, Annalen, 174, 56), and by the oxidation of the methylethyl ketone prepared from pinacolm (Lawimowitsch, *ibid* 185, 126) A colour-less liquid, bp 187°, mp — 14°

7 (a) B-thylbutyne acid of active caproic acid CH<sub>3</sub> CH(C<sub>2</sub>H<sub>3</sub>)CH<sub>2</sub>COOH is obtained by the oxidation of the active hexylalcohol obtained from Roman camomile oil (Romburgh, Rec trav chim 5, 221, Kobig, Annalen, 195, 102), b p 196°-198° (770 mm); sp gr 0 930 at 15°

(b) Inactive \(\beta\)-ethylbutyric acid may formed by heating secondary butylmalonic acid (Romburgh, Rec trav chim 6, 153) or from secondary butyliodide, diethylmalonic ester and sodium ethoxide (Kuhlisch, Monatsh. 14, 561, Bentley, Chem Soc Trans 1895, 267).

CAPRYL ALCOHOL V OCTYL ALCOHOL

CAPRYLIC ACID V OCTOIC ACIDS

CAPSAICIN V RESINS

CAPSICUM (Bird pepper, Cayenne pepper) The dried tipe fruit of Capsicum minimum (Roxb), which was probably a native of tropical America, but is now known only in cultivation, the chief supply coming from Africa and India

The fruit is 1-2 cm long and about onethird as broad, somewhat flattened oblongovoid in shape, and is covered with a crimson or scarlet, semi-transparent, wrinkled corraccous epicarp It is two-celled and contains about 20 yellow, flat, reinform seeds, 3.5 mm long and 2.5 mm broad. It is prepared for use by gunding the whole fruit

Cayenne pepper is sometimes adulterated with flour, corn-meal, or even sawdust Entire capsicum is also frequently substituted by larger Adulteration of the powder may be detected by the estimation of oleo-resin, which should not be less than 5 pc , and of the ash, which should not exceed 7 pc , and by microscopical examination (v Bitto, Chem Soc Absti 1893, D, n 546)

The active principle of capsicum is capsaicin (capsiein, capsicol)  $C_1, H_2, O_3N = (C_1, H_2, O_3N,$ Lapworth and Royle), which is present to the extent of 0.05-0.07 p  $\epsilon$  (Morbitz, Chem. Zentr 1897, n 593) It is obtained from the ethercal extract of capsicum, and crystallises from light petroleum in colourless plates, m p 63 5°, easily soluble in ether, alcohol, chloroform, &c., but almost insoluble in hot water and insoluble in cold water. It is not volatile in steam, and has the properties of a weak, phenol-like acid The benzoyl derivative forms silky needles, m p 74° (Micko, Chem Zenti 1899, i 293)

The other constituents are a volatile, nonacrid alkaloid, red colouring matter, wax, resin, fixed oil, oleic, palmitic, and steams acids, and a minute amount of a volatile oil having the odour of paisley (Pabst Aich Phaim 230, 108)

Capsicum is largely employed as a condiment In medicine, it is used, externally as a powerful subefacient, and internally in the treatment of atonic dyspepsia, chronic alcoholism, and delirium tremens

CAPSICUM RESIN v Resins

CAPTOL. Trade name for a condensation product of chloral and tannin; used in dermatology

CAPUT MORTUUM. A term employed by

CARAMEL 21

the alchemists to denote the residue remaining tion occurs in the retort or alembic after the volatile matter of the former, acquires an orange-yellow colour, has passed away

CARAGHEEN MOSS. Irish pearl moss (Chondrus crispus) (v Carrageen, Alge)

CARAJURÚ, CARCURU, or CRAJURU Brazilian dyestuff of a red colour, said to be identical with chica-red, used by certain Indian tribes to stain their skins, and which is obtained from the leaves of the Bignonia chica (Humb et Bonpland). It is a light, mealy, odourless, tasteless powder, which acquires a coppery lustre on tuturation Insoluble in water, but soluble in alcohol, ether, and alkalis (Viiey, J. Pharm 1844, 151)

CARAMEL. The brown substance produced by the action of heat on sugar glucose or invert sugar, used for colouring liquors, beer, sweet-

meats and gravies

Preparation —On the small scale common sugar is heated, with constant stirring, in a metal pan capable of containing about ten times the quantity taken, till the whole mass melts, turns brown, and at last suddenly froths up, when the heat must be immediately stopped. Not more than 15 pc of the weight of the sugar should be driven off, as the product is hable to become insoluble if further heated

For preparation of caramel colours, Asrymusty recommends the following processes (long kept secret) --

Colour for rum

Potassium or sodium hydroxide . 3 kilos Water Or potassium or sodium carbonate Water

Dissolve with heat in large iron pan, and add Glucose 120 kilos Or syrup of glucose 130

Boil over the fire till irritating vapours begin to appear, then decrease the heat and stir continuously till the required shade is produced, then stop the process by adding 30 to 40 litres of water in a fine jet

### Colour for beer or vinegar

Ammonium carbonate	6	kilos
Water	6	,,
Glucose	120	

Process exactly as above

In the modern method of manufacture the process is conducted in a closed vessel, generally with the addition of ammonia or one of its salts (cf Salamon and Goldie, J Soc Chem Ind. 1900, 19, 301) The colouring power of the caramel seems to depend upon the amount of amn.onia used in its preparation In McCowan's process glucose is heated with from 5 to 10 p c of its weight of liquor ammonia (sp gr 0 8803 in a closed digester to 100° for above 24 hours, and the mixture concentrated

According to Magalhaes (Compt 1end 1896, 123, 896), caramel prepared from cane sugar differs considerably from caramel made from glucose, in that it behaves with certain reagents exactly like a coal-tar colour Thus, when treated with basic lead acetate and then shaken with amyl alcohol, the former caramel communicates an orange-yellow colour to the solver,, whilst with glucose criamel, no coloura- According to Gélis its composition is C<sub>36</sub>H<sub>4</sub>,O<sub>24</sub>

Ether, when shaken with a solution whilst with the latter no colour is extracted Mordanted wool is dyed orange by the former, yellow by the latter Genuine wine, to which no caramel has been added, does not give these reactions (cf D'Aquiar and Da Silva, Compt rend 1897, 124, 408)

reddish-brown. Properties - Amorphous, brittle mass, porous and deliquescent; completely soluble in water, partially soluble in alcohol, of a more or less bitter taste and non-

fermentable Melts at 134°-136°

Little is known of the chemistry of caramel Gelis (Ann Chim Phys 1858 [iii ] 52, 352; 1862, [m] 65, 496) separated it into three amorphous substances, caramelan, caramelen, and caramelin, differing in solubility and colouring power, but not of fixed composition without definite melting-points, or crystalline derivatives and readily forming colloidal solutions formation from sucrose has been represented by the following equations

(i) 
$$6C_{12}H_{22}O_{11} = 12H_2O_{-2} = 6C_{12}H_{13}O_{9}$$
 (caramelan)

$$\begin{array}{ll} \text{(i)} & 6C_{12}H_{22}O_{11} - 12H_2O \\ & = 6C_{12}H_{11}O_{9} \text{ (caramelan)} \\ \text{(ii)} & 6C_{12}H_{22}O_{11} - 18H_2O \\ & = 2C_{36}H_{18}O_{21} \text{ (caramelan)} \\ \text{(iii)} & 6C_{12}H_{22}O_{11} - 27H_2O \\ & = 3C_{24}H_{26}O_{13} \text{ (caramelin)} \\ \end{array}$$

Stolle, by heating caramelan with dilute (3 p c) hydrochloric acid, obtained a hexose, which gave an osazone crystallising in yellow needles, melting at 179°

Cryoscopic observations by Sabanéoff and Antushevitch (J Russ Chem Soc 25, 23) would seem to indicate that the molecular weight of caramelan is much higher than the above formula indicates They point out that carbon dioxide, in addition to water, is given off in its formation. They allege that it is not a carbohydrate, but has the composition

and they represent its production from sugar by the equation

$$11C_{12}H_{22}O_{11} = C_{125}H_{183}O_{50} + 7CO_2 + 27H_2O$$

Gills found on heating sucrose to a temperature of 180°-190° that a loss of weight of 12 p c gave mostly caramelan, a loss of 15 p.c. Caramelen, with a loss of 22 pc caramelin, was the main product. On treating the caramel with 84 pc alcohol the caramelan was extracted, caramelen and caramelin being insoluble in alcohol of this strength. The caramelen could be removed by cold water, when the caramelin could be dissolved out by 60 p.c. alcohol or hot water

Caramelan, the main constituent of ordinary caramel, is a brown brittle solid of bitter taste, deliquescent and very soluble in water Softens at 108° The aqueous solution gives no precipitate with metallic salts, but reduces silver nitrate and Barreswil's (Fehling's) solution An alcoholic solution of lead acetate forms a precipitate C<sub>12</sub>H<sub>16</sub>O<sub>8</sub>,PbO an ammoniacal solution of lead acetate gives C<sub>12</sub>H<sub>16</sub>O<sub>8</sub>,2PbO (Gélis)

Caramelen is of a darker brown than caramelan, and is not deliquescent. It reduces Barreswil's (Fehling's) solution and forms compounds with lead similar to those of caramelan

22 CARAMEL

Caramelin is of a still darker brown. appears to exist in three modifications of which A is soluble in cold water, B in boiling water, and C is insoluble. The modification A passes into B on evaporating its aqueous solution. The soluble forms reduce Baireswil's solution and give precipitates with metallic salts All varie-

ties have the composition  $C_{96}H_{102}O_{51}$  (Gélis)

The molecular weight of 'caramel' was found by Gladstone and Tribe to be 1700, corresponding with Gélis' formula for caramelin.

Stolle (Zeitsch Ruben-Zuckei Industrie, 1899, 49, 800; 1901, 51, 836, 1903, 53, 1149) found on heating sucrose that no carbon dioxide or other volatile products were formed below 180°, and that caramelan is the sole product when this temperature is not exceeded and the loss is not greater than 12 pc, and that its formula 15 C<sub>12</sub>H<sub>18</sub>O<sub>9</sub>

The action of heat on sucrose has been further studied by Cunningham and Dorée with special reference to the production, properties and composition of caramelan (Chem Soc Trans 1917, 111, 589) They found on heating sucrose to temperature 170°-180° that, in addition to water, pungent acid vapours, furfuraldehyde and carbon dioxide were evolved, but that if the loss of weight did not exceed 12 p.c., caramelan free from sucrose and higher caramel products was the sole product When quite div it melts at 136°, is readily soluble in water, 84 p.c. alcohol, pyridine, methyl alcohol, or hot glacial acetic acid, insoluble in ether and benzene A concentrated aqueous solution acidified with hydrochloric acid gives a red precipitate with resorcinol, soluble in alcohol or alkalis Phloroglucinol gives a similar precipitate of a deeper colour It forms a tetra-acctate, yellow powder, insoluble in water or ether, but soluble in benzene, hot alcohol, or glacial acetic acid, mp 107°, a tetra-benzoate, a pale buffcoloured powder, mp 105°-108°, soluble in acetone, chloroform, alcohol or benzene, insoluble in water, ether, or light petroleum, a tetranitrate, a yellow powder which inflames violently on warming, readily soluble in ether, alcohol or benzene, insoluble in water

It appears to be a tetra-atomic alcohol, of the molecular formula C<sub>12</sub>H<sub>18</sub>O<sub>9</sub>, or, more probably, C21H36O1, Compounds formed with phenylhydrazine and semicarbazide indicate the existence of one CO- or CHO-grouping per C21 unit Concentrated nonoxidising acids convert it into caramelin C<sub>24</sub>H<sub>26</sub>O<sub>13</sub>; weaker solutions hydrolyse and dehydrate, producing dextrose,

methylfurfuraldehyde and humic acid

### Detection and estimation of caramel.

Detection of caramel in wines, &c -10 c c of the liquid to be tested is mixed with 30 to 50 c c of paraldehyde, and enough alcohol added to make the liquids mix, if caramel is present, it forms a duty-brown precipitate sticking to the bottom of the vessel, the solution is poured off, the precipitate washed with alcohol, dissolved in a little hot water, and the solution evaporated to 1 cc, when different quantities of caramel may be compared by comparison of colours to confirm, this solution is mixed with one of 2 parts hydrochloride of phenylhydrazine in 20 of water, with excess of acetate of soda Caramel yields an amorphous brown precipitate,

To detect caramel in vinegar 50 c c, are mixed with an excess of calcium carbonate and evaporated to dryness. The mass is then extracted with 20 cc of other; the othereal solution is filtered into a test-tube containing 10 c c of resorginol reagent (1 gram of resorginol in 100 e.e. of hydrochloric acid of sp.gr. 1 125). Should caramel be present in the vinegar, a red zone is obtained at the junction of the two liquids (Ronnel, Ann Falsif 1912, 5, 517) reaction is due to the presence of hydroxy-methylfurfural, which also yields a violet colour with  $\beta$ -naphthol in sulphuric acid, and an orange-yellow colouration with phenol in sul-phuric acid. The liquid to be tested, wine, vinegai, brandy, &c, is neutralised if acid, concentrated to a small bulk, extracted with ethor, the ethereal extract treated with a few drops of a 5 pc sol of phenol in ether, and The residue is mixed allowed to evaporate with about 5 cc sulphuric acid, when the characteristic colour appears (Schenk, Apoth Zeit 1914, 29, 202, J Soc Chem Ind 1914,

Amthor's method, which is the only one capable of distinguishing between caramel and the colouring matters of colour malts, is as follows: 10 cc. of the beer or other liquid is treated with 30 50 c c of paraldehyde, according to the intensity of colour, and absolute alcohol is added until the liquids mix If the mixture is left for 24 hours a brownish precipitate forms in presence of caramel. This precipitate is washed with absolute alcohol, dissolved in hot water, filtered, and the solution concentrated to I ce in vacuó over sulphume acid. From the intensity of its colour the quantity of caramel can be estimated. Or the filtered solution of the paraldehyde precipitate may be poured in a solution of phenyl-hydrazine acetate, when if caramel be present a precipitate slowly forms, more quickly on warming / Heuss (Zeitsch ges Biauw 1918, 41, 108 124, Abti J Inst Brewing, 1918, 312)

Rough test for caramel in beer -Add a quantity of tannic acid, and shake thoroughly If malt only is present, the colour is precipi-Caramel colour remains unchanged

Contrary to the statement of Pasquero and Cappa the presence of furfural is not a sufficient proof of caramel unless the caramel has been added after fermentation

Fradiss (Chem Zentr 1899, 1 1160) determines the amount of caramel in sugar products by treating the dry substance with methyl alcohol of 95°, evaporating on the water-bath, drying the residue in vacub, or in a current of dry air, and again digesting it with methyl alcohol for 2 hours. The caramel is precipi ated from the solution by amyl alcohol, the precipitate redissolved, reprecipitated once or twice more, and finally dried at 90° and weighed caramel may also be determined by titiating with Barreswil's solution, but if dextrose is present, it is necessary to titrate the original solution before and after treating with excess of lead acetate Then if  $\Lambda - c$  c of copper solution required, a=c c of original solution required for 5 e e of copper solution, the volume of the copper solution, corresponding with the caramel, is 5 (a-A) Allowance must also be made for the amount of lead acetate solution ( vol ) used The dextrose may also be destroyed by boiling with calcium carbonate and then precipitating with carbon dioxide Traces of caramel are estimated by treating 200 c c of the solution with excess of ammoniacal lead acetate. The precipitate, after washing with water free from carbonic acid, is suspended in water and decomposed with hydrogen sulphide. The filtrate is again treated with lead acetate, and the solution, from which the hydrogen sulphide has been expelled by evaporating to 10 c c, is treated with copper solution.

Stolle (Chem Zentr 1899, ii 1099) bases a method of determining caramel by means of the spectroscope on the fact that aqueous solutions of that substance partially absorb the rays of the blue end of the spectrum. The results are

said to be accurate to within 0.05 p.c.

Methods for estimating the amount of caramel on the surface of coffee bernes roasted with sugar, have been suggested by Neubauer, Konig, Stutzer, and Hilger These methods have been tested by Fresenius and Grunhut (Zeitsch anal Chem 1897, 36, 225), who give the preference to the method of Hilger

Stutzer's method, which consists in shaking 10 grams of the unground coffee for 5 minutes with 250 c e of cold water, making up to 500 c e ofecanting, filtering, and determining the solid contents (dired at 100°), and the ash, was recommended by the Conference of Bavarian Technical Chemists Neubauer's and Konig's processes, which depend on the extraction of the betties with hot water, give too high results

In Hilger's process, 10 grams of whole coffee are digested three times for half an hour each time, with 100 c c of a mixture of equal vols of water and 90 p c alcohol at ordinary temperatures. Each portion of the extract is decanted, and the united extracts are made up to 500 c c, filtered, and residue and ash determined. It, from the numbers thus obtained, there is deducted a constant 11 07 of dry residue, or 0.83 of ash-free residue per 100 grams of dry coffee, the remainder represents the amount of caramel present.

Upsher Smith (Amer J Pharm 1911, 83, 411) suggests employing the coloured solution prepared by adding Nessler's reagent to a solution of an ammonium salt as a coloumetric test. As an arbitrary value for the colour intensity of caramel, a '100 p e' caramel is regarded as that which has such a colouration that 10 c e of its 0.1 p e solution when treated with 2 c e of the Nessler reagent and diluted to 50 c e matches the colour obtained by mixing 10 c e of a solution containing 0.0417 gram of ammonium oxalate in a litre, 38 c e of water and 2 c e of Nessler solution

CARANNA v. OLEO-RESINS

CARAPA BARK. The bark of Carapa Guanensis, has a bitter taste, and is used as a febrifuge—Said to contain an alkiloid, carapine (Petroz and Robinet, J. Pharm. 7, 293, 349)

CARAPA OIL. 'Carap Oil' or 'Crab Oil' (Fr Hude Carape), is obtained from the seeds of the 'carap,' 'crappo' or 'crab-wood' tree, Carapa Guianensis (Aubl), a native of the West Indies and Central America

The oil is prepared in Trinidad for local consumption by very primitive methods. Accord-

ing to de Verteuil (Trinidad, London, 1858, 272), the seeds are gathered in June and July, boiled for 6 hours, then laid in heaps for 8 or 10 days, during which time they undergo a sort of fermentation, they are then broken, and the pulp they contain carefully taken out and kneaded into lumps of thick paste, each about 15 lbs This paste is laid on boards slightly incurvated and inclined, and placed in a sheltered place, when the oil oozes through the mass, and runs into a vessel placed for its reception paste is carefully remoulded every morning and evening, so as to favour the disengagement of the oil After 12 days, boiling water is poured on the mass, and a fresh quantity of oil of inferior quality is thereby obtained It is a clear yellow oil with a faint vegetable odour, and an intensely bitter taste which precludes its use as an chible oil. It is used locally as an embiocation against rheumatism and for the destruction of ticks which attack domestic animals (de Verteuil The Agricultural Record, Trinidad, August, 1899, 17) It has considerable reputation as a finiment for dressing wounds on horses and cattle Its excessive bitterness repels all insects, and mixed with tai is used for preserving wood. It is well suited for the manufacture of soap, and it is in this direction that its future possibilities lie

The oil from C grandifloid, from Uganda, has been examined by Lewkowitsch (Analyst, 1908, 33, 184). Good kernels contained 30.26 p.e. of oil. The colour of the cold-pressed oil was almost white, with a tinge of pale yellow At the ordinary temperature, it solidities. The hot-pressed oil is much darker in colour, and remains solid at the ordinary temperature

Lewkowitsch (Analyst, 1909, 34, 10) has also examined the oil from *C proceia* (D.C.), the seeds being obtained from Sicra Leone The sound keinels yielded by extraction with ether 57.26 p.c. of oil, whilst the yield of oil by cold and hot extraction at a pressure of 150 atmospheres was 46.7 p.c.

The following analytical results are due to C. H. Wright (Bull Dept Agric Trimdad, ix 1910).—

CARAWAY FRUIT. Carm fractus, B P. The dued tipe fruit of Carum Carri (Linn)

CARAWAY OIL v OILS, ESSENTIAL CARBAMIC ACID CH<sub>1</sub>NO<sub>2</sub> or NH<sub>2</sub>COOH Ammoforme acid An acid not known in the free state Ammonium carbanate is, however, met with in freshly sublimed commercial ammonium carbanate, and may be prepared by mixing gaseous ammonia and carbon dioxide Obtained also by the action of alkaline solution of potasium permanganate on albumen, leucine, tyrosine, and glycocoll

CARBAZOLE C<sub>1,2</sub>H<sub>9</sub>N or C<sub>0</sub>H<sub>4</sub> NH A white erystalline substance found amongst the products of the distillation of coal tar, and also met with in crude anthracene Carbazole

24 CARBAZOLE

compounds are most easily recovered from crude anthracene by converting the former into the easily soluble nitrosocarbazole (Wirth, Eng. Pat 14462; J Soc Chem Ind 1901, 464) May be obtained by passing vapour of aniline or diphenylamine through a red-hot tube, by boiling immodiphenyl sulphide HN  $\subset C_6H_4$   $\subset S_6H_4$ with reduced copper; by passing the vapour of orthoaminodiphenyl over lime heated to a dull redness (Blank, Ber 1891, 306), or by acting on orthoammodiphenylamine with nitrous acid and heating the phenylazimidobenzene so formed to 360° (Graebe and Ullmann Annalen, 291, 16) Forms white lamina, mp 238°, bp 3515° (con) Carbazole dissolves in concentrated sulphune acid to a yellow solution which changes Addition of formaldeto red-violet on heating hyde gives a blue solution changing to a greenishblue on addition of large quantities (Gabietti, Chem Zentr 1907, n 98) 1 mol carbazole, 2 mols, sale ylaldehyde and concentrated sulphuric acid, heated to 100°-110°, give an intense blue colour (Carrara, Gazz chim ital 1899, н [535)

By melting together carbazole and oxalic acid, and extracting with hot water and benzene, dissolving the residue in warm alcohol, filtering and evaporating, carbazole blue is obtained The alcoholic solution of carbazole blue, when treated with glacial acetic acid and zine-dust, is decolourised. Filtered into caustic soda solution, the leuco- base separates out as a white flocculent precipitate. On oxidation with any of the usual reagents, the blue colouring matter is again formed (Bamberger and Muller, Ber 1887, 1903, J Soc Chem Ind 1887, 660) zole ydlow is prepared from the tetrazo-derivative of diaminocarbazole. It is easily soluble in water, and dyes unmordanted cotton in a neutral bath a fast golden yellow and wool in a neutral or acid-bath a yellow, fast to milling (Bad Anil and Sod Fab Eng Pat 14478 and 14479, J Soc Chem Ind 1889, 771) (v Azo- colouring MATTERS)

Nitrocarbazole is obtained by treating nitrosocarbazole with 10 times its weight of benzene and its own weight of intric acid, spgr 1 36 (With, Eng Pat 2899, D R P 128853, J Soc Chem Ind 1901, 890) Dimitrocarbazoles, v Bad Anil u Sod Fab (D R P 46438, Frdl ii 447), With (D R P 128853, Frdl vi 58), Trinitrocarbazole (Akt Ges f anilinfab D R P 295817) These nitro-compounds may be reduced to the amino- compounds by means of alkalı sulphides (Wirth, D. R. P. 139568, Chem. Zentr. 1903, 1. 746). By Bvheating carbazole with concentrated sulphuric acid, a mixture of disulphonic and trisulphonic acids is obtained. Nitration and subsequent reduction of the former yields aminocarbazoledisulphonic acid, which, when diazotised and coupled with  $\beta$ -naphthol, yields a dyestuff dyeing red from an acid-bath. If the nitic acid is added direct to the products of sulphonation, on reduction a second amino- acid is obtained which, when diazotised and coupled with β-naphthol, gives a red dyestuff, and with a-naphthylamine a violet (Schultz and Hauenstein, J pr Chem 1907, 336) The sulphonic acids, preferably the disulphonic, condense with tetralkyldiamino diphenylearbinol to yield

valuable green dyest iffs (Cassella & Co. Eng. Pat 20709; J. Soc. Chem. Ind. 1909, 697). By allowing nitrosophenol, its homologues or derivatives to act on carbazole in the presence of cone sulphuric acid, compounds are obtained which yield blue sulphide dyestuffs with alkali polysulphides (Haas, Eng. Pat. 2918; J. Soc. Chem. Ind. 1909, 517) For N-acyl derivatives of carbazole, see Copisarow. Chem. Soc. Trans. 1918, 816

A method has been patented (Ch. Fab. Act. Gesell in Hamburg, D. R. P. 81237, Ber. 1895, iv 692) for obtaining potassium cyanide or feirocyanide, by heating the potassium derivative of carbazole in the absence or presence of an

CARBITE. An explosive consisting of nitroglycerine (25), potassium nitrate (34), flour (38-5), barium nitrate (1), powdered bark (1), and sodium carbonate (0.5 part)

CARBODYNAMITE V EXPLOSIVES CARBOHYDRATES. The term is applied to polyhydroxy-aldehydes and ketones, and to the substances which give these when hydrolysed by heating with mineral acids Dextrose. ordinary sugar or sucrose, starch, and cellulose are carbohydrates universally distributed in plants Dextrose and glycogen enter into the composition of animal tissues. The simple carbohydrates, monosacchandes, have the empirical composition CH2O, the most important being those containing 5 or 6 atoms of earbon The complex carbohydrates, polysacchandes, are built up from two or more simple carbohydrates with the elimination of water, they have the composition  $(C_8\Pi_{10}O_5)_n\Pi_2O$  (Kiliani, Chem Zenti 1908, 32, 366) Compounds in which nequals 1, 2, 3, or 4 are distinguished by names having the suffix -ose They may be conveniently grouped as follows -

1 Monosaccharides

(a) Pentoses  $C_5H_{10}O_5$ , eg arabinose, xylose (b) Hexoses  $C_6H_{12}O_6$ , aldoses, eg dextrose, mannose, galactose, ketoses, eg lavulose, sorbose

2 Disacchandes n=2  $C_{12}H_{22}O_{11}$ (a) Non-reducing, e.g. sucrose, trehalose

(b) Reducing,  $e \stackrel{g}{g}$  maltose, lactose, &c 3 Trisaccharides n=3  $C_{13}H_{32}O_{16}$ tianose, raffinose, melezitose

4 Tetrasacchandes n=4 C<sub>24</sub>H<sub>12</sub>O<sub>21</sub> Stachyose

5 Polysaccharides

(a) Glycogen, mulin, dextrins, n unknown

(b) Starch, cellulose, n very large

Related to the carbohydrates are those substances which yield simple carbohydrates, together with other substances when hydrolysed Such are glucosides, gums, pectins, &c (q c)

General characters -The members of classes 1, 2, 3, 4, and 5a are soluble in water They have a more or less pronounced sweet taste The monosaccharides are colourless crystalline compounds, characterised by the power of reducing alkaline solutions of the heavy metals, for example, copper They form characteristic compounds with phenylhydrazine

The di- and poly-sacchandes are converted into simple carbohydrates when hydrolysed This change may be effected by means of mineral acids, or, as a rule, more quickly by enzymes The complicated polysacchandes are usually amorphous, they tend to form colloidal solutions, and are chemically relatively mert. In virtue of the hydroxyl- groups which they contain, they react with acetyl chloride, benzoyl

chloride, nitric acid, &c, forming esters

Carbohydrate solutions are generally optically The direction and amount of the active rotation vary with the substance, and also with the strength of the solution, the nature of the medium, the temperature, &c The optical rotatory power of carbohydrates is made use of in their analyses (r Saccharimetry), and as a guide to their structure

Interesting generalisations have been drawn by Hudson affecting the molecular rotations of  $\alpha$  and  $\beta$  forms of sugars now generally accepted that the difference between the molecular rotations of the  $\alpha$  and  $\beta$  forms of mutarotatory sugars is a constant The compounds selected show considerable diversity of type and discordant results have from time to time been explained away by showing that the compound in question is derived from other than the  $\alpha$  and  $\beta$  forms of the sugar (of Hudson, J Amer Chem Soc 1917, 39, 1013) The maximum values for the specific iotations are now arrived at by the indirect method based on solubility measurements (Lowry, Chem Soc Trans 1904, 85, 1551, Hudson, J Amer Chem Soc 1904, 26, 1065) The asymmetric system attached to the  $\alpha$ -carbon atom excits a preponderating influence on the activity of these compounds and determines the sign of the rotation

Hudson's generalisation have enabled the optical rotatory power of carbohydrate derivatives to be used as an important guide to their structure

Constitutional formula of Dextrose -In addition to those carbohydrates which occur naturally, a number of others have been prepared artificially by Emil Fischer, and it is largely to his work that the present complete knowledge of the group is due (Fischer's original work has been republished, Untersuchungen über Kohlenhydrate, Berlin, 1909, J. Springer)

Dextrose and its isomerides C6H12O6, conveniently termed glucoses, have 5 oxygen atoms present as 'hydroxyl,' since they form esters such as dextrose pentacetate

#### C<sub>6</sub>H<sub>7</sub>O(O CO CH<sub>3</sub>)<sub>5</sub>

The sixth oxygen behaves as an aldehyde in dextrose and galactose, as a ketone in Levulose and sorbose. The two classes of compounds are accordingly referred to as aldoses and ketoses Reduction converts the glucoses into alcohols  ${\rm C_6H_{14}O_6},$  dextrose yielding soi bitol and mannitol, and galactose forming dulcitol Secondary hex liodide, a derivative of normal hexane, is formed by the action of hydrogen iodide, hence the glucoses must possess all their six carbon atoms united in normal chain

Dextrose on oxidation yields, in the first place, gluconic acid C5H6(OH)5 CO2H which retains all six carbons and, like dextrose, forms a pentacetyl ester Hurther oxidation converts it into saccharic acid  $C_0H_{10}O_3$ . Galactose behaves similarly, yielding the isomeric galactonic, and mucic acids. Taking further into consideration the reducing power of dextrose, the constitutional formula may be written

 $\mathrm{CH}^{3}(\mathfrak{O}\Pi)$  СП(ОН) СП(ОП) СП(ОП) СП(ОН) СПО

This formula does not fully express the behaviour of dextrose, which lacks many of the well-attested properties of the aldehydes; for example, it is not oxidised in the air, and does not show their various colour reactions Tollens, in 1883, therefore, proposed the lactonic or  $\gamma$ -oxide formula (i), which may also be written (II).

This formula (1 or 11) is in entire agreement with the reactions of dextrose, and has been generally adopted It is supposed that in presence of alkalis and other reagents the  $\gamma$ -oxide ring opens, forming the aldehyde

The discovery of a third methyl glucoside (Fischer, Ber 1914, 47, 1980) and of additional isomerides of other glucose derivatives (Hudson, J Amer Chem Soc 1915, 37, 1589, 1591, 1916, 38, 1223) has involved the recognition of a different internal linking in the sugar molecule The oxygen atom may connect other pairs of atoms as well as the 1st and 4th The new form of sugar termed  $\gamma$ -glucose (dextrose) obtained from this glucoside has not been isolated in the free state, but its tetramethyl derivative is known (Irvine, Chem. Soc. This is far more Trans 1915, 107, 524) reactive than the corresponding derivatives of α or β-dextrose it condenses with alcohol with extreme ease and instantly reduces alkaline permanganate solution, giving rise to a new form of tetramethyl gluconic acid

The work of Tanret (Compt rend 120, 1060) has shown that dextrose exists in more than In addition to the hydrated and anhydrous modifications, he isolated two other anhydrous modifications These differed particularly in optical rotatory power Taniet described as a dextrose having  $[a]_D + 110^\circ$  when first dissolved, and falling in aqueous solution, a  $\beta$ -dextrose having  $[\alpha]_D + 19^\circ$ , and increasing in solution, and a dextrose having  $[a]_D + 52.5^{\circ}$ , and remaining constant in solution modification was called  $\gamma$ -dextrose by Tanret It is not the same, of course, as the  $\gamma$ -glucose mentioned above lt had long been known that the optical rotatory power of fieshly dissolved dextrose diminished to about one-half its initial value in solution, and the term mutarotation or bi-rotation was applied to this phenomenon

Dubrumfaut ascribed the change to purely physical causes Fischer considered that the aldehyde dextrose underwent hydration to an alcohol C<sub>6</sub>H<sub>44</sub>O<sub>7</sub> of lower rotatory power view of Taniet's discoveries, it is now considered that the change in rotatory power is due to the mutual interconversion of the  $\alpha$ - and  $\beta$ -dextioses, until equilibrium is attained Tanret's y-dextrose represents such an equilibrium mixture. It is supposed that both  $\alpha$  and  $\beta$ -dextrose have a closed y-oxide ring structure, and it is still a matter of controversy whether some proportion of open-chain aldehyde is present in solution in the equilibrium mixture (For the full discussion of this question, see E. F. Armstrong's The Simple Carbohydrates, Longmans, 1919)

To understand fully the relation of  $\alpha$ - to 8dextrose, it is necessary to refer to the van't Hoff-Le Bel conception of space isomerism Chemical compounds which rotate the plane of polarised light contain an asymmetric carbon atom, that is, one in which the four affinities are satisfied by four distinct radicals earbon atom is considered as lying in the centre of a tetrahedron, and each of the four different radicals with which it is combined as being at the four solid angles thereof. Two modifications of the compound are possible, which are related to one another like an object and its reflected image

In the Tollens formula for dextrose, the carbon atom (C) has the four different groups, H, OH, the oxygen of the ring, and the complex  ${
m C_5H_{10}O_4}$  attached to it—It is asymmetric, and purplicating acid  ${
m C_4H_9}$  (HMcCO.H—This betwo isomerides are possible, which are representation establishes Levulose as a ketohexose. It sented on a plane surface by writing H and OH on one or other side of the carbon atom, as the following formulæ show

Corresponding to these two isomenic forms, dextrose gives use to a double senes of denvatives

The compound represented by the formula си<sub>2</sub>(он) си(он) си(он) си(он) си(он) сио contains four asymmetric carbon (marked \*), and should, therefore, be capable of existing in 16 stereoisometic forms, 8 of which would be mirror images of the other 8, and of equal but opposite rotatory power

The carbohydrate group has afforded a unique opportunity of testing this hypothesis, and although only three of the isomerides occur naturally, no less than 12 have been prepared artificially by Fischer, who has, in addition, made them in such ways that then structure is established

The known aldohexoses are the dextro- and lævo- isomerides of mannose, dextrose, idose, gulose, galactose, and talose Two further isomerides, namely, d-allose and d altrose, were obtained by Levene and Jacobs in 1910 (Ber 43, 3141), starting from d-ribose This is a component of many nucleosides, and so a considerable quantity had been accumulated for the purpose of applying the cyanohydrin process It will suffice to give the constitutional formula as established by Fischer of the natural members -

Mannose and galactose, like dextrose, exist in  $\alpha$ - and  $\beta$ - forms, and it is more correct to write their formulæ in the form adopted for  $\alpha$ and B-dextrose

As is to be expected, the isomeric glucoses differ but little in their chemical behaviour

Formula of Lavidose —Lævulose, when oxidised, forms glycollic and trihydroxyglutaric acid, or other acids with less than 6 carbon atoms It forms an additive compound with hydrogencyanide, which yields lævulose carboxylic acid C<sub>7</sub>H<sub>14</sub>O<sub>8</sub> on hydrolysis, and this, when boiled with hydriodic acid, is converted into methyl-. has the formula

Fructose shows a pronounced tendency to exist in reactive forms other than the normal  $\gamma$ -oxide type—probably many of its compounds, including sucrose, are derived from the ethylene oxide type

The ethylene oxide form of methyl fructoside readily condenses with acctone and rapidly reduces permanganate

Formulae of the Pentoses and Tetroses —Eight aldopentoses are possible, of which seven have been artificially prepared, viz d- and l-arabinose and xylose, d-lyxose, and d- and l-ribose. The two most common naturally occurring pentoses have the constitutional formula-

Like dextrose, they occur in two forms, and are more correctly written with a y-oxide A pentose believed to be d-arabinose structure has been isolated from the glucoside barbaloin

(Léger). Levene (Ber 1909, 42, 3247; 1910, 43, 3147) obtained d-ribose from nucleic acid

Three out of the four possible aldotetroses are known, viz. d- and l-crythrose and l-threose, but they have not been found in nature

Reaction with Phenylhydrazine—The behaviour of the carbohydrates with phenylhydrazine is particularly characteristic, and it has further an historical interest, as phenylhydrazine, in the hands of Fischer, served as one of the chief aids in the elucidation of the relationships of the group.

Dextrose reacts with the reagent in acctic acid solution in two stages. In the cold a phenylhydrazone is formed

$${\rm C_6H_{12}O_2}{+}{\rm C_6H_5} {\rm NH~NH_2 \atop C_5H_{12}O_5~CH}$$
 . N NH  ${\rm C_6H_5}{+}{\rm H_2O}$ 

This is a colourless substance, soluble in water, and is obtained in two modifications, one or the other predominating according to the method of preparation. Similar compounds, with asymmetrically disubstatuted hydrazine—for example, benzylphenylhydrazine—are often less soluble and more characteristic. Mannose is remarkable in forming an almost insoluble phenylhydrazone. The hydrazones of lactose and maltose are very soluble.

At the temperature of boiling water, dextrose reacts with excess of phenylhydrazine to form the phenylosazone

Dextose (1 molecule) is heated with 3-4 molecules of phenylhydrazine, which should be almost colourless, and free from oxidation products, and an equal volume of 50 p.c. acetic acid in a flask immersed in boiling water for an hour or more. Usually the osazone begins to separate in 20 minutes or less. In the case of the disaccharides, no separation of osazone takes place from the hot solution.

The yellow osazone is filtered and carefully washed, it may be crystallised from most organic solvents, but the most suitable appears to be a dilute solution of pyridine. Dextrose, mannose and Levulose form the same phenylosazone, as they differ only in the relative positions of groups which are destroyed in the formation of the osazone.

Too much dependence must not be placed on the melting-points of the osazones in identifying unknown sugars in solution, as these depend very largely on the rate of heating, and the method of purification adopted. Disubstituted hydrazines do not directly form osazones with dextrose, though these may be prepared from the osones.

Diphenylmethanedimethyldihydrazine

(J. von Biaun, Bei 1917, 50, 42, Votoček, Ber 1917, 50, 35) appears likely to be of use in determining the configuration of aldoses Hydrazones are only produced when at least two of the CH(OH) groups following the aldehyde group have the same spatial airangements Thus hydrazones are formed with airabinose, lyxose, rhamnose, ribose, rhodeose, fucose, galactose, mannose, but not with xylose, isorhodeose and glucose

To recover the original sugar from the

phenylhydrazone, it is boiled in water with a slight excess of benzaldehyde. The phenylhydrazine is removed as benzaldehyde phenylhydrazone, the excess of aldehyde extracted by ether, and the sugar solution concentrated in warno. With the disubstituted hydrazones better results are obtained on using formaldehyde.

The phenylhydrazine residues may be removed from the osazones by heating with fuming hydrochloric acid. Compounds termed osones are formed.

### CH<sub>2</sub>(OH) [CH (OH)]<sub>3</sub> CO CHO

These are colourless syrups, they act as strong reducing agents, combine directly with phenylhydrazine, and are non-ferimentable. The slightly soluble osazones of the disaccharides, and of the pentoses, are converted into osones on boiling with benzaldehyde.

When reduced by means of sodium amalgam, the osones are converted into ketoses, and not into the aldoses from which they were formed. Thus it is possible to pass from dextrose to levulose—a transformation of great importance—the stages being

dextrose→ phenylosazone→ osone→ lævulose

Another important transformation is that from dectrose to mannose, which is based on the fact that gluconic acid (q|r|), when heated with quinoline, is converted into a mixture of gluconic and mannonic acids. The stages in this case are

$$\begin{array}{c} \text{oxidation} & \text{reduction} \\ \text{Dextrose} \rightarrow \left\{ \begin{array}{c} \text{gluconic} \\ \text{acid} \end{array} \right\} \rightarrow \left\{ \begin{array}{c} \text{mannonic} \\ \text{acid} \end{array} \right\} \rightarrow \text{mannose} \end{array}$$

By the aid of these two reactions, Fischer was able to pass from the synthetical  $\alpha$ -across to d-glucose, d-fructose, and d-mannose, and so effect the complete synthesis of the naturally occurring hexoses

The scheme on next page shows the successive operations

Cyanohydrin synthesis.—The aldoses combine directly with hydrogen cyanide, forming nitriles, which, when hydrolysed, give rise to acids containing one carbon atom more than the original carbohydrate. The lactones of these acids, when reduced with sodium amalgam, yield the corresponding aldoses with one carbon atom more than the original carbohydrate:

$$\begin{array}{l} C_5 H_{11} O_5 \text{ CHO} + \text{HCN} = C_5 H_{11} O_5 \text{ CH(OH) CN} \\ C_5 H_{11} O_5 \text{ CH(OH) CO}_2 H \longrightarrow C_5 H_{11} O_5 \text{ CH(OH) CHO} \end{array}$$

In this manner arabinose is converted into dextrose, dextrose into glucoheptose. Fischer has continued the process as far as the aldononose.

Actually two isomerides are formed at each stage, and arabinose gives both dextrose and mannose

Degradation—The converse change from dextrose to arabinose has been effected by several different methods

Wohl (Ber 1893, 26, 730, &c) heated dextrose oxime with concentrated sodium hydroxide, so converting it into glucome acid nitrile, from which, on further heating hydrogen cyanide was eliminated and d-arabinose formed

$$C_5H_{11}O_5 CHO \Rightarrow C_5H_{11}O_5 CH NOH \Rightarrow C_5H_{10}O_5$$

In practice the method adopted is to heat the oxime with acetic anhydride and a grain of zinc chloride; a vigorous reaction ensues, and the pentacetate of glucome acid mitrile is formed, from which hydrogen cyanide is eliminated by treatment with ammoniacal silver oxide

Ruff (Ber 1898, 31, 1573) oxidises the calcium salt of gluconic acid, with hydrogen peroxide in presence of a ferrous salt (Fenton's method). The carboxyl-group is eliminated, and arabinose formed

Neuberg (Biochem Zeitsch 1908, 7, 527) effects the climination of the elements of formic acid from glucome and similar acids by electrolysis

Weerman (Chem Soc Abstr 1915, 1 387) obtains gluconamide by saturating gluconolactone in alcoholic solution with ammonia On subsequent treatment with hypochlorous and the amide is decomposed according to the scheme

R CH(OH) CO NH<sub>2</sub>
$$\rightarrow$$
R CH(OH) N C O $\rightarrow$ R CHO

According to Livine the reactions proceed with the utmost smoothness and constitute a great improvement on the methods litherto in use

The reaction has been applied to glucose, galactose, l-mannose and l-arabinose

Action of Acids —Dilute acids are without action on the aldoses, but when submitted to the continued action of acids, hexoses yield levulic acid (acetopropionic acid)

and formic acid, together with brown or black humus substances The first product from the 2-ketohexoses is 4-hydroxymethylfurfuraldehyde

and it is to the condensation products of this aldehyde that the colour reactions of the ketoses with phenols are due—Blanksma and Ekenstein have shown that this aldehyde is also produced on heating mannose or dextrose with oxalic acid, and Fenton obtained 4-halogenmethylfurfurol from Levulose, and more slowly from the aldoses, on treatment with dry halogen hydride—The aldoses apparently undergo a 1-, 2-enolisation and conversion into 2-ketohexose.

Action of Alkalis —Although absolutely stable in pure aqueous solution, dextrose, nannose,

and fructose pass over into one another in presence of traces of alkalis in the cold. The optical rotation of a dextrose solution containing alkali, for example, slowly falls to zero. This change was observed by Lobry de Bruyn and Alberda van Ekenstein (Rec. trav. Chim. 1895, 14, 150, 204). It is due to the conversion of the sugar originally present into enol.

 $CH_2(OH)[CH(OH)]_3 C(OH) CH(OH)$ 

which is reconverted into all three hexoses

Guandine (Morrell and Bellars, Chem. Soc. Trans 1907, 91, 1010-1033) brings about similar changes.

The action of alkalis on the carbohydrates is exceedingly complicated, and leads to the formation of a great variety of substances, in addition to humus compounds. The concentration of the alkali is of great importance, a larger number of products being formed when the relatively sparingly soluble lime and bartya (Kihani) are used, than when concentrated sodium hydroxide is employed (Nef, Annalen, 1910, 376, 1, 1914, 403, 204) The latter paper contains a summary of many years' work, and is the main source of information on this complex subject In contact with dilute alkalis protound changes ensue in a hexose, an equilibrium being finally established between the various enolic forms The number of possible forms is diminished as the concentration of the alkali 18 reduced The unsaturated molecules formed undergo fission at the double bond

The decomposition takes place quickly on heating, slower in the cold, with the production of acetol, acetone, lactic, acetoe and formic acids, also glucinic and saccharumic acids, and other substances. With calcium hydroxide saccharim or calcium saccharimate is produced

In addition to these substances, intermediate products are formed, more closely related to the monosaccharides, and from which these are reconstructed by the synthetic action of the alkali. It is established that hexoses break down into a molecule each of diose and aldotetrose, or into 2 molecules of glycerine aldehyde, that is, the 2:3 and 3 1-dienois decompose. The 1:2-dienois never break down into aldopentose and form aldehyde. Conversely, hexoses are never built up from pentoses.

Pentoses form 1.2-dienols, which, in the main, give addoted oses and hydroxymethylene on decomposition, they also form 2.3-dienols, breaking down to diose and glycerine aldehyde

Dextroses exclusively form 2 3-dienols, breaking down to 2 molecules of diose, they never give 1:2-dienols yielding hydroxymethylene and glycerine aldehyde. The strongly dissociated zine hydroxide ammonia acts on the monosaccharides in the cold, producing methyl-

glyoxalıne | CMe NH GH•N (Wındaus, Beı 1905,

38, 1166, 1906, 39, 3886, 1197, 40, 799)

Saccharinic acids. According to Net (Annalen, 1910, 376, 1) there are 24 isomeric saccharinic acids, with 6 carbon atoms, namely a-meta-saccharinic acids ( $a\gamma\delta\epsilon$ -tetrahydroxy-hexoic acids).

CO<sub>2</sub>H CH(OH)·CH<sub>2</sub> CH(OH) CH(OH) CH<sub>2</sub>OH derived from the 16 aldohexoses, 4 to sacchar-

mic acids (a-hydroxymethyl  $\alpha\gamma\delta$ -trihydroxyvalerie acids).

 ${\rm CO_2H~C(OH)(CH_2~OH)~CH_2~CH(OH)~CH_2(OH)}$  derived from the 8  $\beta$ -ketohexoses , 8 saccharing acids ( $\alpha$ -methyltetrahydroxyvalene acids).

CO<sub>2</sub>H CMc(OH) CH(OH) CH(OH) CH<sub>2</sub>(OH) derived from the 8  $\gamma$ -ketohexoses; and 1 parasaccharinic acids (a,  $\omega$ -hydroxyethyltinhydroxybutyiic acid).

CH<sub>2</sub>(OH) CH<sub>2</sub>·C(OH)(CO<sub>2</sub>H) CH(OH) CH<sub>2</sub>(OH) The lactones of these acids are known as saccharins. They give use to characteristic alkaloid salts and phenylhydrazides, and possess optical activity. The saccharins are obtained by the action of lime on dextrose, maltose, or lactose.

Synthesis of Monosaccharides —The condensation of formaldehyde under the influence of bases to carbohydrates has been the subject of repeated study. Butlerow, using milk of lime, obtained an uncrystallisable syrup with a sweet taste, which behaved as a sugar, but was nonfermentable and optically mactive Ho termed the product methylemian Locw improved the technique of the method by saturating a 4 p c. solution of formaldehyde with slaked lime in the cold, and allowing it to stand The syrupy product was termed 'formose,' and supposed by Loew to be homogeneous, but subsequently Fischer showed that on treating it with phenylhydrazine, a mixture of osazones was formed, one of which was identical with a-acrosazone Net has given reasons for believing formose (prepared by means of lead oxide) to be a mixture in approximately equal parts of isometic hexoses and pentoses its composition obviously depends on the alkali employed and its concentration

Fischer and Tafel effected the condensation of acrolem dibromide by means of baryta, and showed the syrupy product to consist of two sugars, distinguished as a- and B-acrose. Subsequently, crude glycerose was made the starting-point of the synthesis. It is a mixture of glycerine aldehyde and dihyroxy acctone, both of which substances have, in after-years, been separately used as the initial material. Fenton has used glycollic aldehyde in the same manner

A product of synthesis by all these methods is a acrose, which is partly fermentable by yeast, and this Fischer isolated as phenylosazone, and showed to be identical with mactive dl-lævulose. From this by the series of reactions already given, he obtained the natural d-glucose, d-mainose, and d-fluctose (lævulose), as well as their optical antipodes and a number of new isomerides. The application of the methods of degradation, elsewhere described, enabled pentoses and tetroses to be synthetically prepared from these hexoses, whilst the cyanolydim reaction made it possible to obtain monosaccharides with 7, 8, and 9 carbon atoms.

The full explanation of the synthesis of carbohydrates in the green leaves of growing plants has still to be given. It is generally supposed that formaldehyde, the first product of assimilation, undergoes polymerisation to carbohydrates, a theory advanced by Bacyer in 1870 (Ber. 3, 63). Various compounds, such as glycolhe and glyceric aldehydes and dihydroxy

actione, have been suggested as intermediate stages in the polymerisation, but it has never been possible to detect any of these in the plant. Apparently the synthesis is asymmetric, hexoses of the dextro-series, and their polysaccharides being the only products of assimilation. It is supposed that the formaldehyde elements are superposed under the influence of the asymmetry of the protoplasm molecule, according to a definite plan, and are split off when six are minted.

Synthesis of Disaccharides—Though often attempted, the synthesis of disaccharides, by purely chemical means, has only been partially successful. Fischet and Armstrong have prepared a syrupy compound, probably identical with the natural sugar melibiose, by the interaction of acctochlorogalactose with sodium glucosate.

Fischer and Delbruck found that when actiobromoglucose is shaken in dry ethered solution with silver carbonate and traces of water, the octacetyl derivative of a disaccharide is obtained. This is hydrolysed by cold barium hydroxide to a non-reducing disaccharide of the type of trehalose. The octacetyl-derivative is a mixture of isomerides, and yields isomeric disaccharides.

disacchandes.

In the plant the di-acchandes are formed from hexose by the agency of enzymes, which exercise synthetic as well as analytic functions. It is undecided whether the same enzyme can cause both synthesis and hydrolysis, or whether special enzymes alone act as synthetic agents. It is proved, however, that an enzyme effects the synthesis of a carbohydrate isometre with that which it normally hydrolyses, the two compounds being apparently related in the same manner as the  $\alpha$ - and  $\beta$ -methyl glucosides (v- Croft Hill, Chem. Soc. Trans. 1898, 73, 634, 1903, 83, 587, E. F. Armstrong, Prot. Roy. Soc. 1905, 76, B, 592, and monograph on Carbohydrates, 1919)

It has been established by Bourquelot that the equilibrium between a sugar and a glucoside when in contact with the appropriate enzyme can be displaced in the direction of the glucoside when the solvent contains excess of the hydroxy component of the glucoside. A large number of glucosides have been synthesised by Bourquelot from sugars dissolved in alcohols containing varying amounts of water in every case the glucoside synthesised being that normally hydrolysed. This reaction, however, is not on all fours with that taking place in a concentrated solution of sugar in the absence of an alcohol, and so far all attempts to synthesise maltose or sucrose in this manner have been definitely without result.

In the following pages the occurrence, preparation, properties, and derivatives of the natural, mono-, di-, tii-, and tetra-sacchandes, also glycogen and mulin, are dealt with Sucrose, the dextrins, starch, and cellulose, are described in separate articles.

**Dextrose.** Dextroglucose, grape sugar, starch sugar  $C_6H_{12}O_6$  and  $C_6H_{12}O_2$ ,  $H_2O$ .

Occurrence—Reducing sugars are very widely distributed in nature, but dextrose is almost always accompanied by lævulose, the two hexoses being probably derived from sucrose. It is thus found in honey, in the juice of most

fruits, and generally in vegetable tissues in small quantities. In the animal kingdom it is found in blood and in diabetic urine.

Formation — Dextrose is formed on hydrolysing most of the known polysaccharides and glucosides, either with acids or enzymes, it is similarly formed from glycogen. Thus cellulose, statch, dextrins, the disaccharides maltose, lactose, and sucrose, all yield dextrose.

Preparation —Dextrose is usually prepared from starch or sucrose—It can be obtained from any of the substances mentioned, but they are less suited for the preparation in quantity

Crude commercial dextrose is purified by dissolving in 8-10 pc of hot water, and adding dry boiling methyl alcohol, until a cloud is produced. This solution may be decolourised by shaking with animal charcoal, and filtering. On standing, anhydrous dextrose in a pure state separates abundantly. To prepare dextrose from sucrose, the latter must first be inverted. This is best effected by treatment at a temperature not exceeding 50°, with a small quantity of invertase or of pressed yeast. After a few hours the solution is evaporated in vacu6 to a syrup, which solidities on standing. The mass is washed with cold ethyl alcohol (sp.gr. 0-830), and the residue dissolved in more alcohol. Dextrose crystallises on cooling.

Sulphure acid may be used for inversion, it must be neutralised with baryta before evaporation. Soxhlet advises the use of alcoholic hydrochloric acid at 50° for 2 hours. Dextrose crystallises in a few days without neutralisation.

Properties - Dextrose crystallises from strong (93-95 pc) ethyl or methyl alcohol in the anhydrous state,  $({}^{\circ}_{3}\Pi_{12}O_{6}, \text{ and from concentrated aqueous solutions at }30^{\circ}-35^{\circ}$ , with special treatment, crystals of this composition may also be obtained. The crystals formed in aqueous solutions at ordinary temperatures contain a molecule of water of crystallisation.  $C_6H_{12}O_6, H_2O_6$ The anhydride forms white crystalline crusts or powder and, when it separates from the solvent slowly, fairly well-defined glassy prisms, the hydrate crystallises in cauliflower-like masses, but with care and slow erystallisation well-defined crystals can be obtained Both bodies dissolve easily in water, the anhydride with evolution of heat. The hydrate dissolves freely in strong ethyl or methyl alcohol, especially on the application of heat, but the anhydride is practically insoluble in those liquids

a-Dextrose exists in contact with boiling saturated alcoholic solutions it forms hard brittle needles. From aqueous solutions monohydrate crystallises in six sided leaflets. As purified by crystallisation from dilute methylaleohol a mixture of the different forms is obtained. A homogenous product is obtained by allowing the mixture to soak several days or weeks at a constant temperature with the solvent until the whole of the  $\beta$ -sugar present has been converted into the  $\alpha$ -isomeride Hudson and Dale (J. Amer Chem Soc 1917, 39, 320) obtain the  $\alpha$ -form by dissolving two parts of sugar in one part of water and adding 4 parts of glacial acetic acid, crystallisation being allowed to take place at the ordinary temperature

β-Dextrose is forme by heating dextrose at

105°-110° for some hours or by crystallisation from water above 98° From a solution in boiling pyridine a monopyridine salt separates which on exposure rapidly loses pyridine An even better method of prepara-(Behrend) tion is said to be the following (Hudson and Dale) 10 parts of dextrose are dissolved in 1 part of water on a water bath, and 12 parts of glacial acetic acid heated to 100° are added. The whole is well mixed and removed from the water bath when crystallisation at once commences After four such crystallisations pure  $\beta$ -dextrose is obtained

 $\gamma$ -Dectrose (the equilibrium mixture) is obtained on precipitating with alcohol a concentrated aqueous solution which has stood for some time

The initial optical rotatory powers of the two forms and that of the equilibrium mixture are as follows in aqueous solution -

$$a-[a]_{D}+113 \ 4^{\circ}$$
  
 $\beta-[a]_{D}+19 \ 0^{\circ}$   
 $\gamma-[a]_{D}+52 \ 2^{\circ}$ 

(Hudson and Dale, J. Amer. Chem. Soc. 1917, 39, 320)

An aqueous solution of dextrose containing 10 grams anhydrous dextrose in 100 cc of solution at 155°, has a spgr 10385 Its solutions are optically active, ie possess the power of rotating the plane of polarisation of a ray of polarised light. The rotation is righthanded Hesse (Annalen, 176, 106) and Tollens (Ber. 17, 2234) have carefully determined this constant, and the latter's results are expressed by the formula

 $[a]_D = 52.5^{\circ} + 0.018796P + 0.00051683P^2$ for the dry sugar, and

 $[\alpha]_D = 47.73^{\circ} + 0.015534P + 0.0003883P^2$ 

for the hydrate  $C_6H_{12}O_6, H_2O$ , in which P =the percentage of anhydride and hydrate in solution In dealing with solutions containing 10 p e diy sugar, the factors  $[a]_D = 52.7^{\circ}$  and [a] = 58 3° may be used The optical activity of dextrose solution is not materially affected by temperature. The activity is nearly twice as great in freshly prepared solution, diminution taking place slowly in cold, but rapidly in boiling solutions, until the constant value is arrived at It is only crystallised dextrose that exhibits this: property of bi-rotation, as it is called, dextrose fused and allowed to solidify does not show it (Hesse, Annalen, 176, 113) The solution of devtrose in strong alcohol retains the power of bi-rotation.

When dextrose is heated to 170°, the elements of a molecule of water are eliminated, dextrosan (glycosan)  $C_6H_{10}O_5$  being produced. If the temperature is increased, that body is caramelised and chaired Dextrosan is again converted into dextrose by digestion with water or dilute acids It is a hygroscopic, dextro-rotatory, non-fermentable substance If the temperature is raised to 200°, and maintained at that point without being increased until these products calciumdextrosates are described containing cease to be evolved, the brownish-black residue varying proportions of dextrose, lime, and (caramelised mass) becomes gradually solid, water. Dextrose is not precipitated with lead

This substance is soluble in water, completely if the temperature was not too high, and constitutes the colouring matter used in winc, beer, cookery, &c Should the heat be further continued so that the body is destructively distilled, carbon mon- and di-oxide, and methane are evolved, aldehyde, furfuraldehyde, acetone, propionic, acetic, and formic acids, furane and furfurol distil over, and a black carbonaceous V CARAMEL mass is left

The action of alkalis and of acids on dextrose has been discussed elsewhere. When reduced by sodium amalgam, the main product (35-10 pe) is sorbitol, some quantity of mannitol is also formed in alkaline, but not in neutral or acid solution. It is derived from the mannose produced by the action of alkali on dextrose

Oxygen has no action on dextrose in neutral or acid solutions, but alkaline solutions absorb the gas Ozone oxidises it to formic acid, saccharic acid, &c., being produced. Strong nitric acid converts dextrose into saccharic acid, and finally into exalie, carbonic, and formic acids Treated with chlorine or bromine in the presence of water, the resulting product yields gluconic acid when submitted to the action of silver oxide

Dextrose in alkaline solutions reduces the oxides of gold, platmum, silver, mercury, bismuth, lead, copper, non, manganese, &c , in the case of gold, platmum, silver, and mercury, the reduction is complete, the metal being formed, in the other cases lower oxides are produced Ferrocyanide of potassium, indigo, pieric acid, litmus, and such substances are also reduced by dextrose in alkaline solution. The products from the dextrose are not the same in all cases, but they consist chiefly of carbonic, formie, oxalie, and glycollic acids, other products being also formed

Nearly all the true yeasts (Saccharomyces membrana factors is an exception), a great number of torulæ, moulds, and other organisms ferment dextrose, yielding carbon dioxide and alcohol as the chief products—Glycerol, succinic acid, and other bodies (fuscl oil) are formed at the same time, the proportions of these bodies varying materially with the organisms and the conditions under which the growth takes place The work of Ehrlich suggests that most of these by-products are derived from amino-acids, produced from the yeast and not from dextrose (v. Fermentation)

Pressed yeast-juice, zymase, which contains no living protoplasm, also ferments dextrose

In the presence of growing bacteria of various species, dextrose yields many products, one species converts it into lactic acid, another into butyric acid, another into cellulose, the so-called slimy fermentation, and so on Other oxidise dextrose (v Fermentation) Other organisms

Dextrose combines with sodium chloride, bromide, and iodide, forming well-defined crystalline compounds, these decompose in aqueous solution. Compounds with bases are indefinite in character, and unstable Sodium and potassium dextrosate (6H11MO6 are for a little time, gas, water, and volatile acids obtained on adding sodium or potassium ethoxide are given off, and if the heating is continued to an alcoholic solution of dextrose. Several acetate, but basic lead salts are obtained in presence of ammonia.

The methylglucosides. These are of importance, as types both of glucosides generally, and of the two isomeric series of dextrose derivatives. They are regarded as stereoisomeric y-oxides, and have the following structural formula.—

 $\alpha\text{-Mothylglucoside}$  crystallises in long needles, in p. 165°  $[\alpha]_D + 157^\circ$ ,  $\beta\text{-methylglucoside}$  forms rectangular prisms, in p. 104°  $[\alpha]_D$  –33°

They are hydrolysed by warm mineral acids to methyl alcohol and dextrose, the \$\beta\$-isomeride being attacked 18 times as rapidly as the \$\alpha\$-isomeride. Each glucoside requires its own particular enzyme to hydrolyse it \$\alpha\$-Methylglucoside is hydrolysed by maltase alone, \$\beta\$-methylglucoside only by emulsin. They are used as test materials in studying enzyme action.

The isomerides are both formed when dextrose is heated with methyl alcohol containing

hydrogen chloride.

To obtain a-methylglucoside, 1 part of dextrose is heated with 4 parts methyl alcohol containing 0.25 p.c. hydrogen chloride, for 50 hours in an autoclave. The solution deposits crystals of the glucoside on evaporation, and the mother liquors, after further heating, give a second and third crystallisation, as the  $\beta$ -isomeride present is converted into the  $\alpha$ - by the acid. A yield of 80 p.c. or more is obtained

To obtain B-methylglucoside, solid anhydrous glucose is dissolved in methyl alcohol, nearly saturated with dry hydrogen chloride, at room temperature As soon as etherification is complete, as witnessed by the absence of reducing power, the solution is neutralised and evaporated. and a mixture of  $\alpha$ - and  $\beta$ -isomerides obtained The a- is partly in about equal quantities separated by crystallisation from strong alcohol The residue is dissolved in water, and fermented by a pure culture yeast The a-methylglucoside is hydrolysed, and the dextrose fermented, the  $\beta$ -methylglucoside remains untouched, and is recovered and punfied

In addition to the crystalline a- and  $\beta$ -methylglucosides obtained in the reaction between a-glucose and methyl alcohol containing 1 pc HCl, a considerable amount of syrup is formed which after distillation in a vacuum is an oil,  $C_7H_{14}O_6$ , bp  $200^\circ-215^\circ/0.2$  mm,  $[a]_D-4^\circ$ . It is named  $\gamma$ -methylglucoside to differentiate it from the a- and  $\beta$ -forms (E

Fischer, Ber. 1914, 47, 1980)

It is stable to alkalis, Fehling's solution or hot water, scarcely attacked by emulsin or by yeast extract at 37° C., but is hydrolysed to

glucose and methyl alcohol by dilute acetic acid at 100°, or by dilute hydrochlone acid at 100° or 18°

The other carbohydrates form analogous methylglucosides, and similar compounds are obtained with ethyl alcohol (For other artificial glucosides, v Glucosides)

The methyl derivatives of the sugars have proved of great importance in the clucidation of their structure. Purdie and Irvine's method of methylation is employed, consisting in dissolving the sugar in methyl iodide and a little acetone and boiling the mixture with silver oxide. By protecting some of the hydroxyl groups from methylation those remaining may be methylated and the configuration thus established.

A very large number of dextrose compounds have been prepared, in some of which the aldehydic hydroxyl is concerned, whilst others, eg the acetates, involve all five hydroxyls. As already stated, in most cases two isomerides derived from a- and  $\beta$ -dextrose have been prepared. Few of these compounds are really characteristic of dextrose, and it must suffice

in the space at disposal to indicate the properties of some of them in tabular form.

Since acetobromoglucose is the starting-point for many other glucose derivatives its preparation is given in detail 200 grams powdered crystalline anhydrous glucose are heated on the water-bath with 100 grams of alcoholic sodium acetate and 1 litre of acetic anyldride for 2\{\} hours. The product is poured into 4 litres of ice water, and the crude \(\beta\)-pentacetylglucose is recrystallised from 96 p.c. alcohol after freeing it from acetic anhydride by water (yield 74 p.c.).

150 grams of the penta-acetate are treated with the commercial solution of hydrobromic acid in glacial acetic acid (300 grams) for 2 hours at ordinary temperatures, 600 c c chloroform added and the whole poured into 2 libres of ice water. The chloroform layer is separated, and the rest shaken with 150 c c chloroform; the united chloroform extracts are washed with 1 libre of water, dried over calcium chloride, concentrated in a vacuum, and the residue gradually treated with light petroleum. The resulting crystals are rapidly recrystallised from 75 c c amyl alcohol, washed with light petroleum and stored in a vacuum desiccator over soda-lime. (See E. Fischer, Ber. 1916, 49, 584.)

The reduction of accobromoglucose with zinc-dust and a ctu acid yields the acetyl derivative of glucal,

$$CH_2(OH)$$
  $CH$   $CH_2$   $CH(OH)$   $C=CH(OH)$ 

a soluble viscid syrup, b p 170°-180°/0 2 mm Glucal can be further reduced by hydrogen and palladium to hydroglucal,

which melts at 86°–87°, tastes slightly sweet, and has  $\lceil a \rceil_D + 16$ °.

d-Glucosumine (Chitosamine) or aminodextrose has the formula

It is obtained by boiling the shells of lobsters, particularly the claws, with concentrated hydrochloric acid, when the hydrochloride results. The shells of lobsters consist of carbonate of lime and chitin. Chitin is a constituent of various invertebrate skeletal structures, and of the cell walls of fungi; it is considered by Irvine to contain acetylamino-dextrose and amino-dextrose residues in the proportion of 3 to 1  $(C_{30}H_{50}O_{19}N_4)n$ . It is prepared from the hydrochloride by decomposing if with Vol., II—T.

diethylamine (Breuer, Ber 1898, 31, 2193) or sodium methoxide (Lobiy de Bruyn, did 1898, 31, 2476) Fischer and Leuchs (Ber 1903, 36, 24) effected the synthesis by the combination of d-arabinose and ammonium eyanide to d-glucosamine acid, the lactone of which was reduced to d-glucosamine. Glucosamine forms a colourless crystalline powder, or long needles; mp. 115°  $[a]_{\rm p}+48^{\circ}$  The aqueous solution reacts alkaline, but is stable. It is not fermentable. The pentacetate exists in two forms, needles, mp. 183.5° and 133° respectively; the former is optically inactive, the latter has  $[a]_{\rm p}+86.5^{\circ}$ . The oxime forms prisms, mp. 127°. Two modifications of the hydrochloride are known glistening monoclinic crystals  $[a]_{\rm p}^{23}+100^{\circ}$ , falling to  $+72.5^{\circ}$  on standing, and hexagonal needles  $[a]_{\rm p}^{23}$  constant at 72.5°.

It cannot be converted into dextrose directly, though it gives dextrose phenylosazone when heated with phenylhydrazine. Irvine and Hynd (Chem. Soc. Trans. 1912, 101, 1128) have converted it into aminomethyl glucoside, and this by the action of baryta into methylglucoside and ultimately to d-glucose. When methylglucosamine is treated with sodium nitrite a mannose derivative is obtained almost quantitatively. Probably a Walden inversion takes place (see Chem. Soc. Trans. 1914, 105, 698). By the action of nitrous acid, a compound, C<sub>6</sub>H<sub>10</sub>O<sub>5</sub>, is formed, which was at one time regarded as a carbohydrate, and termed chitose, but was shown by Fischer and Andreae (Ber. 36, 2587) to be a hydrated furfurane derivative

Chitose forms an oxime and phenylhydrazone and is oxidised by bromine to chitome acid (flucosamine was formerly regarded as a derivative of chitose, and termed chitosamine

An isomeride of glucosamine is reglucosamine CH<sub>2</sub>(OH) [CH (OH)]<sub>3</sub> CO CH<sub>2</sub> NH<sub>3</sub>, which Fischer obtained by reducing phenylglucosazone with zinc-dust, and which is converted by the action of introis acid into Levulose

The glucosumines were formerly believed to be immo compounds, but Irvine, Thomson and Garrett (Chem Soc Trans 1913, 103, 238) suggest that they are amino-glucosides. Levene (J Biol. Chem 1916, 24, 59) shows that the nitrogen content of glucosumine, galactosimine, xylosimine, and lyxosimine as given by (i) Kjeldahl's method, and (ii) by van Slyke's nitrous acid method indicates the presence of a primary amino group.

Chondrosamine (Levene, J. Biol Chem. 1916, 26, 143) gives galactosazone, and is therefore probably a lyxohexosamine

By condensing bromotriacetylglucosamine with hydroxy compounds in the presence of a base such as morphine, acctylated amino glucosides are obtained. The compounds formed are of two types: stable N-cyclic compounds and normal glucosides, such as a-aminohelicin and a-aminosalicin (Irvine and Hynd, Chem. Soc. Trans 1913, 103, 41).

A new glucosamine derivative, lycoperdin  $C_{13}H_{24}O_{9}N_{2}$ , has been isolated from the fungus

Lycoperdum gemmatum (Kotake and Sera,

Zeitsch physiol Chem 1913, 88, 56)

Manufacture of commercial dextrose-se. destro-glucose, glucose, saccharum, saccharine, &c -These products, varying much in character and composition, are all prepared by the action of acids on starch or starchy substances, such as rice, maize, &c., and when these latter are the raw material, it has been proposed to employ the combined action of diastase and acids When starch is acted upon by dilute acids, it is dissolved, dextrins and maltose being produced These bodies, by the further action of the acid, yield dextrose; this itself does not resist the action of acids, so that during the process of conversion, a portion of it is attacked, with the production of substances imperfectly studied (v ISOMALTOSE)

The phases of the action of dilute acids on starch are easily followed. After heating has been continued for a short time, a portion of the solution cooled ceases to give a blue colouration with iodine, this indicates absence of starch, in the place of this a reddish-brown colouration is produced, this indicates the presence of a-dextrin After a time this disappears, and at length the solution ceases to give a precipitate, when to a portion of it twice its bulk of alcohol (sp.gr 0 \$20) is added, or when to a portion from which the sulphuric acid has been separated by baryta-This estabammoniacal lead acetate is added lishes the absence, not of maltose, but only of For syrup the boiling is stopped as soon as the jodine test gives a port-wine colour; for solid dextrose it is continued till alcohol The processes involve causes no precipitate in the manufacture may be conveniently arranged as follows -

- (a) The conversion
- (b) The neutralisation
- (c) The filtration(d) The decolourisation.
- ( ) The concentration
- (f) The purification.
- (a) The conversion—In this country the materials chiefly employed in the manufacture of commercial dextrose are sago, maize, and rice starch, finely ground rice itself, as well as granulated maize and rice being at times used Potato starch is also used in Germany In America green-maize starch is the chief material, hence the term 'corn sugar' The acid usually employed in Europe is sulphuric; hydrochloric acid is generally used in America, and nitric acid as well as a mixture of nitric and sulphuric acids have been recommended The use of sulphurous and orthophosphoric acids has also been The proportions of material, water, advocated and acid generally employed in the case of sulphuric acid are 100 · 250 · 5, and when green starch, ie. undried purified starch, is used, 14 parts are taken instead of 1 part dry starch. When pressure converters are used, the acid can be reduced to 0.5 p c.

Formerly open converters made of wood, lined with lead and provided with steam coils of lead and stirring gear, were used, but these are now abandoned nearly everywhere for closed These are made of cast iron, copper, or gun metal, and are worked at a prossure of 30 lbs of steam.

The operations involved in the manufacture. whatever converter is used, are as follows: Half the sulphuric acid is mixed with half the water in a separate vat constructed as the converter, with or without coil, and at such a temperature that the heat of the dilute acid will be less than the gelatinising point of the starch of the material employed. This vat is furnished with stirring gear, and placed under a hopper, in which is stored the starch or starchy substance When the dilute acid is at the right temperature, the material is allowed to flow into it, the stirring gear being kept in motion; a milk of starch in dilute acid is thus obtained Meanwhile the remaining half of the acid and water are introduced into the converter, and heated to boiling, then the starch milk is run in at such a rate that the temperature does not fall far below boiling, and the introduction should be effected as rapidly as possible

The time required for conversion depends on the rate of introduction of the starch milk, and on the pressure employed, &c. For corn syrup an average time from the commencement of the starch introduction to the discharge is a little over an hour, for solid sugar about 14 hours is required When converted, the liquid

is blown into the neutralising vats

(b) The neutralisation -Finely-ground chalk is used to neutralise the acid employed in the conversion The chalk is converted into a milk with water, and gradually introduced into the converted liquid About 12 lbs of powdered chalk are taken for every 10 lbs sulphuric acid employed: this is more than the theoretical quantity, but it is found to answer in practice. owing, no doubt, to the insolubility of a portion The neutralised liquid is kept of the chalk stirred for some time, and is then allowed to rest It is found best to allow it to cool and settle gradually, and then draw off the clear portion, but where vat room is a consideration, the neutralised liquid is run immediately to the filter presses (r FILTRATION)

(c) (d) The clear filtered solution is passed through bone-char filters of the same construction as those described under Sugar acid is sometimes used in bleaching the product.

(e) Concentration -This operation is effected in vacuum pans (1 Sugar), and is considered complete when the syrup contains about 82 p c solid matter, ie reaches a sp gr of 150 then run into moulds, usually cone-shaped vessels, in which, on standing and cooling, it solidifies after a short time. This is hastened by the introduction of some previously solidified The solidified mass extracted from the mould by a short immersion in hot water is broken into irregular lumps, in which form it appears in the market. The colour of the commercial parcels varies from pure white to darkbrown, this depends on the character of the material employed (the purity and variety of the starch), on the mode of conversion, and the extent to which the decolourisation was carried The composition is also very variable, but the constituents in all are the same, viz. dextrose, maltose, dextrin, unfermentable organic bodies, and ash Very few samples contain dextrin, some few maltose, and the proportion of unfermentable bodies varies very much, being sometimes as high as 15 p.c. The syrups,

which are used in confectionery, contain a large percentage of dextrin and maltose

In the United States the conversion is carried out by stirring the green corn starch, made in the same factory, with a large body of water, and subjecting this mixture to a high heat under pressure, the process being a hydrolytic one. A small amount of pure hydrochloric acid is added to facilitate the catalytic action. The conversion is performed in large vessels 6 feet in diameter, and about 20 feet high, made of hammered copper 1 inch in thickness.

After the required conversion, the traces of acid are neutralised with soda ash, the mixture being left very slightly acid to litmus, and excess of alkali being very carefully avoided, as the least trace colours the liquid. In the case of glucoso syrup, conversion is complete in less than 10 minutes; conversion into anhydrous dextrose takes considerably longer The converted starch, now an almost white liquor, is run from the neutralisers through filter presses, to remove the dissolved gluten, &c, which is precipitated during neutralising, and then through an evaporator, which reduces the gravity to 30° B It is then run successively over three bone-char filters, each 10 feet in diameter and 24 feet high, and containing 70,000 lbs of bone-char each The liquors receive a much greater amount of bone-char treatment than is the custom in sugar refineries. passing, in all, over 72 feet. The remaining traces of acid are completely neutralised, and the liquid has a brilliant crystal-white appear-The bone-char is revivited after each The liquor is concentrated in vacuum pans to the required density 42°-45° B, and crystallises on cooling (A full account of the American industry of corn products is given by Wagner (J. Soc. Chem. Ind `1909, 28, 343) )

The average composition of these products, according to the older analyses, is as follows —

	Corn syrup	70 sugai	89 sugar	An- hydrous sugar
Water . Dextrose . Dextrin . Ash	P 6	P c	P c	P 6
	19 0	19 7	11 2 1	4 0
	38 5	70 2	79 91	94 6
	42 0	9 3	18 0	0 7
	0 5	0 8	0 9	0 7

The ash consists principally of chlorides Wesener and Teller (J Ind Eng Chem 1916, 8, 1009) give the following analysis as representing the modern product—

and Dextria (or dextrins) not fermented by yeast, but made fermentable by pancreatin, takadiastase, &c.

From which it appears that the proportion of maltose present generally exceeds that of dextrose. In the older analyses all the reducing sugar was regarded as dextrose

(f) Purification.—Behr 'Eng. Pat. 9797,

1884; 1767, 1885) manufactures pure commercial crystalline anhydrous dextrose by adding crystals of dextrose to a solution concentrated to 85 p.c., and allowing the mixture to stand at about 35°. After a short time an abundant crop of crystals separates, and by treatment in a centrifugal machine, the uncrystallised syrup is removed (v. Sugar)

In the older process of Soxhlot, the concentrated syrup was dissolved in about an equal weight of boiling methyl alcohol, and allowed to stand. The crystals were drained, and the loaves washed with methyl alcohol, which was recovered from the loaves and mother liquous by distillation in a vacuum.

Dextrose from Cellulose —Cellulose is disintegrated by boiling with acids only with great difficulty, and at high temperatures, with the formation of dextrose, and the process cannot compete industrially with the preparation from starch. Numerous attempts have been made to obtain dextrose from wood cellulose, with the industrial objective of the manufacture of alcohol.

Simonsen (Zeitsch angew Chem 1898, 195, 219, 962, 1007) found the most favourable conditions for the conversion of 40 grams of cellulose to be a digestion for 2 hours at 6–8 atmospheres, with 1000 c c. of 0.5 p.c. sulphung acid 45 p.c. of reducing sugar was obtained, but, according to Korner (ibid 1908, 2353), this is not all termentable dextrose.

Ekstrom (Fr. Pat. 380358, July 29, 1907) treats sawdust with 95 p c sulphune acid at the ordinary temperature for 20 minutes, dilutes to 1 p c free acid, and heats from 1 to 5 hours under a piessure of 3–8 atmospheres , 55–57 p c, conversion is claimed

Ewen and Tomlinson (US Pat. 938308, Oct. 26, 1909) heat sawdust with a minimum of 5 p e acid to a temperature between 135° and 162°. The use of 2–6 p c. hydrofluorie acid has also been suggested (Orlowski, Fr. Pat. 405187, July 17, 1909)  $d\text{-Mannose} \ C_6 H_{12} O_6 \ \text{occurs in nature in the}$ 

form of anhydride-like condensation products, known as mannosans It is best prepared from the vegetable ivory nut (sternnuss) which is used in Beilin and elsewhere for the manufacture of buttons and collar studs. The waste turnings are hydrolysed to mannose by boiling for 6 hours with 2 parts of hydrochloric acid It was originally obtained by Fischer and Hirschberger by oxidising mannitol with nitric acid. Mannose is characterised by forming an insoluble yellow phenylhydrazone, mp. 186°-188°, and use is made of this compound in isolating it from solution The hydrazone is subsequently decomposed with benzaldehyde, or better, formaldehyde, and the resulting solution concentrated in vacuô till the sugar crystallises It may even be isolated in the solid form without the intermediate formation of the phenyl hydrazone (Hudson and Sawyer, J Amer Chem Soc. 1917, 39, 470)

Mannose separates in colourless rhombic crystals  $[a:b:c=0\ 319:1\cdot 0\ 826]$  of sweet taste, mp. 132°; spgr. 1·539 100 cc of the saturated aqueous solution at 17·5° contain 24 8 grams, in absolute alcohol it is almost insoluble. It shows muta-rotation, the equilibrium value being  $[a]+14\cdot5°$ . The a-form has

 $[a]_{\rm p}+34.0^{\circ}$ , and the  $\beta$ -form  $[a]_{\rm p}-17.0^{\circ}$  (Hudson | (III) m p. 98°,  $[a]_{\rm p}-42^{\circ}$  (in chloroform); and Dale, J. Amer. Chem. Soc. 1917, 39, 320)

It is very similar to dextrose in all its properties, yielding the same phenylosazone fermented by all yeasts which attack dextrose and levulose Bromine oxidises it to mannonic acid, sodium amalgam reduces it to mannitol. a-Methyl mannoside had m p 190°,  $[\alpha]_{\rm p}^{20} + 80^{\circ}$ The oxime crystallises in colourless needles, mp 167°-180° Like the phenylhydrazone, the substituted hydrazones are all sparingly soluble

Caroubmose, a carbohydrate isolated from the seeds of the carob bean, is identical with

mannose.

d-Galactose  $C_2H_{12}O_6$  Milk sugar, when hydrolysed by means of acids or enzymes, yields dextrose and galactose in equal proportions On a commercial scale, sulphuric acid is used to effect hydrolysis under pressure at 105°, after which the solution is neutralised and concentrated until an amount which contained 500 grams of milk sugar weighs 640 grams syrup is set aside with a few crystals of galactose, and, after some days, the crystalline mass is washed with 80 p.c. alcohol, and the galactose purified by recrystallisation from aqueous alcohol Even the very best commercial galactose contains minute quantities of dextrose; to remove this it must be treated with a pure culture of some yeast, such as S Ludwign, which ferments dextrose, but not galactose

Galactose is a constituent of raffinose and stachyose, and is widely distributed in the polymene form, galactan, particularly in gums and seaweeds It occurs in a few glucosides It is a colourless crystalline powder,  $+1\rm{H}_2\rm{O}$ , m p  $118^\circ$ - $120^\circ$  (from water), anhydrous m p  $165^\circ$ (from alcohol), less soluble than dextrose, and has the same general properties as dextrose The most characteristic behaviour is the formation of mucic acid on oxidation with nitue acid.

Galactose exhibits muta-rotation; the aisomeride has  $[\mathbf{a}]_{\mathrm{D}}^{20} + 144^{\circ}$ , the  $\beta$ -modification +52°. The equilibrium value is  $[a]_{D}^{20}$  +80 5°. The influence of concentration and temperature on this value is expressed by the equation

 $[\alpha]_{\rm D}\!=\!83\!\cdot\!883\!+\!0.0785p\!-\!0.209t$ 

where p and t denote concentration and temperature respectively

Galactose derivatives are prepared similarly to the corresponding dextrose compounds The a-pentanitrate (Will and Lenze, Bei. 31, 68) forms needles, mp 115°-116°; the  $\beta$ -isomeride has mp. 72°-73°; the  $\beta$ -pentacetate has mp 142°, amethylgalactoside has mp  $[a]_{D}^{110}-112^{\circ}$ ,  $[a]_{D}^{20}+179.3^{\circ}$ , and crystallises in transparent doubly refractive needles; the  $\beta\text{-isomeride}$  forms needles, m p  $173^\circ\text{--}176^\circ\text{,}$  $[a]_{D}^{20}+2.6^{\circ}$ ; the phenylhydrazono has mp 158°, the phenylosazone when quickly heated melts at 193° -194°.

Galactose penta-acetate has been isolated in

(1) m p.  $142^{\circ}$ ,  $[a]_{p} + 25^{\circ}$  (in chloroform),  $+8^{\circ}$  (in

benzene); (ji) m p. 95.5°,  $[\alpha]_D + 107^\circ$  (in chloroform);

(iv) m.p.  $87^{\circ}$ ,  $[a]_{D} + 61^{\circ}$ .

(Hudson and Parker, J Amer Chem. Soc 1915, 37, 1589, 1591; Hudson and Johnson, *ibid*. 1916, 38, 1223).

Some yeasts ferment galactose, but not all those which ferment dextrose and Levulose is apparently possible to grow a yeast in presence of galactose and dextrose, until it acquires the power of fermenting galactose. Galactose is identical with the sugar cerebose, isolated from the brain by Thudichum, where it is a constituent of the cereborsides, phrenosin and kerasin

Lævulose or d-Fructose ('<sub>6</sub>H<sub>12</sub>O<sub>6</sub> is a keto-hexose or ketose sugar. It is found together with dextrose in honey and in many fruits, and, combined with dextrose, it occurs in sucrose, raffinose, stachyose, &c Inulin, found in dahlia tubers is completely converted into fructose on hydrolysis. It has not so far been produced by the hydrolysis of any glucoside

It is termed d-fructose, in spite of the lavorotation, to indicate that it belongs to the d-mannitol series

After prolonged heating at 165°-170°, cane sugar becomes converted into a mixture of levulosan (C<sub>6</sub>II<sub>10</sub>O<sub>5</sub>) and dextrose, without change of weight. On fermenting the aqueous solution of the mass with yeast, the dextrose is decomposed, while the levulosan remains unchanged, and may afterwards be converted into Levulose by treatment with dilute acids

Preparation —It is best prepared from mulin 100 grams of mulin with I pc ash are heated with 250 c.c. water and 0.5 gram hydrochloric acid for half an hour in a boiling water-bath, neutralised with 15 grams sodium carbonate evaporated on the water-bath at 60°, and finally over sulphurie acid in vacuô to a thick syrup This is extracted with absolute alcohol, put aside for 24 hours, the solution poured off clear, and inoculated. Complete crystallisation of the lievulose is obtained in 3 days, and it is quite pure after one more crystallisation

Inulin may also be hydrolysed with 0.5

vol p c. oxalic acid.

(For the preparation from Jerusalem artichokes, see U.S. Pat 789422, Feb. 18, 1908.)

To obtain lævulose from sucrose, the latter is first inverted by means of mineral acids or invertase, and the acid removed by neutralisation with baryta or silver oxide. The invert sugar resulting contains both dextrose and lavulose, which may be separated as follows · 6 grams of finely powdered slaked lime is added to every 100 cc. of a neutral ree-cold 10 pc solution of invert sugar, and the solution, which at first sight is merely milky, is agitated, the vessel being preferably immersed in ice-cold water until it acquires a creamy consistency. The mass, which consists of the difficultly soluble calcium levulosate CaO C<sub>6</sub>H<sub>12</sub>O<sub>6</sub> H<sub>2</sub>O, tegether with the easily soluble calcium dextrosate, is filtered through linen, and strongly pressed to remove the greater part of the liquid, and is suspended in water and decomposed by addition of oxalic acid or by passage of carbonic acid gas. The filtered solution is evaporated in vacuo over sulphuric acid, with production of anhydrous lavulose. Calcium lavulosate dissolves in 1.27

parts of water at 15°, and is almost insoluble at  $0^{\circ}$ .

Levulose, when pure, crystallises from alcohol, and even from aqueous solution, in needles, also in crusts of transparent prisms, which are not hygroscopic It has mp 95°, D<sup>17</sup>5 1 669 It sublimes unchanged but very slowly at 100°/1-2 mm (Ghosh, J. C. S. Abstr. 1917, 112, (1) 80). It is very soluble in water, almost insoluble in cold absolute alcohol. It is much sweeter than dextrose, and somewhat sweeter than sucrose It exhibits muta-rotation, and, no doubt, exists in solution as an equilibrated mixture of stereoisomeric y-oxide forms, The initial rotation  $[\alpha]_{\rm p}^{20} = -104^{\circ}$  falls to  $\left|\alpha\right|_{D}^{20}$  -92° (Parkus and Tollens, Annalen, 257. The specific rotatory power is very considerably influenced by changes of temperature and concentration, which cause an alteration in the proportions of the isomerides in the equili-The rotatory power usually brium mixture taken is  $\left[\alpha\right]_{D}^{15}$  =93.8° It falls 0.6385° for each degree centigrade of increase in temperature, and at 873° is equal but opposite to that of dextrose. This property is taken advantage of m determining its proportion in presence of other sugars, the rotation being observed at two different temperatures

According to Soxhlet, the relative reducing powers of levulose and dextrose on Fehling's solution, in 1 p.c. solution, are 475–513, but Allihn finds that if the solutions be boiled for 30 minutes (instead of for 2 minutes, as in Soxhlet's experiments), their reducing powers are identical. On Knapp's mercurial solution their action is the same, but on Sachsse's mercurial solution their action are 100 (levulose)

and 148 6 respectively

Oxidation converts levulose into acids with fewer carbon atoms, glycollic and trihydroxybutyric. On reduction with sodium amalgam, mainited and sorbited are formed. Acids attack it far more readily than dextrose with the production of levulic and formic acids, alkalis somewhat less readily. Heating concentrated solutions with oxalic acid forms 1-hydroxymethylfurfurol, whilst it interacts with hydrogen bromide in othercal solution, forming 4-bromomethylfur

CH . C(CH<sub>2</sub>Br) O (Fenton and Gostling, CH : C(CHO)

Chem Soc Trans 1899, 75, 423, 1901, 79, 301)
It is fermented by all yeasts which attack destrose.

By the action of methyl alcohol and hydrogen chloride (0.5 pc) at  $35^\circ$ , a syrup is obtained which probably represents a mixture of methyl fructosides. It is partially hydrolysed by yeast extract

Fructose diacetone  $C_{12}H_{20}O_{6}$ , prepared in a similar manner from acetone, forms needles, mp 119°-120°  $[\alpha]_{\rm D}$ -161°. An isomeride has mp 97°  $[\alpha]_{\rm D}$ -33 7°.

The osazones of lavulose are identical with those of dextrose. Lavulose is more easily oxidised by disubstituted phenylhydrazines, and forms a characteristic osazone with methylphenylhydrazine, long yellow needles, mp. 158°-160°.

To prepare this, 4 grams of methylphenylhydrazine are added to 1 8 grams levulose, in 10 c.c. water, and enough alcohol to make a clear solution further 2 c.c. of acetic acid are added, and the mixture heated 5-10 minutes at most on the water-bath. It is then covered and allowed to stand. Within 2 hours red crystals are obtained, which may be recrystallised from 10 p.c. alcohol.

Fructose penta-acetate melts, when pure, at  $108^\circ-100^\circ$ , has  $\lfloor \alpha \rfloor_D = 121^\circ$ , and crystallises in billiant colourless needles, 1 cm. in length (Hudson and Brauns, J Amer Chem. Soc

1915, 37, 1283)

Sorbose (Sorbinose)  $C_6H_{12}O_6$  is the ketohexose obtained from the juice of the mountainash berries, which has been exposed to the air and allowed to ferment. The juice contains sorbitol, this is oxidised by bacterium xylinum to sorbose

The juices are evaporated to 1.05 sp gr, allowed to stand some days till the sugar is fermented, and the clear liquid poured into flat dishes and moculated with an active culture of B-xylinum (Bertrand, Ann Chim Phys 1904, [viii ] 3, 181). This is left at 30° till the reduction is a maximum, clarified with lead acetate, excess of lead precipitated as sulphate, and the neutral filtrate concentrated in view When pure sorbitol is available, 100 grams are dissolved in 500 c.c. water, some nutrient solution for the bacterium added, and the fermentation carned out as above

Sorbose forms thombic crystals of a sweet taste, in p 151°, it reduces Fehling's solution, and generally behaves as Levulose, but yields sorbitol on reduction. It is not fermentable by yeasts. It is Levo-rotatory, having  $[\alpha]_D - 42^\circ$ 

Sorbose phenylosazone is similar to the dextrose compound, but has m p 164°.

The properties are in agreement with the structural formula

### HO H OH CH<sub>2</sub>OH CO C · C · C · CH<sub>2</sub>OH H OH H

Methyl sorbinoside crystallises in transparent thick plates, in p 120°-122° (Fischer, Ber. 28, 1159)

#### HEPTOSES.

d-Mannoketoheptose Occurs in the Avocado pear (Persat gratissima) (La Forge, J Biol. Chem 1917, 28, 511) It has in p 152°, [a]<sub>p</sub>+29°. It is not fermented by yeast, and does not show mutarotation. It gives a colour reaction with oremol and hydrochlone acid like other heptoses. The p-bromophenylhydrazone melts at 179°, the phenilosazone is identical with that from d-mannoaldoheptose.

On reduction the sugar yields d-persital and

d-mannoheptitol

Since the p-bromophenylhydrazone of d- $\alpha$ -mannoaldoheptose melts at  $207^{\circ}$ - $208^{\circ}$ , and that of d- $\beta$ -mannoaldoheptose is an oil, the configuration of the sugar must be :—

 $\begin{array}{cccc} \textbf{Perseulose} \ (l.c.) \ \text{is shown to be } l\text{-}galaheptose: --- \\ & \text{H} & \text{OH} & \text{OH} & \text{H} \\ & \text{CH}_2(\text{OH}) \ \text{CO} \ \text{C} & \text{C} & \text{C} & \text{C} & \text{CH}_2(\text{OH}) \\ & \text{OH} & \text{H} & \text{H} & \text{OH} \\ \end{array}$ 

Sedoheptose Occurs in Sedum spectabile (La Forge and Hudson, J. Biol Chem 1917, 30, 61) as a non-fermentable, reducing syrup

Phenylosazone, mp 197°; p-bromophenyl-hydrazone, mp 227°-228°; the osone is a syrup, its o-phenylenediamine derivative melts at 163°-165°

Bromine water does not oxidise the sugar, but it reduces with sodium amalgam to two alcohols  $C_7H_{18}O_7$ —

a-Sedoheptitol, m p  $151^{\circ}-152^{\circ}$ ,  $[\alpha]_{D}+225^{\circ}$ .

 $\beta\text{-Sedoheptitol}, \quad \text{m p} \quad 127^\circ\text{--}128^\circ, \quad \text{optically mactive}$ 

The two alcohols are separable by their benzylidene derivatives

These reactions indicate that the sugar is a ketose

Anhydrosedoheptose  $C_7H_{12}O_6$  is formed when sedoheptose is heated with dilute acids. It forms long white prisms, melting at 155°,  $\lfloor a \rfloor_D - 146$ °. It shows no mutatotation, does not reduce Fehling's solution, and, when boiled with dilute acid, gives an equilibrium mixture which contains 20 p.c. of sedoheptose

These are widely distributed in plants, where they are present in the skeletal structure, and do not, like the hexoses, serve as food products Pentoses also appear to be a constituent of many of the tissues of the animal body, and are sometimes found in urine. Both the natural pentoses, *l*-arabinose and *l*-xylose, belong to the lavo- senes Dextrose (dextro-glucose), when degraded by the methods of Ruff or Wohl, gives rise to the isomeric d-arabinose. However, the natural pentoses are closely related to the natural hexoses For example, the space arrangement of the groups attached to the upper four carbon atoms is the same in d-glucose as it is in l-xylose

A similar relationship exists between galactose and arabinose, which occur together in many gums, whilst some polysaccharides yield both xylose and glucose on hydrolysis. The pentoses do not occur as such, but in the form of condensation products of high molecular weight, termed 'pentosans' (araban or xylan). These are comparable with the hexose condensation products, starch and cellulose, as a rule, the pentosans contain both C<sub>5</sub> and C<sub>6</sub> carbohydrates.

The mechanism of the formation of pentoses

in the plant is not yet clear. Some authorities consider they are derived by oxidation from the hexoses, others advocate the view that they are duectly formed in the cell, like the hexoses, but independently of these Such a transformation as that from dextrose to l-xylose has not been effected in the laboratory the chemical degradation of dextrose by oxidation leads to d-arabinose. The pentoses show all the general chemical properties of the hexoses Biochemically. they are different, being not fermentable by yeasts, whilst their glucosidic derivatives (e q. the methyl arabinosides and xylosides) are not hydrolysed by any of the better-known plant enzymes. They are attacked by a number of bacteria Characteristic of the pentoses is the formation of furfurol on distillation with hydrochloric acid They, therefore, show colour reactions with original and phloroglucinol. Equal parts of concentrated hydrochloric acid and water are taken, together with the pentose and a little oremol or phloroglucinol, and the mixture warmed in the water-bath. With oromol the solution becomes red, then violet, and finally blue or blue-green, with the separation of a precipitate which dissolves in amyl alcohol, giving a blue-green solution, this shows an absorption band between C and D. With phloroglucinol the solution becomes cherry-red, and a precipitate is formed, giving a red solution in amyl alcohol, with an absorption band between D and E

l-Arabinose  $\mathrm{C_5ll_{10}O_5}$  is obtained by hydrolysis of most gums, particularly gum arabic and cherry gum

Preparation -A solution of gum arabic, or allied gum (dextro-rotatory, and yielding little mucie acid by the action of nitric acid, by preference), containing 30-40 grams of the gum, and 2-3 c c sulphune acid in 100 c c, is boiled for 7-12 minutes, cooled, the acid neutralised with calcium or battum hydroxide or carbonate and alcohol, sp gr 0 83 added as long as a precipitate is produced. This precipitate soon settles, leaving the alcoholic solution clear. On distilling off the alcohol and evaporating to a syrup, arabinose crystallises out. The substance is obtained in well-defined thombic prisms, with monoclinic termination, by recrystallising from water. With some gums the digestion of the acid solution can be continued for 2 hours with increased yield of arabinose, and without impairing the purity of the product. The crystals are anhydrous, mp. 160°

Arabinose has  $[a]_D+104^\circ$  to  $+105^\circ$ , the activity increasing with the strength of the solution, and decreasing as the temperature at which it is observed is raised

It exhibits muta-rotation,  $\alpha$ -arabinose having the initial rotatory power  $[\alpha]_D + 175^\circ$ , decreasing to  $+104^\circ$   $\beta$ -Arabinose has not been isolated. Accordingly, like dextrose, it has a  $\gamma$ -oxidic structure.

The heat of combustion is 558 cals

Arabinose reduces Fehling's solution, the amounts of copper oxide produced by equivalent weights of arabinose and dextrose being as 111:100

Bromine oxidises it to l-arabonic acid  $C_5H_{10}O_6$ , which crystallises as the lactone  $C_5H_8O_5$ , m p. 95°-98°,  $[a]_D$ -73 9°. Nitric acid

forms oxalic acid as the final product, but in dilute solution, firstly arabonic acid, and secondly *l*-trihydroxyglutaric acid, in p 127°, are formed. On reduction, amongst other products, *l*-arabitol, in p 102°, is formed, which is optically inactive, but becomes law-rotatory in presence of borax

Arabinose forms an additive compound with hydrogen cyanide, which is hydrolysed to arabinose carboxylic acid. This is, in reality, a mixture of two acids, of which the lactones on reduction give rise to l-glucose and l-mannose.

The diphenylhydrazone, mp 218°, is almost insoluble The other hydrazones have the following melting-points: phenyl, 151°; p-biomophenyl, 150°, α-methylphenyl, 161°, α-othylphenyl, 153°; α-benzoylphenyl, 170°, β-naphthyl, 141° Arabinose phenylosazone, mp 160°, is prepared similarly to the dextrose compound. It is slightly more soluble, and, when boiled with benzaldehyde, arabinosone is formed. The p-biomophenylosazone has mp 196°-200°.

Arabinose forms crystallisable compounds with the aromatic diamines and diamino-acids

l-Xylose is obtained by the hydrolysis of wood gum (xylan) extracted from wood by dilute soda solution

According to Bertrand (Bull Soc chim [3] 5, 554), it may be obtained from wheat or oat straw by first extracting the straw with tepid water, and then boiling it for several hours with dilute (1–2 p c) sulphuric acid. The liquoi, after removal of the sulphuric acid by baryta, is concentrated on the water-bath and treated with alcohol; this extracts the xylose, which forms a syrup on evaporation of the alcohol, solidifying on the addition of a crystal of xylose. The yield is about 2 p c from wheat straw, and 4 p c from oat straw

Another convenient source are oat hulls, which are cleaned by soaking in dilute ammonia, washed and hydrolysed with sulphume acid Hudson and Harding (J Amer Chem Soc 1917, 39, 1038) obtained a yield of 8-12 p c of xylose by direct acid hydrolysis of cottonseed hulls A more suitable source is maize cobs (*idem* 1918, 40, 1601) Xylose crystallises in orthorhombic prisms, in p. 144°–145° or 150°–154° It exhibits muta-rotation, a xylose having  $[a]_p$ +79°, falling to +19°, which is the rotation of the equilibrated mixture The heat of combustion is 561 cals Bromine oxidises it to xylonic acid, a syrup which is at first levo-rotatory, but reaches  $[\alpha]_D + 17.5^\circ$ , as it is transformed into the lactone in solution It forms a very characteristic insoluble compound C5H9O6CdBr, H2O with cadmium bromide Nitrie acid in the cold forms an optically mactive trihydroxyglutaric acid

On reduction, mactive xylitol, a syrup, is formed

a-Methylxyloside has mp 90°-92°,  $[a]_{\rm D}+152$ , the  $\beta$ -isomeride has mp 156°-157°,  $[a]_{\rm D}-65$ 9° With hydrogen cyanide two xylose carboxylic acids are formed, which yield l-gulose and l-idose on reduction.

The phenylhydrazone has m p.  $116^{\circ}$ ; the  $\beta$ -naphthylhydrazone, m p  $70^{\circ}$ , and the phenylosazone, m p  $166^{\circ}$ 

The methyl pentoses are pentose carbohydrates, in which one of the hydrogen atoms in

the primary alcohol group is replaced by methyl They appear to be widely distributed, but their brochemical significance is not yet understood. They show the same reactions as the pentoses, and, like these, are not ferimented by yeasts. Characteristic is the formation of methylfurfuraldehyde on distillation with acids

Rhamnose (Isodulettol) C<sub>6</sub>H<sub>12</sub>O<sub>5</sub>,H<sub>2</sub>O, on account of its empirical formula, and the ease with which it crystallised, was formerly classed with dulettol and mannitol, hence the original name of isodulettol. Its chemical behaviour shows it to be a methyl pentose. It appears to be widely distributed in nature in the form of glucosides, the best known of which are xanthorhamnin, the colouring matter of Persian berries and querettiin. Other glucosides containing rhamnose are baptism, fisetin, frangulin, fustin, datiscin, glycyphyllin, hesperidin, natingin, tutin, sophorm (v. Glucosides).

It is prepared by extracting Persian berries with hot alcohol, distilling off the alcohol, and heating the xanthorhammin on the water-bath for 2 hours, with 6 pc sulphune acid. The precipitated rhamnetin is filtered, the filtrate neutralised with barium carbonate, and, after removal of the barium sulphate, evaporated to a syrup. This is diluted hot with absolute alcohol, and the solution allowed to stand, when it deposits hard lustrous crystals of rhamnose About 15–20 grams are obtained per kilo of berries.

It is advantageously prepared from the residues of the manufacture of quereitron extract, when these are available

Rhamnose has the constitutional formula

Until recently the positions of the groups attached to the carbon atom next to the  $\mathrm{CH_{1}}$ -group were uncertain, but Fischer and Zach (Ber 1912, 45, 3761) have obtained d-isothamnose by a series of reactions from triacetyl dibromoglucose, in which compound the two halogen atoms are attached to the terminal carbon atoms of the sugar chain.

The hydrate softens at 89°; m p 92°-93° When anhydrous, it crystallises from acctone in needles, m p 122°-126° (Fischer), 108° (Tarret) Like dextrose, it exists in  $\alpha$ - and  $\beta$ - modifications, which are in equilibrium in solution. The  $\alpha$ -torm has  $\lfloor \alpha \rfloor_{\rm p} -17^{\circ}$ ; the  $\beta$ - form  $\lfloor \alpha \rfloor_{\rm p} +31.5^{\circ}$ , and the equilibrated mixture has  $\lfloor \alpha \rfloor_{\rm p} +9^{\circ}$ . It sublimes slowly and unchanged at 105°/1-2 mm

Bromine oxidises it to rhamnonic acid, with intric acid it yields a mixture of formic, oxalic, and trihydroxyglutaric acids C<sub>5</sub>H<sub>4</sub>O<sub>7</sub> On reduction, the corresponding alcohol rhamnitol is formed

The phenylhydrazone has m p 159°; methylphenylhydrazone, m p 124°, ethylphenylhydrazone, m p. 124°; allylphenylhydrazone, m p. 135°, amylphenylhydrazone, m p. 99°, diphenylhydrazone, m p 134°, benzylphenylhydrazone, m.p 121°,  $\beta$ -naphthylhydrazone, m p 170°. Rhamnose phenylosazone crystallises in slender yellow needles, slightly soluble in bolling water; m p. 190°–192°.

Methylrhamnoside has m.p.  $108^{\circ}-109^{\circ}$ ,  $[\alpha]_{D}-62^{\circ}$ ; acctone rhamnoside, m.p.  $90^{\circ}-91^{\circ}$ .

Other derivatives are rhamnose ethylmercaptal, m p 135°-137°; rhamnose oxime, m p 127°-128°; rhamnose anilide, m p 118°.

Fucose C<sub>6</sub>H<sub>12</sub>O<sub>5</sub>

is obtained by hydrolysing the polymer fucosan, which is a component of the cell-wall of many marine algae. It is also present in Fucus vesiculosus, in laminatia and Carragheen moss. The seaweed is washed with water and dilute hydrochloric acid, and boiled for 12 hours with 3 p c sulphuric acid. The acid is neutralised with baryta, the filtrate concentrated to a syrup, taken up with alcohol, concentrated again, and the sugar isolated as hydrazone Reduction with sodium amalgam gives d-fucitol (Votoček, 1913, 46, 3653), mp 153°–154°, which combines with ihodeitol to form i-fucitol.

Fucose crystallises slowly in minute needles, in p 130°-140° . It exhibits muta-rotation [ $\alpha_D$ ], being initially  $-112^\circ$ , falling to  $-74.4^\circ$  to  $-77^\circ$ .

The phenylhydrazone has mp 170°–172°, the phenylmethylhydrazone, mp 177°, phenylbenzylhydrazone, mp 172°–173°; diphenylhydrazone, mp 198°; p-bromophenylhydrazone, mp 181°–184°. Fuconic acid lactone has mp 106°–107°,  $\lfloor a \rfloor_p + 73$ ° to + 78 3°.

Epifucose. Fucome acid lactone, heated with pyridine at 145°-150°, is converted to epifuconic acid lactone (Votoček and Cervený, Ber 1915, 48, 658), which on reduction with sodium amalgam gives epifucose

$$\begin{array}{cccc} \mathrm{CH_3} \; \mathrm{CH(OH)} & \begin{array}{ccccc} \mathrm{H} & \mathrm{H} & \mathrm{OH} \\ \mathrm{C} & \mathrm{C} & \mathrm{C} & \mathrm{CHO} \\ \mathrm{OH} \; \mathrm{OH} \; \mathrm{H} \end{array}$$

a syrup,  $\begin{bmatrix} a \end{bmatrix}_0 - 9^\circ$ , whose phenylhydrazone and p-bromophenylhydrazone are identical with those of fucose

Rhodeose is the optical antipode of fucose (Muther and Tollens, Ber. 1904, 37, 306). It has  $\lfloor a \rfloor_p + 73^\circ$  to +75 2°, and forms derivatives having the same melting-point as those from fucose just described. Rhodeome and lactone has mp 105 5°,  $\lfloor a \rfloor_p - 76$  3° to -69 4°. Rhodeose is obtained from the glucoside convolvulin

The configuration of thodcose is shown by the following reactions (Hudson, J. Amei. Chem Soc. 1911, 33, 405, Votoček, Ber. 1910, 43, 476).—

(a) Oxidation of rhodeonic acid lactone gives l-trioxyglutanic acid

(b) Reduction of rhodeose gives rhodeitol, not attacked by sorbose bacterium

(c) The rhodeohexonic acid produced by applying the cyanohydrin reaction to ihodeose yields, on oxidation, saccharic acid

Hence thodeose is

Epirhodeose (Votoček, Ber 1911, 44, 362) Rhodeonic acid, heated with pyridine at 150°-160°, is epimerised to epithodeonic acid, the lactone of which on reduction gives epithodeose:

$$\mathrm{CH^3\,CH(OH)} \cdot \overset{H}{\overset{\circ}{\mathrm{C}}} \overset{H}{\overset{\circ}{\mathrm{C}}} \overset{H}{\overset{\circ}{\mathrm{C}}} \overset{H}{\overset{\circ}{\mathrm{C}}} \overset{H}{\overset{\circ}{\mathrm{C}}}$$

The sugar is a syrup which gives the same osazone as rhodeose, it oxidises to trioxyriboglutaric acid, m p  $~184^{\circ}\text{--}185^{\circ}, \left[\alpha\right|_{D} + 12^{\circ}.$ 

Isorhodeose (Votoček, Ber. 1910, 43, 476; 1911, 44, 819, 3287)

This occurs combined with rhodeose, rhamnose, and other compounds in the glucoside convolvulin, it is the optical antipode of Fischer's isonhamnose. The configuration is shown by the following reactions.—

(a) Oxidation with intric acid produces

i-trioxyglutaric acid

(b) Oxidation with bromine water gives isorhodeonic acid, which reacts —

(1) With pyridine at 150° to give antirhamnonic acid, which reduces to anti-hamnose. HCN converts this sugar to anti-hamnohexomic acid, which may be further oxidised, giving macic acid

(ii) With H<sub>2</sub>O<sub>2</sub> in presence of iron to give a methyltetiose, which oxidises to l-taitaric acid

Isorhodcosc is therefore

$$\mathrm{CH^3\,CH(OH)} \, \cdot \, \overset{\mathrm{OH}}{\overset{\mathrm{CH}}{\overset{\mathrm{CH}}{\overset{\mathrm{OH}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{CHO}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{\mathrm{Cho}}{\overset{Cho}}}{\overset{Cho}}{\overset{Cho}}{\overset{Cho}}{\overset{Cho}}{\overset{Cho}}}{\overset{Cho}}{\overset{Cho}}{\overset{Cho}}}{\overset{Cho}}{\overset{Cho}}{\overset{Cho}}}{\overset{Cho}}}{\overset{Cho}}}{\overset{Cho}}}}}{\overset{Cho}}}}}}}}}}}}}}}}}}}}}}$$

it has  $[\alpha]_p+31.5^\circ$ , and the melting-points of the phenylosazone and p-biomophenylosazone are respectively  $186^\circ-187^\circ$  and  $222^\circ$ 

#### Tetroses

By reduction of dioxyvalerolactone, a mixture of a methyltetrose and the corresponding alcohol were produced. The methyltetrose is a syrup, giving an osazone, in p. 140°-142°, and a phenylbenzylhydrazone, in p. 99°-100°. The methyltetritol is also a syrup, its tetrabenzoate melting at 136°-137° (Gilmour, Chem Soc Trans 1914, 105, 73)

Rhodeotetrose. Rhodeose is degraded by Wohl's method to a rhodeotetrose, the p-bromophenylhydrazone of which melts at 143°-144° (Votoček, Ber. 1917, 50, 35)

Chinovose  $C_8H_{12}O_5$  is only known as a constituent of the glucoside chinovin, which, on hydrolysis with alcoholic hydrochloric acid, yields ethylchinovoside  $C_8H_{11}O_4$   $OC_2H_5$ , originally termed chinovite,  $[\alpha]_D + 78^\circ$ .

Chmovite, when hydrolysed with dilute sulphuric acid, yields chinovose, which is a syrup, showing all the reactions of the carbohydrates. Phenylchmovosazone forms yellow needles, in p. 193°–194°.

Aplose  $C_5^\dagger H_{10}O_5$  is an altogether remarkable sugar, obtained together with dextrose on hydrolysing the glucoside apin present in the seeds and leaves of parsley. It contains a branched chain of carbon atoms, having the

constitutional formula

$$\begin{array}{c} \mathrm{CH_{2}(OH)} \\ \mathrm{CH_{2}(OH)} \end{array} \hspace{-0.5cm} \hspace{-0.5c$$

(Vongerichten, Annalen, 1901, 318, 121, 1902, 321, 71, Bei 1996, 39, 235).

It is a pale yellow syrup, optically mactive,

non-fermentable, does not yield furfurol, and yields isovaleric acid when reduced by hydrogen iodide and phosphorus. Bromine oxidises it to apionic acid.

The phenylhydrazone has mp. 135°; phenylosazone, m p 156°, and the bromophenylosazone,

mp 209°-212°

Digitoxose C<sub>6</sub>H<sub>12</sub>O<sub>4</sub> is obtained on hydrolysing digitoxin, one of the glucosides of digitalis crystallises in plisms or plates, in p 102°, and is dextro-rotatory It has the composition (Kiliani)  $CH_3 CH(OH) [CH(OH)]_2 CH_2 CHO$ 

Digitalose C7H14O5 is similarly obtained from

digitalin.

#### THE CARBOHYDRATE ACIDS

are those containing the same number of carbon atoms as the aldose carbohydrates from which they are derived. They are either mono- or dibasic. Ketoses yield acids with fewer carbon atoms than the original carbohydrate on oxidation.

The monobasic acids are formed on oxidising the aldehyde group to acid, generally by means of bromine or dilute nitric acid. More energetic oxidation converts also the primary alcohol

(-CH<sub>2</sub>OH) group into acid (CO<sub>2</sub>H)

Glucuronic acid, which is of importance physiologically, is a type of monobasic acid, in which the aldehyde group is intact, and the primary alcohol group oxidised to acid monobasic acids are transformed in aqueous solution, particularly on evaporation on the water-bath, into lactones which crystallise well. The dibasic acids similarly sometimes form double lactones

The most important property of gluconic and isometic acids is their behaviour on heating with pyridine or quinoline, when they are transformed into isomerides, rearrangements of the groups attached to the a-carbon atom taking place. Thus, when glucome acid is heated with quinoline or pyridine at 130°-150°, it is partially converted into mannonic acid. This behaviour has been of the utmost importance in effecting

the synthesis of the carbohydrates.

Glueonic acid  $C_6H_{12}O_7$  always contains a proportion of lactone. It is slightly Levorotatory at the instant of solution, but becomes dextro-rotatory as the transformation to lactone takes place, the final figure for a mixture in equilibrium of acid and lactone being about +19°. The lactone crystallises in slender needles, in p 130°-135° -1t has  $[\alpha]$  +68° when  $+19^{\circ}$ . first dissolved, falling to +19° for the solution in equilibrium with the acid. The calcium salt is sparingly soluble and characteristic, likewise the phenylhydrazide C<sub>6</sub>H<sub>12</sub>O<sub>6</sub> N<sub>2</sub>H<sub>2</sub>Ph, which forms colourless prisms, m p 200°

Mannonic acid. The lactone crystallises in

needles, m p.  $149^{\circ}$  –  $153^{\circ}$ ,  $[\alpha]_{\rm p}$  +  $53.8^{\circ}$ . The phenyl

hydrazide has m p 214°-216°.

Galactonic acid is obtained by oxidising galactose or hydrolysed lactose with bromine In the latter case, 100 grams lactose are boiled 4 hours with 100 grams 5 pc. sulphuric acid, the acid precipitated as barium sulphate, and the filtrate evaporated to 300 c c, cooled to 35°, and 200 grams of bromme added with constant shaking. After standing for a short time, the excess of bromine is removed by a current of an, hydrog n bromide by lead carbonate and silver oxide, and the solution is sturated with cadmium carbonate, and concentrated till the cadmium galactonate crystallises. The mother liquors yield a second crop, about 50 grams in all being obtained. This salt is purified and decomposed

with sulphure acid

Galactonic acid crystallises in needles, which, on heating to 100', lose water, forming the lactone The lactone crystallises with difficulty, it has mp 90°-92°, and forms a crystalline hydrate, mp 65°. The acid has  $\lfloor a \rfloor_D - 10.5$ °, which becomes -57° on heating. The lactone has  $[a]_D$  70°, and the crystalline hydrate  $[a]_D$  -58°. The cadmium salt is characteristic, the phenylhydrazide has mp 200°-205°. On heating with pyridine at 150°, galactonic acid is partially converted into d-talonic acid.

Lactobionic and maltobionic acids, obtained by the action of bromine on the corresponding disacchandes, are colourless syrups or amorphous

compounds

Glucuronic acid (glycuronic acid) C<sub>6</sub>H<sub>10</sub>O<sub>7</sub> is frequently found in urine, combined with a variety of substances, forming compounds of a glucosidic nature. It was synthesised by Fischer (Ber. 24, 521), by reduction of saccharic glucosidic nature acid lactone, and has the formula

## CO, II [CH OH], CHO

It is conveniently prepared from euvanthic acid, which is readily hydrolysed by dilute acids to glucuronie acid and euxanthon

$$C_{10}H_{16}O_{10}+H_{2}O-C_{6}H_{10}O_{7}+C_{13}H_{8}O_{4}$$

Euxanthic acid, known in commerce as Indian yellow or puri, is a pigment made almost exclusively in Bengal, and is obtained from the urine of cows which have been fed upon mango leaves (v. Indian Yellow)

According to Thierfelder (Zeitsch physiol Chem, 11, 388), I part of euxanthic acid is heated with 200 parts of water in an autoclave at 120°, the euxanthone separated by filtration, and the solution concentrated Owing to the introduction of aniline dyes, piuri has become very rare

and expensive

Neuberg and Lachmann (Brochem Zeitsch 1910, 24, 416) propose to obtain glucuronic acid by feeding menthol to rabbits. Menthol has the advantage that it is not poisonous, the paried glucurome acid is fairly easily isolated and readily hydrolysed 2 grams menthol are dissolved in 1 c c alcohol and shaken with 20 ce lukewarm water, this emulsion is administered to rabbits, and the urine collected, rendered acid, and extracted with other. Excess of ammonia is added to the ethereal solution, and the ether distilled off. The residue of insoluble ammonium menthylglucuronate is dissolved in water, precipitated by lead acetate, the precipitate decomposed with hydrogen sulphide, and the filtrate evaporated when pure menthylglucurome acid is obtained is decomposed by boiling with dilute sulphuric acid to give glucuronic acid

Glucuronic acid is a syrup, and is transformed into the crystalline lactone on evaporation. This is very soluble in water, it has m p. 175°, [a]<sub>D</sub>+19°. It reduces Fehling's solution, yields furfurol on distillation with mineral acids, showing positive reactions with oremol and

phloroglucinol, and is not fermentable

A number of substances when introduced

into the animal body are excreted in the urine as Levo-rotatory-paned glucuronic acid derivatives. These are isolated by precipitation with basic lead acetate, of which an excess should be avoided.

Saceharic acid 
$$C_6H_{10}O_2$$
  
 $OH H OH OH$   
 $CO_2H-C-C-C-C-CO_2H$   
 $H OH H H$ 

is obtained on oxidising dextrose and all carbohydrates which contain dextrose, also from sorbitol, glucome acid and glucurome acid. It is prepared from starch or dextrose (50 grams) by heating with nitric acid (350 grams) (sp gr 1 15) on the water-bath, and evaporating to a syrup whilst stirring continually. A little water is added, and the solution again evaporated The residue is dissolved in 150 grams of water, neutralised with a concentrated solution of potassium carbonate, 25 c c acetic acid (50 p c) added, and the solution evaporated to 80 c c On standing, the monopotassium salt separates, and is recrystallised from a little hot water the mother liquois, Neuberg (Biochem. Zeitsch 1910, 28, 355) has recently found 10 pc of an acid identical or isomeric with glucuronic acid

Saccharic acid is a syrup,  $[a]_D + 8^\circ$ , increasing to  $+22.5^\circ$ . The lactone  $C_6H_4O_7$  has m p  $130^\circ$ – $131^\circ$ ,  $[a]_D +37.9^\circ$ , decreasing to  $2.25^\circ$  for the equilibrium mixture with the acid. Characteristic is the monopotassium salt  $C_6H_9O_8K$ , formed on the addition of acetic acid in excess to a solution of the normal saccharate. This crystallises in small orthorhombic needles, sparingly soluble in water (1.12 parts per 100°). The diphenylhydiazide has m p 210°.

The continued action of intric acid forms tartaric and racemic acids, and, finally, ovalic acid. On dry distillation it decomposes with the evolution of carbon dioxide, yielding pyromucic and isopyromucic acids.

Mucie acid  $C_6 H_{10} O_8$ 

is obtained on oxidising galactose, lactose, laffinose, dulcitol, and all carbohydrates which yield galactose when hydrolysed.

100 grams of lactose are heated on the waterbath with 1200 c c, of nitic and sp gr 1 15 till the volume is reduced to 200 c c, this residue is taken up with an equal volume of water and left to crystallise, the yield is about 38 grams

Mucie acid is a microcrystalline powder, m p 213°-214°, it dissolves in 300 parts of water at 14°, or 60 parts at 100°. It is optically mactive, and cannot be resolved into optically active isomerides

It forms normal and acid salts with metals, and normal salts with alkaloids. The monophenylhydrazide has mp 190°-195°, the diphenylhydrazide, prepared by heating with phenylhydrazine acetate on the water-bath, has m.p 240°

### THE CARBORYDRATE ALCOHOLS

are widely distributed in the vegetable kingdom, where they occur, as a rule, uncombined with other substances. As a class they are readily soluble in water, crystallise well, and have a small

notatory power. On cautious oxidation they give in turn a reducing sugar, monobasic acid, and dibasic acid. They are obtained by reduction of the corresponding aldose or ketose carbohydrates with sodium amalgam, but, as a rule, owing to transformations in the alkaline solution, a mixture of alcohols is produced. They are not fermentable, and do not reduce Fehling's solution. Only those which occur naturally will be described here, though the alcohols corresponding to the synthetical sugars are known.

Erythritol C4H10O4

$$\begin{array}{c} \text{OH OH} \\ \text{CH}_2(\text{OH}) - \text{C} - \text{C} - \text{CH}_2(\text{OH}) \\ \text{H} \quad \text{H} \end{array}$$

occurs in a number of lichens, particularly the varieties of  $Roccella\ timetoria$ , where it is present in the form of the ether crythrin  $C_{20}H_{22}O_{10}$ , which is a diorsellmate of crythritol. This is saponified by boiling with baryta or lime

 $\mathbf{C_{20}H_{22}O_{10}+2H_{2}O=C_{4}H_{10}O_{4}+2C_{7}H_{8}O_{2}+2CO_{2}}$ 

Erythrin is heated for about 2 hours at 150° in a closed iron vessel, with a quantity of milk of lime somewhat less than sufficient to decompose it, the exclusion of air prevents the formation of a large quantity of resinous matter The liquid filtered from calcium carbonate, on evaporation at a gentle heat, deposits orcinol in fine crystals, and the mother liquors on further evaporation yield a crystalline mass of orcinol and crythritol, from which the former is extracted by ether (*i* De Luynes, Compt rend. 56, 803) Stenhouse (Chem Soc. Trans [2] 5, 222) dissolves the erythrin in a slight excess of milk of lime, boils for half an hour in a vessel with a long condensing tube to exclude air, precipitates the lime in the resulting solution with carbon dioxide, or (on a large scale) by exact neutralisation with dilute sulphune acid, and evaporates the filtered solution to dryness On digesting the residue for 20-30 minutes with a mixture of benzene, toluene, &c (bp. 110°-150°), in a metallic vessel provided with a condenser, an undissolved portion is left free from ordinol, which, on evaporation and filtering from resin, &c, deposits crystals of erythritol. These may be purified by washing with cold alcohol, pressing, and recrystallising once or twice from hot water

Erythitol crystallises in large, colourless, transparent quadratic prisms, having an adamantine lustre Sp gr 1 542-1 449. It melts at 126° (Liebermann, Ber 17, 873), and may be cooled far below its melting-point without solidifying

It is optically mactive even in presence of boax, and has no action on litmus, but the addition of borax renders it acid. Its taste is sweet, but less so than that of oremol. It is very readily soluble in water, its heat of solution being at 18°, 5·2 cals, and at 9°, 5·12 cals (Colson, Compt. rend. 104, 113), sparingly in cold alcohol and insoluble in other. It does not lose water below 100°, and does not piccipitate neutral or basic lead acetate, copper salts, or animonium lead nitrate (Stenhouse).

Erythitol is not altered by ammonia, by bromine, or by chloride of lime. Heated to 260° with solid potassium hydroxide, it yields oxalic and acetic acids with evolution of hydrogen. With fuming hydriodic acid, it gives secondary butyl iodide C<sub>4</sub>H<sub>8</sub> III It is attacled by atmospheric oxygen ir presence of platinum

black, forming trihydroxybutyric and oxalic acids (De Luynes, Compt. rend. 56, 803, Sell, ibid. 61, 741).

With dilute nitile acid, oxalic acid, taitaric acid, and a large quantity of hydrocyanic acid are produced; and with chromic acid and potassium permanganate, or with chromic mixture, formic acid, carbon dioxide, and oxalic acid are obtained (Przybytek, Bull Soc chim [2] 35, 108)

E Fischer and J. Tafel (Ber. 20, 1088), by the oxidation of crythritol with dilute nitric acid, procured a reducing sugar, erythrose, which formed a crystalline phenylosazone C16H18N4O2, m p 166°-167°, sparingly soluble in water, more readily in other and benzene. The tetranitrate C4 II6(NO3)4 forms large shining laminæ, m p 61°

When eightritol is dissolved in concentrated sulphuric acid, and the mixture heated to 60°-70°, the compound  $C_8H_{11}O_2(SO_1H)$ , is produced, which forms salts with inetals (Hesse,

Annalen, 117, 329)

Erythritol dissolves easily in chlorosulphonic acid, forming eightritol tetrasulphune acid C4H6(SO4H)4, which crystallises in snow-white masses consisting of small prisms - It is decomposed by hot water with regeneration of erythritol. The metallic salts are sparingly soluble

By heating crythritol for about 100 hours 12-15 parts concentrated hydrochloric acid, De Luynes (Ann Chim Phys [4] 2385, J 1864, 497) obtained erythritol dichlorohydrin C<sub>4</sub>H<sub>6</sub>(OH)<sub>2</sub>Cl<sub>2</sub> By raising the temperature to 120°-130°, the result is more quickly attained, or the compound may be produced by heating eightritol to 120°-130° in a current of hydrochloric acid (Przybytek, Ber 14, 2072) It melts at 124°-125° (m p 145°, De Luynes)

Eigthritol tetrachloride C4H6Cl4, produced by the action of phosphorus pentachloride, melts at 73°, and crystallises in prisms (Henninger, Bull Soc chim 34, 194, Bell, Ber 12, 1271) Dinitro-

dichlorhydiin  $C_4\Pi_6(Cl_2)(NO_2)_2O_2$ , has m.p. 60°. Erythritol dibromhydiin  $C_4\Pi_6(Br_2)(OH)_2$ is formed by heating with a saturated solution of hydrobiomic acid for 3 hours at 100° in a sealed tube. It is insoluble in water, and melts at 130° (Champion, Compt 1cnd 73, 114) Dinitiodibromhydiin  $C_4H_4(Bi_2)(NO_2)O_2$  is a flaky precipitate, mp  $75^{\circ}$  It does not detonate under the hammer (Champion)

The tetraformate forms long slender needles, m p  $150^{\circ}$ , the tetracetate has m p  $85^{\circ}$ , and

the tetrabenzoate, m p 186°-187°. (Characteristic is the dibenzylideneacetal  $_4^{\rm H}_6{\rm O}_4({
m C}_7{
m H}_6)_2$ , obtained on shaking with 2 parts of benzaldehyde and 3 parts of 50 p c sulphuric acid (Fischer, Bei 27, 1524) which forms slender needles sparingly soluble in hot water

It is not fermentable by yeasts Bacterium xylinum transforms it into a reducing keto-tetrose (Bertrand, Compt. rend. 126, 762), and it is attacked by bacteria in cow-dung and hay water, succinic acid in the one case and volatile acids in the other being the main products of change (Fitz, Bei 11 1890, 12, 474)

The anhydride αδ-oxy-βγ-butanediol is obtained by heating erythritol for some hours with acids, it is a liquid, b p 154°-155° at 18 mm

The second anhydride  $C_4H_6O_2$  was prepared by Przybytek (Ber. 17, 1091) by the action of potash on erythritol dichlorhydrin. It is a colourless mobile volatile liquid, b.p. 138°, sp.gr. 1.1322 It combines with water, acids, and ammonia, and forms compounds with hydroand aniline Its constitutional CH<sub>2</sub> · CH CH · CH<sub>2</sub> cyanic acid and aniline formula is

When heated with anhydrous barium oxide for 3 days at 200°-220°, the anhydride yields furfurane, when heated with phosphoius pentasulphide it gives thiophene.

Adonitol C<sub>5</sub>H<sub>12</sub>O<sub>5</sub>

$$\begin{array}{c} \text{OH OH OH} \\ \text{CH}_2\text{(OH)} - \text{C} - \text{C} - \text{C} - \text{CH}_2\text{(OH)} \\ \text{H} \quad \text{H} \quad \text{H} \end{array}$$

is the only naturally occurring pentose alcohol, it corresponds to ribose, and is obtained on reducing this It is found in Adonis vernalis (Podwyssotzki, Arch Pharm 1889, 141) It separates from water in transparent prismatic crystals mp 102° It has a sweet taste, and is When shaken with benzaldeoptically mactive hyde and 50 pc sulphune acid, the dibenzylidene acctal is formed quantitatively, it crystal-lises in slender needles, mp 164°-165°. The The corresponding diformylideneacetal has m p 145° It is oxidised to a mixture of pentoses (Fischer, Ber 1893, 26, 633, 27, 2491, Meick, Aich Pharm 1893, 231, 129).

Mannitol or d-mannite C<sub>6</sub>H<sub>8</sub>(OH)<sub>6</sub>

is the alcohol corresponding to mannose was first found in the dried exudation from the manna ash, Fravinus ornus, by Proust, in 1806, and is widely distributed in plants. It is contained in the sap of the laich, in monkshood, in the leaves of Syringa vulgaris, in celery, sugar cane, in fungi, where it exceeds dextrose in quantity or even replaces it Thus Lactarius pallidus, when dried, contains from 10 to 15 p c (Bourquelot, Compt rend 108, 568), and Agaricus integer is also a good source Kylin (Zeitsch physiol Chem 1913, 83, 171) has found it in several Fucus and Laminaria species It also occurs in the sap of French beans on keeping It is prepared from manna by extraction with boiling alcohol Mannitol is obtained on reducing mannose, Levulose, or dextrose with sodium amalgam. In many cases it seems to be a fermentation product derived from trehalose (Busolt, Chem Soc Abstr 1913, 803) Its formation may be avoided by preserving plant extracts under sterilised conditions

It crystallises in colourless thombic prisms, тр 166° 100 parts of water dissolve 15 parts at 16°, 100 parts of alcohol dissolve 0 07 part at 14°. It is optically mactive, but on the addition of boiax it becomes strongly dextro-rotatory, a mixture containing 10 p c mannitol and 8 p c borax having  $[a]_D + 225^\circ$ . This mixture With caustic soda and other is strongly acid alkalis it becomes levo-rotatory

Mannitol has a slightly sweet taste, is not fermentable by yeast, sorbose bacteria oxidise it to Levulose, and it is attacked by many other It does not reduce Fehling's solution, or races interact with phenylhydiazine

Mannitol is easily oxidised An in presence of platinum black forms mannosaccharic acid, and a mixture of mannose and Levulose, which is also formed with hydrogen peroxide and an iron salt. Bromine gives mainly Levulose. Nitric acid transforms it into mannosaccharic acid and finally into glycollic acid and oxalic acids.

Derivatives—On heating at 280°, mannitol is converted by loss of water into mannitan  $C_6H_{12}O_5$ , which is formed at 100° in presence of strong acids. The hexanitrate, also known as intromannitol  $C_6H_*(NO_3)_6$ , is prepared by the action of a mixtune of sulphuric and nitric acids; it forms colourless accular crystals, in p 112°-113°,  $[\alpha]_0+40$ °, which explode violently on being struck or when suddenly heated

The dichlorohydrin has m p  $174^{\circ}$ ,  $[\alpha]_{\rm D} - 3.75^{\circ}$ , and its tetranitiate forms slender needles, m p  $145^{\circ}$ . The hexacetate (Franchimont, Ber 12, 2059) separates from alcohol in orthorhombic crystals, m p  $119^{\circ}-120^{\circ}$ ,  $[\alpha]_{\rm D} + 18^{\circ}$  The hexacetate

benzoate has m p 149°

The tribenzylidene acetal crystallises in slender needles, insoluble in water, in p. 218°–222° (Fischer, Ber. 28, 1975). Triacetone manntol (Fischer, thid. 28, 1167) forms colourless prisms, in p. 68°–70°,  $[\alpha]_p+12.5$ °. It tastes bitter. Mannitol monoacetone, treated with benzoyl chloride and quinoline at 15° for five days, yields tetrabenzoylmanntol monoacetone, in p. 122°–123°, which hydrolyses partially to tetrabenzoylmannitol, in p. 122°–123°,  $[\alpha]_p+8$ ° (E. Fischer, Ber. 1915, 48, 266)

For the conversion of mannitol into methyl-

a-pyren

sec Windaus and Tomich (Chem. Zentr. 1918, n 109).

The anhydride mannitan exists in amorphous and crystalline modifications, the latter having m p 137°,  $\left[a\right]_{\rm D}-24^{\circ}$  A second anhydride is mannide  ${\rm C_6H_{10}O_4}$ , which exists in several forms One obtained by reducing the dichlorohydrin crystallises in slender needles or large prisms, m p 119°,  $\left[a\right]_{\rm D}+94^{\circ}$ ; iso-mannide produced by the dry distillation of mannitol in vacuó, forms prisms, m p 87°,  $\left[a\right]_{\rm D}+914^{\circ}$ 

$$\begin{array}{cccc} \textit{d-Sorbitol} \text{ or sorbit } \mathrm{C_6H_8(OH)_6} \\ & \text{OH H} & \text{OH OH} \\ \mathrm{CH_2OH-C-C-C-C-CH_2OH} \\ & \text{H} & \text{OH H} & \text{H} \end{array}$$

is the alcohol corresponding to dextrose, from which it is obtained on reduction with sodium amalgam in faintly alkaline solution. Sorbitol was discovered in mountain-ash berries by Boussingault (Compt rend 1872, 74, 939), and occurs in the fruits of a large number of plants belonging to the Rosaccæ. It was found as a crystalline network on the dried heads of the fungus Boletus bovinus (von Lippmann, Ber. 1912, 45, 3431)

It is prepared from the expressed juice of mountain ash berries, which is fermented to remove carbohydrate, defecated with basic lead ace ate, and concentrated to a syrup in vacuo.

This syrup is taken up with alcohol, and usually gives crystals of sorbitol. In other cases an equal weight of 50 pc. sulphuric acid, and a little less benzaldehyde is added, and the mixture agitated. After 24 hours it sets to a crystalline mass of dibenzylidene sorbitol. This is separated, washed, and decomposed by boiling with dilute sulphuric acid.

The benzaldehyde is removed by steam distillation, sulphuric acid by baryta, and the benzoic acid extracted by ether. The liquid is concentrated to a syrup, and inoculated with a crystal of sorbitol (Vincent and Delachanal, Compt. 1916, 147). This method permits of the separation of sorbitol in small quantities

from plants

Sorbitol crystallises with 1 mol  $H_2O$  in slender needles, mp 55°. The anhydride has mp 110°. It is very soluble in water, sparingly so m alcohol. It has  $[\alpha]_D - 17.3$ °, which becomes +1.4° in presence of borax. It is faintly sweet, non-fermentable, but is oxidised by B-xylinum to sorbose  $(q, \nu)$ .

The hexacetate has m p 99°. The dibenzylidene acetal as obtained above is a mixture of two isomerides, one of which has m p. 163°-164°

Triacetone sorbitol has m p 45°

Styracitol, a naturally occurring substance isolated by Asahina (Ber 1912, 45, 2363) from Styrax abassia, is isomeric with the anhydrosorbitol obtained by reduction and hydrolysis of anhydromethylglucoside (Fischer and Zachs Ber 1912, 45, 456, 2068). This suggests that such anhydrides of glucose and of glucoside occur in nature.

**Dulcitol.** Duloin, Dulcose, Melampyrite, Melampyrin

is the alcohol corresponding to galactose

Occurrence —Found m a manna or clude preparation from a bulbous root of unknown origin from Madagascar (Laurent, Annalen, 76, 358, Jacquelain, ibid. 80, 345, in Scrophularia nodosa and Rhinanthus Crista galli (Eichler, Ueb. d Melampyrin, Moscow, 1885), in Melampyrim nemorosum (Hunefeld, J. pr. Chem. 4, 233, Gilmer, Annalen, 123, 372), in Euonymus europæa (Kubel, P. Pharm Chim. 85, 372), and in dulcite manna (Hecht, Annalen, 165, 148)

Preparation—Dulcitol is prepared from the Madagascar material by extracting with boiling water and allowing the filtrate to crystallise. To prepare it from the plants above-mentioned, they are gathered at a suitable time and dired A decoction is made of them, rendered alkalino with milk of lime, boiled, filtered, concentrated, and acidified with hydrochloric acid. Dulcitol crystallises out on cooling. Dulcite manna is extracted with boiling alcohol, dulcitol crystallises from the solution filtered hot. The manna yields 72 p.c. dulcitol (Hecht).

Dulcitol may also be prepared by the reduction of galactose with sodium amalgam, the soda produced being from time to time neutralised with sulphuric acid. It is obtained mixed

with mannitol on reducing lactose.

Properties.—Dulcitol, both of natural and synthetical origin, crystallises in colourless, highly lustrous monoclinic prisms with octahedral summits The crystals are gritty between the teeth, and taste very faintly sweet, m p. 118° One part dulcitol dissolves in 34.41 parts water at 165°; it is but slightly soluble in alcohol, even at a boiling temperature. It is optically mactive, even in presence of borax, the denivatives are also mactive. Its solutions are not coloured brown by potash, nor do they reduce alkaline copper solutions. Nitrie acid oxidises it to mucic acid, oxalic and racemic acids are also produced (Carlet, Compt rend. 51, 137. 53, 343) Yeasts do not ferment it, but other organisms, such as exist in cheese, convert it, in presence of calcium carbonate, into alcohol, lactic, and butyric acids A saturated solution containing dulcitol and borax in the proportion of 2 mols dulcitol to 1 mol borax is neutral, but if the proportion of borax is less, the solution is strongly acid, when the proportion of borax is greater the solution is alkaline (dulcitol being neutral and borax slightly alkaline) A solution of a mixture of dulcitol and sodium paratungstate has an acid reaction after boiling (Klein, Compt. rend, 99, 144)

Dulcitol sublimes partially on careful heating, at 200° it gives off water, and is converted into dulcitan; at 275° it decomposes

Sodium, potassium, calcium, barium and

copper compounds exist

Neither lead acctate nor subacctate precipitates dulcitol, but a white precipitate is thrown down with an ammoniacal solution of acctate. This is an unstable lead compound

Dulcitol heated with hydriodic acid in an atmosphere of carbon dioxide yields hexyliodide,

water, and iodine.

The hexantrate is obtained by the action of fuming intrie and sulphuric acids on dulcitol it crystallises from alcohol in beautiful colourless flexible needles, which melt between 68° and 72°, and give off intrie acid vapours continually, being thereby converted into the tetranitrate. This latter is soluble in alcohol, from which it crystallises in translucent prisms, mp. 130°–140°, and decomposes at 145°.

Dulcitol forms with hydrochloric acid an unstable hydrochloride  $C_0H_{14}O_0$ - $HC_13H_2O$  Similar hydrobromides and hydroiodides exist, they are rather more stable (Bouchardat, Ann.

Chim Phys [4] 27, 145)

Dulcitol yields chloro- and bromo- hydrins  $C_6H_{12}O_4Cl_2$  crystallises in tables insoluble in water,  $C_6H_{12}O_4Br_2$  and  $C_6H_{12}O_4BrCl$  are of much the same nature. The corresponding dulcitan bodies  $C_6H_{11}O_4Cl$ , &c, exist. When these bodies are dissolved in fuming nitric or sulphuric acids, the corresponding tetranitrates are formed, as  $C_6H_8(l_2(NO_3)_4)$ , &c

With the acids of the fatty and aromatic groups, dulcitol forms a number of neutral compound ethers. Some of these are ethers of

dulcitol and some of dulcitan

The hexacetate forms hard crystalline plates, mp 171°; the hexabenzoate has mp. 147°, both are insoluble in water and ether, sparingly soluble in cold alcohol

The dibenzylidene acetal forms needles, mp 215°-220°. Dulcitol diacetone crystallises in prisms of bitter taste, mp. 98°.

Dulcitol diacetone, m p 98°, may be fractionally crystallised into . Dulcitol  $\alpha$ -diacetone, m p.  $145^{\circ}$ – $146^{\circ}$ ; and dulcitol  $\beta$ -diacetone, m p.  $113^{\circ}$ – $114^{\circ}$ 

The α- form, when treated with benzoyl chloride and quinoline at 15°, gives monobenzoylduleitol α-diacetone, an oil which, when shaken in chloroform solution with 5N/HCl, gives monobenzoylduleitol, in p 155°-156°.

If the benzoylation is conducted at 100°, the first product is dibenzoylduleitol a-diacetone, mp 185°-186°, which with 5 pc HCl in cold acetic acid gives dibenzoylduleitol, mp 210° (see

E Fischer, Ber 1915, 48, 266)

Perseitol  $C_7\Pi_{16}O_7$  was discovered in the fruits of Laurus persea, and occurs in Persea quatissima. It is identical with d-mannoheptitol, synthesised by Fischer (Ber 23, 930, 2226) by reducing the lactone of d-mannoheptonic acid. It crystallises in colourless slender needles, in p. 188°; dissolves slightly in cold water (6 parts per 100), readily in hot water, and is insoluble in absolute alcohol. It has  $[a]_D = 1.3^\circ$ , but becomes slightly dextro-rotatory in presence of borax.

Dilute nitile acid in the cold converts it into mannoheptose, the sorbose bacterium oxidises

it to a ketcheptose

The heptanitrate forms needles, m p 138°;

the heptaacetate has m p 119°.

The optical isomeride of persented has not been found naturally, but is prepared artificially from *l*-mannoheptose.

**Volemitol**  $C_7\dot{H}_{16}O_7$  was obtained by Bourquelot by extracting dired *Lactarius volemus* with alcohol. It crystallises in slightly sweet slender needles, in p. 151°–153°,  $[\alpha]_D+1$  92°, which is not altered on the addition of borax. The constitution is not yet determined

An octitol  ${}^{\prime}_{s}H_{1s}O_{8}$  was obtained by Vincent and Meunier (Compt' rend 127, 760) from the mother liquous of the sorbitol preparation from the fruit of some of the Rosacea. The syrup had  $[a]_{i}=3.42^{\circ}$ , the compound with benzaldehyde crystallised in slender needles, in p. 230°; an isomeride formed at the same time having in p. 140°.

#### THE DISACCHARIDES.

The disaccharides consist of two monosaccharides, united through an oxygen atom. One residue is fixed through the oxygen of the aldehyde group in just the same manner as is dextrose in the glucosides. In the second residue, the aldehyde or ketonic group may be still present, in which case the junction takes place through one of the alcohol groups, or it may have disappeared, being concerned in the junction. The disaccharides are accordingly of In the first type, in which the aldetwo types hyde group is present, they reduce cupric salts, and behave just as dextrose does. In the second type, all these properties are absent Most of the best-known disaccharides are derived from hexoses.

In establishing the structure of a disaccharide, three points demand attention: (1) the nature of the constituent hexoses; (2) whether it represents an a- or  $\beta$ -glucoside; (3) which hydroxyl- group is concerned in the attachment of the two hoxose residues. As a rule, they form no really characteristic derivatives, so that

their isolation and identification is far from easy. Those of Type I. contain, like dextrose, an aldehyde group or its equivalent, and since they exhibit muta-rotation and exist in two modifications, there is no doubt that, like dextrose, they possess a closed ring structure rather than a free aldehyde group. In solution, therefore, they exist as an equilibrated mixture of interconvertible isomerides. This is in agreement with their crystallising properties and in marked contrast to the carbohydrates of Type II, equivorose and trehalose, of which only one form exists, and which are characterised by crystallising readily.

Accordingly, both halves of the molecule possess a  $\gamma$ -oxidic structure, but only one section retains the aldehydic grouping potentially functional

The disaccharides are selectively hydrolysed by enzymes, and are attacked with very different degrees of readiness by mineral acids

Important conclusions as to their structure are based on this behaviour, for the full discussion of which reference should be made to The Simple Carbohydrates, by E. F. Armstrong, ch. v. and vi. (Longmans, 1919)

The following table gives a list of the di, tiland tetra-saccharides and their products of hydrolysis —

### DISACCHARIDES

Carbohydrate Components

Tune I Ald hade group motentially

Type V Aldehyde group, potentially functional

Maltose Dextrose-a-glucoside Dextrose-β-glucoside Isomaltose Gentiobiose Dextrose-\(\beta\)-glucoside Cellose Dextrose-\(\beta\)-glucoside Lactose Dextrose-\(\beta\)-galactoside Isolactose Dextrose-galactoside Melibiose Dextrose-galactoside Turanose Dextrose and Levulose Vicianose Dextrose and arabinose Galactobioses Galactose-galactosides

Type II. No reducing properties.

Sucrose Dextrose and Levulose Trehalose Dextrose (2 mols )
Glocoxylose Dextrose and xylose

TRISACCHARIDES.

Type I

Mannotriose Dextrose and galactose (2 mols) Rhamninose Dextrose and rhamnose (2 mols.)

Type II

Raffinose Galactose and dextrose and lævulose

Gentianose Dextrose (2 mols) and lævulose Melezitose Dextrose (2 mols) and lævulose

TETRASACCHARIDES

Type II.

Stachyose Lævulose and dextrose and galactose (2 mols)

Sucrose, Saccharose or cane sugar. The preparation and properties of this are dealt with under sugar, accordingly only the more theoretical aspects of its properties will be considered here In contrast to most of the sugars it crystallises

exceedingly well, this is almost certainly due to the fact that one substance only is present in solution, and not a mixture of isomerides lacks both aldehydic and ketonic properties, being without action on Fehling's solution Considerable difficulty has been experienced in ascribing a constitutional formula to sucrose which is entirely satisfactory. It is probably a derivative of α-glucose, but since it is not attacked by maltase, it is not a simple  $\alpha$ -glucoside. The methyl fructosides of the butylene oxide type are not attacked by invertase, and are far more stable to acids than sucrose. These facts are far more in agreement with the assumption that the fructose in the disaccharide has an ethylene oxide structure. and this is confirmed by the hydrolysis of octamethyl sucrose to tetramethyl glucose and tetramethyl fructose The former was of the stable butylene oxide type, the latter of the reactive ethylene oxide type

Sucrose may be formulated accordingly as

On hydrolysis of sucrose the following series of changes take place, the final products consisting of the equilibrium mixtures A and C together, probably, with a small proportion of B (cf. Hawoith and Law, Chem. Soc. Trans. 1916, 109, 1314)

Sucrose  $\rightarrow \alpha$ -glucose  $\rightarrow \alpha$ -fructose  $\rightleftharpoons \alpha$ -fructose

 $\begin{array}{c|cccc} & & & & & & & & & \\ & & & & & & & & \\ & \beta \text{-glucose} & & \beta \text{-fructose} & & \beta \text{-fructose} \\ & A & Butylene- & B & Ethylene- & C & Butylene- \\ & \text{oxide forms} & \text{oxide forms} & \text{oxide forms} \end{array}$ 

Sucrose contains eight hydroxyl groups, as evidenced by the formation of oetacetyl-, octanitro-, and octamethyl- derivatives. It forms saccharates  $C_{12}H_{21}O_{11}Na$  with sodium or potassium hydroxides, and more complex saccharates with lime, strontia and baryta

Lactose or milk sugar  $C_{12}H_{22}O_{11}$  was first separated from whey by Fabrice Bartoletti in 1619, and termed nitrum seri lactis. It is found in the milk of all mammals. Human milk contains from 5 to 8 p.c. of milk sugar, cow's and ewe's milk, from 4½ to 5 p.c.; mare's and ass's milk, about 6 to 7 p.c. It has not been found in plants

Lactose is hydrolysed by mineral acids to dextrose and galactose; it is a  $\beta$ -galactoside, that is, the active aldehyde group is in the dextrose residue. It is uncertain whether the primary alcohol group of the dextrose molecule takes part in the union with the galactose residue. Accordingly, lactose has one of the following formula:—

 $C_6H_{11}O_6$ — $O \cdot CH_2 \cdot CH(OH) \cdot CH[CH \cdot OH]_2 \cdot CH(OH)$ (1)

 $C_6H_{11}O_5$ —O·CH[CH $_2$ ·OH] CH[CH OH] $_2$  CHOH)

The following details of the manufacture of lactose from whey are given by Aufsberg (Chem Zeit. 1910, 34, 885). Cheese makers usually send their supply of whey to a central factory, where the lactose is separated. Before the whey is concentrated, it is heated and treated with

from 1 to 3 p.c of acid (whey vinegai), in order to coagulate any albuminous substances present. The whey is then concentrated at a temperature of from 60° to 70° under reduced pressure, until it contains about 60 pc. of total solids, the concentrated liquid is run into rectangular vessels, each holding about 700 lities and surrounded by a cold-water jacket, and after the lapse of 10 hours the thick liquid is stirred, this operation being repeated at intervals the end of 24 hours, the pasty mass is submitted to centuringal action, the crude, moist lactose amounting to about 3.85 p.e. of the weight of the original whey, a further quantity of crude lactose, amounting to about 0 5 p c, is obtained by evaporating the mother liquor and allowing it to crystallise The crude lactose is now refined by dissolving it in water so as to form a solution having a density of 13° to 15° B, adding to the solution a quantity of bone charcoal and about 0 2 p c of acetic acid, heating the mixture to 90°, then adding a small quantity of magnesium sulphate, and heating the whole to boiling The flocculent precipitate is removed by filtration, and the filtrate is evaporated by heating under reduced pressure until it has a density of 35° B. Crystallisation is then allowed to take place, and the crystals are separated The lactose thus obtained is again subjected to a similar refining treatment, the final yield of crystalline lactose being dried in a centrifugal machine supplied with a current of hot air The dry product, amounting to about 25 pc of the weight of the original whey, is then ground and sifted See also MILK SUGAR

Milk sugar is deposited from its aqueous solutions in hemihedral rhombic or monoclinic crystals. The crystals are white, semi-transparent, hard, and grate between the teeth, their sp gr is 1.53–1.54. They contain 1 molecule of water ( $\rm C_{12}H_{22}O_{11},H_{2}O$ ), which they retain at 100° over  $\rm H_{2}SO_{4}$ , but give up completely at 130°, leaving a colourless melted mass of anhydrous milk sugar, which solidifies in the crystalline state on cooling, and is strongly hygroscopic.

If a solution of milk sugar is evaporated to dryness on the water-bath, an anhydrous milk sugar remains behind, which is not hygroscopic

Hydrated milk sugar is slightly hygroscopic, soluble in 5 or 6 parts of cold or  $2\frac{1}{2}$  of boiling water, from the latter solution the crystals only separate out slowly on cooling. An aqueous solution saturated at  $10^{\circ}$  has a density of 1055, and contains 1455 p.c. of hydrated milk sugar; when lett to evaporate it begins to deposit crystals as soon as the density =1063, and the solution contains 2164 p.c. of sugar. It is insoluble in alcohol or ether.

According to Hudson (J. Amer. Chem Soc. 1908, 30, 1767), lactose hydrate crystalises from aqueous solution at the ordinary temperatures, whilst above 95° the  $\beta$ -anhydrous form separates Schmoeger, and later Hudson, have described three forms of lactose. The  $\alpha$ -hydrate  $[\alpha]_{\rm D}+86^{\circ}$  and the  $\beta$ -anhydride  $[\alpha]_{\rm H}+35^{\circ}$  both change in solution into the equilibrium mixture or  $\gamma$ -isomeride of constant rotatory power  $[\alpha]_{\rm D}+55^{\circ}$ . Lactose was the first carbohydrate of which more than one modification was observed, and the relauonship of these isomerides has been the

subject of much discussion (see v Lippmann, Chemie der Zuckeiaiten). It is to be explained in the same way as the muta-rotation of dextrose.

Lactose loses the water of crystallisation at  $130^{\circ}$  when heated, turns brown at  $160^{\circ}$ , begins to decompose at  $175^{\circ}$ , forming lactocaramel  $C_{12}H_{20}O_{10}$ , and melts at  $203^{\circ}$ 

On oxidation with biomine water, lacto-biomic acid,  $C_{12}H_{22}O_{12}$  is formed, and this is converted into galactose and gluconic acid, when hydrolysed by boiling with mineral acids, proving that lactose is a galactoside. Nitric acid first causes hydrolysis, and then forms mucie acid from the galactose, and saccharic acid from the dextrose. Take dextrose, lactose gives rise to two series of derivatives, corresponding to the  $\alpha$ - and  $\beta$ - forms of the sugar already mentioned. It contains 8 hydroxyl- groups, and therefore forms octacetates on heating with acetic anhydride and a dehydrating agent. These are colourless, crystalline substances, and well characterised. Other lower acetates are less definitely characterised.

Lactose octacetate may be converted into acetochlorolactose, and this into methyl lactoside, which crystallises in needles, in p. 171°. The octacetate, obtained by heating with acetic anhydride, crystallises in rectangular plates or needles, in p. 86° (Herzfeld), 98° (Kremann, Schmoeger), 106° (Fischer and Armstrong), according to the method of purification. It is obviously a mixture. Acetochlorolactose forms prisms, in p. 57°-59° (Fischer and Armstrong, Bei. 35, 841), [a]<sup>20</sup>+76·2°. The isomeride

forms prisms, m.p.  $118^{\circ}-120^{\circ}$ ,  $[a]_{D}^{20}+73.5^{\circ}$  (see also Bodart, Monatsh. 23, 1, Dittmar, ibid 23, 865)

On heating with phenylhydrazine, acetic acid and sodium chloride in a boiling water-bath for 1½ hours, phenyllactosazone  $C_{24}H_{32}O_{9}N_{4}$  is formed. This does not separate until the solution is cold, and is thus readily distinguished from phenylglucosazone. The yellow needles melt at 200°, and dissolve in 80 parts of boiling water. With very dilute sulphuir acid they form an anhydride  $C_{24}H_{30}O_{8}N_{4}$ , which melts at 223°–224°, and is almost insoluble in water (Fischer, Ber. 20, 830). The phenylhydrazine residues are eliminated by boiling with benzaldehyde, lactosone being formed:

# C<sub>6</sub>H<sub>11</sub>O<sub>5</sub> O CH<sub>2</sub> [CH OH]<sub>3</sub> CO CHO

This is obtained as a colourless syrup on concentration of the aqueous solution in a vacuum, and is similar in properties to glucosone

Lactose forms characteristic hydrazones with some of the substituted phenylhydrazines. The amylphenylhydrazone has mp 123°, allylphenylhydrazone, mp. 132°, benzovlphenylhydrazone, mp. 128°,  $\beta$ -naphthylhydrazone, mp. 203°. Lactal  $C_{20}H_{12}O_{9}$ , which is analogous to glucal from glucose, has mp 184°–186°,  $[\alpha]_{\rm D}+27^{\circ}$ .

Alkalis decompose lactose, giving a variety of products. Strong alkalis produce ultimately lactic acid; on fusion with potassium hydroxide, oxalic acid is formed. The prolonged action of lime results in the formation of saccharins  $(q\ v)$ 

Hydrolysis —Lactose is hydrolysed with difficulty by cold mineral acids, and resists even

boiling with weak organic acids. Towards sulphune acid it is 1240 times as stable as sucrose, and slightly more stable than maltose. Stronger acids hydrolyse it to dextrose and galactose, the optical rotatory power of the solution changing from  $+52^{\circ}$  to  $+68^{\circ}$ .

Lactose is also hydrolysed by an enzyme lactase (q v.) which is present in Kephir grains, in almonds, and in some yeasts. It is not fermented by yeasts, with the exception of a few torula (S fragilis, &c; see Armstrong, Proc Roy Soc 1905, 76 B, 600) which contain lactase It is more susceptible to bacterial attack, and readily undergoes lactic and butying acid fermentations

The synthesis of lactose has not been effected, but an isometide named provisionally iso-lactose, was obtained by Fischer and Armstrong by the synthetical action of Kephir lactase on a concentrated mixture of equal parts of galactose and dextrose. It was isolated as phenylisolactosazone A galactosidoglucose was prepared by the same workers from acetochlorogalactose, and shown to be probably identical with melibiose

Maltose C<sub>12</sub>H<sub>22</sub>O<sub>11</sub> was perhaps obtained from starch by De Saussure in 1819 · it was prepared by Vairy, who failed to recognise it as a distinct substance. Dubrunfaut, in 1847, further examined it and gave the name maltose, but regarded it as a trisaccharide O'Sullivan showed, in 1872, that it is a disaccharide, and gave a tuller description of its characters

Maltose is primarily a decomposition product of starch, and its occurrence in nature is mainly under conditions where it has been derived from Thus it is found in the leaves of plants, in germinating seeds, and in malt, &c abnormal conditions, it is found in the urine It is a constituent of commercial glucose. Its occurrence in the form of a glucoside is doubtful, amygdalin does not contain maltose, and it is

improbable that lotusin does

Starch is converted by the enzyme diastase first into dextims and then into maltose Diastase also acts on glycogen, forming maltose amongst other products. It is also obtained when starch is hydrolysed by acids workers have denied the presence of maltose amongst the products of acid hydrolysis, but Fernbach and Schoen (Bull Soc chim 1912, 11, 303) have completely identified it They regard the processes of hydrolysis of starch by diastase and by acids as essentially identical in the first

Preparation —Maltose is always prepared by the action of diastase, usually malt extract, on starch paste; its purification from the dextrins present, which are soluble in alcohol, is often a matter of difficulty. Baker and Day (But Ass Report, Dublin, 1908, 671) recommend the use of ungerminated barley diastase, which converts starch into maltose, about 60 p.c., and a-amylodextrin: this can easily be separated by one precipitation with alcohol Precipitated barley diastase is added to a 3 pc starch paste, and hydrolysis conducted at 50° for 5 or 6 hours, and subsequently in the cold. The solution is evaporated to a thin syrup and poured into 95 p.c. cold alcohol, so that the resulting strength is about 80 p.c. The a-amylodextrin is precipidistilled off the maltose syrup, seeded with a few crystals, and a little alcohol added few hours it sets to a solid magma of pure maltose. To purify it further the sugar is triturated with strong alcohol, filtered, dissolved in a little water, and poured into boiling 95 p c alcohol, again filtered and crystallised from the filtrate

When malt diatase is used, the procedure is similar, but the entire removal of admixed dextrins requires repeated purification. Maltose of this degree of purity separates readily

from strong aqueous solution

Properties.—Maltose crystallises from water in plates which contain C12H22O11,H2O, from alcohol (sp. gr. 0.810) it crystallises in crusts, and at times in cauliflower-like or waity aggregations which contain  $C_{12}H_{22}O_{11}$ . The hydrate casily parts with its water at  $100^\circ$  in a current of dry air. The anhydride is but slightly soluble in strong ethyl alcohol, it is more soluble in methyl alcohol The hydrate dissolves more freely in both solvents. Both bodies are very soluble in water, but less so than dextrose The solution is optically active, the activity being less when the solution is freshly prepared than after standing

The specific rotatory power for dry maltose is  $[a]_i = 154^{\circ} - 155^{\circ}$ ,  $[a]_D = 139^{\circ} - 140^{\circ}$  at 15.5° in solutions containing 10 grams per 100 c.c. and under (O'Sullivan, Chem Soc Trans. 35, 771, and 45, 5) Meissel (J. pr. Chem [2] 25, 114)

gives the formula

$$[a]_{D} = 140.375^{\circ} - 0.01837P - 0.095T$$

to represent the specific rotatory power of dry maltose at 0°, in which P=percentage of maltose in solution, and T the temperature of observation Brown, Morris, and Millar give +137 93° The value depends on the concentration as well as on the temperature The initial rotation is  $[a]_D = +119^{\circ}$ Brown and Moriis have shown that maltose is first formed in this low rotatory modification

Maltose reduces Fehling's solution, 100 parts being equivalent to 625 parts of dextrose (O'Sullivan), or 619 parts (Brown and Heron, Chem Soc Trans 1879, 35, 618) It is inactive towards cupric acetate (Barfoed's reagent). The density of a solution containing 10 grams maltose in 100 c c at 15 5° is 1 0393.

Maltose is hydrolysed on heating with mineral acids to two molecules of dextrose. Sulphuric acid at 80° attacks it 1.27 times as readily as lactose. The weaker organic acids are almost without effect except after prolonged

Bromine oxidises maltose to maltobioric acid (Fischer and Meyer, Ber. 22, 194) This has the formula C<sub>12</sub>H<sub>22</sub>O<sub>12</sub>, and is hydrolysed by mineral acids to dextrose and gluconic acid. The behaviour towards maltase classes maltose as dextrose-a-glucoside, and the following constitutional formula is provisionally applied .-

The compounds of Maltose.—The octonitrate tated and removed by filtration. The alcohol is (Will and Lenz', Ber 31, 68) crystallises in lustrous needles, m p.  $163^{\circ}-164^{\circ}$ ,  $[a]_{D}^{20}+128^{\circ}$ The octacetate exists in two isomeric forms. Prepared by heating maltose with acetic anhydride and sodium acetate, it has m p. 159°-160°,  $[a]_{\rm D}+63^{\circ}$  in chloroform The a-isomeride has m p. 125°,  $[\alpha]_p+122^\circ$  (Hudson and Johnson, J Amer. Chem. Soc 1915, 37, 1276)

 $\alpha$ - and  $\beta$ -heptacetylchloro- and -biomomaltose have been described (Fischer and Armstrong, Ber. 34, 2895, 35, 840; Foerg Monatsh.

23, 44),

a-Methyl maltoside (Foerg, ibid 23, 44) crystallises in slender plates, in p 125°-127°. β-Methyl maltoside (Fischer and Aimstiong, Ber 13, 34, 2895; Konig and Knorr, wid. 34, 4343) forms concentrically grouped needles, m p. 93°-95°,  $[a]_D^{20}+70^\circ$ .  $\beta$ - Phenyl maltoside, m p. 96°, and menthyl maltoside (Fischer, Ber 1910, 43, 2521), have also been described

The hydrazones are not characteristic.

The phenylosazone C24H32O9N4 is prepared by heating maltose with excess of phenylhydrazine and acetic acid for 11 hours on the waterbath. It separates after the solution has cooled (difference from dextrosephenylosazone) cording to Fischer (Ber. 17, 579; 20, 821) it crystallises in slender bright yellow needles and not in aggregates, having m p 206°, Ost (Chem Zeit 19, 1503) gives 202°–208°.

J. L. Baker states that the osazone prepared from his pure maltose had mp 195°, and consisted entirely of characteristic broad prisms, resembling ribbons in the microscopic field The stellate aggregates of crystals present in the osazone, from maltose containing traces of dextrm, were absent Maltosazone does not form an anhydride

Maltose-p-bromophenylosazone has m p. 198°. The p-mitrophenylosazone crystallises in ied needles, m p 261° (Hyde, Ber 32, 1815).

Maltose-p-diammobenzoie acid

$$C_6H_3(CO_2H) \underbrace{\begin{array}{c} NH \\ NH \\ \end{array}} C_{12}H_{20}O_{10}$$

is formed in small quantities on prolonged boiling of concentrated solutions of the components. It crystallises anhydrous in plates, in p 235°, or hydrated with 1 mol,  $\rm H_2O$  in needles. The metallic compounds of maltose are amorphous and ill-characterised. It does not form double salts with the alkali chlorides.

Fermentation —Maltose is fermented only after hydrolysis to dearrose. This hydrolysis is effected by maltase, which is present in most yeasts but absent in S. Ludwigu, S. Marxianus, S. eviquus, S membranæfactens, some forms of S. anomalus, W. saturnus, and many others. Accordingly, these yeasts do not ferment maltose. Maltose is also fermented by most moulds, and readily undergoes lactic and butyric acid fermentation

Synthesis -- Maltose is perhaps formed to-gether with isomaltose by the action of concentrated hydrochloric acid on dextrose. It is also formed by the action of emulsin on concentrated solutions of dextrose (E F Armstrong, Proc Roy. Soc 1905, 76 B, 592) In each case, however, only amorphous or syrupy products could be obtained.

Isomaltose (Revertose, Gallisin) was obtained and repeatedly crystallised from 95 p.c. alconol Vol II -T

by Fischer (Ber. 23, 3024, 3687) by the action of 400 grams of cold concentrated hydrochloric acid on dextrose (100 grams) at 10°-15°. It is a viscid syrup,  $[a]_D + 70^\circ$ , and characterised by being non-fermentable and forming a crystalline phenylosazone, mp from 140° to 155° (Fischer),

according to the purity.

Scheibler and Mittelmeier (Bei 23, 3075) claimed that the gallism of Schmitt and Cobenzl (Ber 17. 1000, 2456) consists mainly isomaltose.

Gallisin is found in commercial glucose may be obtained as a white amorphous deliquescent powder, by treating the unfermentable syrup, after evaporation, with absolute alcohol, and finally with ether alcohol. It has a slightly sweet taste; is insoluble in ether, slightly soluble in absolute ethyl alcohol, more easily soluble in methyl alcohol and acetic acid. It reduces silver nitrate, and Fehling's solution, the cupric reducing power of 10 98 grams-that of 5 giams of glucose. It gives no precipitates with solution of lead acetate, mercuin chloride, ferric chloride, or barium chloride. On boiling with dilute acids it is converted into dextrose

Subsequently, a large number of products obtained in the hydrolysis of starch or of glycogen have been stated to be identical with isomaltose, but, failing any characteristic derivative, definite proof of its presence in such cases is lacking (v Lippmann's Chemie der Zuckeiarten) It is possible that gallisin and most of these products represent dextrins of low molecular weights or admixtures of these with maltose

By the action of maltase on a concentrated solution of dextrose, Croft Hill (Chem Soc. Trans 1903, 83, 578) has obtained a disaccharide which he terms Revertose Possibly this is

identical with isomaltose

By a similar process, E F Armstrong (Proc. Roy Soc 1905, 76, B, 592) has obtained an asomaltose which, like that obtained by the action of acids, is hydrolysed by emulsin isoMaltose is not attacked by maltase, and the behaviour towards enzymes suggests that it is dextrose-\(\beta\)-glucoside

According to Gatterbauer (Zeitsch. Nahr. Genussm 1911, 22, 265), the difficultly fermentable part of starch-syrup, formerly termed gallisin, consists of a new carbohydrate glucosin and small amounts of maltose, dextrins are

not present

Glucosin is isomeric but not identical with maltose, it is a yellowish-white powder, hydrolysed with difficulty by beer-yeast, more readily by yeast maltase or emulsin, to glucose

Dilute mineral acids give glucose, with concentrated mineral acids the reaction is reversible The phenylosazone melts at 97°-100°, the p-nitrophenylosazone at 240°

Cellose (Cellobrose) is prepared by hydrolysis of the octacetate formed by the action of acetic

anhydride on filter paper

To prepare the octacetate C<sub>12</sub>H<sub>14</sub>O<sub>11</sub>(OC<sub>2</sub>H<sub>3</sub>)<sub>8</sub>, 7 5 grams of finely divided filter paper are shaken with 20 c c acetic anhydride, the mixture cooled to 70°, and at this temperature a mixture of 7 c c acetic anhydride and 4 c.c. concentrated sulphuric acid is added. The temperature rises to 110°, the product is poured into 500 c c water, and the amorphous acetate collected, washed,

in colourless needles, m p 228°

Five grams are moistened with alcohol and hydrolysed with 15 pc alcoholic potassium hydroxide. A granular powder separates is dissolved in a little water, excess of alkali neutralised with acetic acid, and the solution evaporated to a syrup, which, after treatment with absolute alcohol and inoculation with a crystal, ultimately yields cellose as a colourless microcrystalline powder It tastes faintly sweet, dissolves in 8 parts of cold and 15 parts of hot water, and reduces Fehling's solution It has  $[\alpha]_D^{20}$  about  $+25^\circ$  when freshly dissolved, increasing to  $+35\,0^\circ$ . It is not fermentable, acids hydrolyse it to 2 molecules of dextrose, as also does the emulsin of almonds

The phenylosazone forms long yellow needles, m p.  $208^{\circ}-210^{\circ}$ ,  $[\alpha]_{D}-17.5^{\circ}$ , soluble in

135 parts of boiling water

Hudson and Johnson (J Amer Chem Soc 1915, 37, 1276) consider that cellose is composed of two glucose residues united similarly to the glucose and galactose residues in lactose. They quote an a-octacetate, mp 229°, [a], -|-42°, and a \$-octacetate prepared with acetic anhydride and sodium acetate, mp 202', [a] -15° On reduction of ocetobromocellose with zinc and acetic acid and hydrolysis of the acetyl derivative cellobial is obtained, in p 175°-176°, [a]<sub>D</sub>+1° Emulsin hydrolyses this to glucose and hydroglucal (Fischer and Fodor, Ber 1914, 47, 2057)

Hudson and Dale ( $l\epsilon$ ) give the specific iotation in water of the a- and B- forms of cellose as +72 0° and + 16 0° respectively

Gentiobiose is obtained by the action of invertase or of very dilute acids on the tri-saccharide gentianose. It may be prepared from old gentian roots in which this hydrolysis has already taken place by extraction with water and removal of the Levulose by fermentation with top-fermentation yeast separates from alcohol in anhydrous crystals, mp 190°-195°. It exhibits muta-rotation, the initial value for  $[\mathfrak{a}]_{D}^{20}$  being  $+9.6^{\circ}$  It is not fermented by yeast Emulsin, derived either from almonds or Aspergillus niger, hydrolyses it to dextrose The phenylosazone has mp

The  $\beta$ -octacetate, m p 195°,  $[\alpha]_D$ -6°, crystallises well, and may be used to isolate gentiobiose from gentian roots or other plant products The phenylosazone crystallises in stellate needles, in p  $160^{\circ}$ - $170^{\circ}$ , [a]<sub>D</sub>- $76^{\circ}$ . An isomeride obtained on heating this with acetic anhydride and zinc chloride has m.p.  $188^{\circ}-189^{\circ}$ ,  $[\alpha]_{D}+52^{\circ}$ .

Melibiose was first obtained, together with lævulose, by the partial hydrolysis of raffinose (Scheibler and Mittelmeier, Ber 22, 1678, 23, 1438); this may be effected by dilute acids of certain bottom-fermentation years. Bau gives the following methods of preparation

20 grams of raffinose in 250 cc water are sterilised and fermented for 1 day at 30° with a pure culture of a top-fermentation yeast The filtrate is sterilised and fermented during several days with a further portion of the yeast. It is

or from ethylacetate It is ultimately obtained then concentrated, poured into hot alcohol, and, after cooling, precipitated with ether syrup, after further treatment with alcohol and inoculation, crystallises with difficulty after

Alternatively, 20 pc solutions of raffinose are hydrolysed by boiling with 2 pc acetic acid, and concentrated to a syrup in a porcelain vessel. This is rubbed with 2 vols of 95 p c alcohol, the alcohol decanted, and ether added till a cloud appears After 2 days, this solution is decanted from any precipitate, inoculated with a few crystals, and set aside in closed vessels

Melibiose hydrate C<sub>12</sub>H<sub>22</sub>O<sub>11</sub>,2H<sub>2</sub>O forms doubly refractive monoclinic plates:

[a b  $c=1.19227.20124, \beta=7716^{\circ}$ ]

m p 84°-85° The hydrate has  $\left[\alpha\right]_{D}^{20} + 129.5^{\circ}$ as stable value, and shows muta-rotation, the ınıtıal value, 5 minutes after solution, being The anhydride has  $\left[\alpha\right]_{D}^{20}+143^{\circ}$ very soluble in water, sparingly so in ethyl alcohol Strong acids hydrolyse it to dextrose and galactose it is slightly more resistant than lactose It is very sensible to traces of alkali It is reduced by sodium amalgam to melibiositol, a syrup which is hydrolysed to galactose and mannitol. It is attacked by bottom- and not by top-fermentation yeasts, and thus affords a means of distinguishing between these two varieties of yeast. The former variety contains the enzyme melibiase. It is slowly hydrolysed by emulsin

The following derivatives are known phenylhydrazone, light-yellow needles, m p 145°, allylphenylhydrazone, m.p. 197°; 8-naphthylhydrazone, m.p. 135°, phenylosazone, yellow needles from toluene, m.p. 178°–179°. This dissolves in 110 parts of boiling water, and interacts with benzaldehyde to form melibiosone The p-bromophenylosazone has mp 181°-182° The octacetate by  $\left[\alpha\right]_{D}+102^{\circ}$ 

Melibiose was the first natural disaccharide to be obtained synthetically (Fischer and Armstrong, Ber 35, 3144) It was prepared by the interaction of acetochlorogalactose with dex-

Trehalose (mycose, trehalabiose) was originally discovered in ergot, and has since been proved to be very widely distributed in fungi (Bourquelot) It apparently replaces sucrose in those plants which contain no chlorophyll and do not manufacture starch. Trehalose was found in 142 out of 212 species investigated, but only in certain parts of the fungus and at certain stages of the vegetative period. The quantity is a maximum just before the formation of spores When fungi are picked, trehalose is rapidly converted into mannitol, and after a few The trehala hours it has entirely disappeared manna from Syria and Persia is stated to contain 20 pc of trehalose. To prepare trehalose, suitable fungi (particularly Agaricus and Boletus species) are boiled with much strong alcohol immediately after picking. It was found as an incrustation on flowers of Carex brunescens (flowering rush) after a sudden sharp July frost (von Lippmann, Ber. 1912, 45, 3431).

Trehalose  $C_{12}H_{23}O_{11}$ ,  $2H_2O$  crystallises in lustrous glass-like rhombic prisms

[ $a \cdot b : c = 0.6814 \cdot 1.04171$ ;  $\beta = 1111^{\circ} 31'$ ] m p. 97°. It becomes anhydrous at 130°. It has  $[a]_{\rm b}^{20} + 178^{\circ}$  for the hydrate and  $+197^{\circ}$  for the anhydride, without any muta-rotation Acids hydrolyse it to 2 molecules of dextrose, but according to Winterstein, only with considerable difficulty, and it contrasts markedly in this respect with sucrose

It does not reduce Fehling's solution or form a phenylosazone, and has the formula

It is not hydrolysed by invertase and most enzymes, but is affected by a special enzyme, named trehalase, present in most fungi, moulds, and some yeasts, and conveniently prepared from Aspergillus inger. Accordingly, trehalose is fermented by those yeasts which contain trehalase. It forms few derivatives the octanitrate has m.p.  $124^{\circ}$ ,  $|\alpha|_{\rm p}^{18}+173.8^{\circ}$ ; the octacetate has m.p.  $97^{\circ}$ ,  $|\alpha|_{\rm p}^{1}+162^{\circ}$ , the tetrabenzoate, m.p.  $81^{\circ}-83^{\circ}$ 

Turanose  ${\rm C}_{12}{\rm H}_{22}{\rm O}_{11}$  is obtained from the trisaccharide melezitose, together with dextrose on hydrolysis with 20 p c acetic and solution. The dextrose is destroyed by yeast, and the turanose isolated from an alcoholic extract of the residue in transparent non-crystalline rounded grains of the composition.

They melt at  $60^{\circ}$ - $65^{\circ}$ , lose their alcohol at  $100^{\circ}$  and yield the pure sugar  $[\alpha]_{\rm p}$ + 7.18° without muta-rotation (Taniet, Compt. rend. 1906, 142, 1424)

Turanose has a reducing power of 60 (dextrose—100), and is hydrolysed by mineral acids to an equal molecular mixture of dextrose and levulose, and not to dextrose only, as originally stated by Alekin (Ann Chim Phys [6] 18, 532) Invertase, maltase, emulsin, and diastase are without action. The phenylosazone has mp. 215°-220° (Fischer, Ber. 27, 2486). It thus differs from sucrose in containing a free aldehydic group.

# OTHER LESS-KNOWN DISACCHARIDES.

Glucoapiose  $C_{11}H_{20}O_{10}$  is contained in the glucoside apin. It has not yet been isolated, as hydrolysis of apin by dilute acids yields only apiose and gluco-apigenin, and enzymes are without action

Galacto-arabinose was obtained by Ruff and Ollendorf (Ber 32, 352, 33, 1806) by oxidation of lactobionic acid from lactose—It is a dextrototatory syrut, the phenylosazone has m. p. 238°

10tatory syrup—the phenylosazone has mp 238° Glucoxylose. By hydrolysis of the glucoside dihenzoylglucoxylose, occurring in Daviesta latifolia, the carbohydrate glucoxylose  $C_{11}H_{20}O_{10}$ , is produced as an amorphous horny mass, very soluble in water (Power and Salway, Chem Soc Trans 1914, 105, 767, 1062)—It has  $\left[\alpha\right]_{\rm D}$ -36°, does not reduce Fehling's solution, and does not

give an osazone  $\,$  Acid hydrolysis yields glucose and xylose. Its constitution is therefore given as —

Strophantobiose  $C_{12}H_{22}O_{10}$  is obtained in the form of the methyl-derivative from the glucoside strophantin (Fiest, Ber. 31, 535, 33, 2063, 2069, 2091). It forms colourless crystals, in p. 207°, does not reduce Fehling, and is not fermentable. Acids hydrolyse it to mannose, thamnose, and methyl alcohol.

Vicianose  $C_{11}H_{20}O_{10}$  is prepared by Bertrand and Weisweiller (Compt. 1end. 1910, 150, 180) by hydrolysing the glucoside in the seeds of Vicia angustifolia by the enzyme occurring in them. It crystallises in aggregates of small needles, in purpose about 210°, has  $\lfloor a_{\rm D}^{20} \rfloor + 39.7$ °, the initial value being much higher. It reduces Fehling, and is converted into dextrose and arabinose on hydrolysis

Diglucose from amygdalin When amygdalin is hydrolysed by the digestive junce of Helix pomatia, the first product is a biose obtained as an amorphous powder. This is nonferimentable, and does not reduce Fehling solution. It probably has a constitution resembling that of trehalose (Giaja, Compt. rend 1910, 150, 793–796)

### TRISACCHARIDES

Mannotriose  $C_{18}H_{32}O_{16}$  is obtained by the action of either invertase or acetic acid on mannotetrose (stachyose). It is a colourless, faintly sweet crystalline substance, in p. 150°  $[\alpha]_{\rm b}+167^{\circ}$ . It reduces Fehling's solution Bromine oxidises it to mannotrionic acid, which is hydrolysed on warming with acids to 2 molsid-galactose and 1 mol gluconic acid. It is slowly hydrolysed by emulsin and by some yeasts, and is then ferimented, but whether completely so is not known.

The phenylosazone has mp 192°-194°, according to Neuberg, and 122° as given by Tamet Bierry (Compt rend 1911, 152, 465) confirms mp 122°-124°

Rhamniñose  $C_{18}H_{34}O_{14}$  is only obtained from the glucoside xanthorhammin present in the Persian berry (Rhamnus infectoria). In addition to the glucoside, the fruits contain an enzyme, termed rhamnunase, which hydrolyses it to the trisaccharide and rhamnetin. Rhamninose forms colourless crystals of faintly sweet taste, in p. 135°–140°,  $\lceil \alpha \rceil_D - 41^\circ$ , it reduces Fehling's solution. Acids hydrolyse it to galactose and 2 molecules of rhamnose. Sodium amalgam reduces it to the alcohol rhamnintol  $\lceil \alpha \rceil_D - 57^\circ$ , which is hydrolysed by acids to dulettol and 2 molecules of rhamnose. Bromine oxides it to rhamninome acid  $C_{18}H_{32}O_{15}$ , which is obtained, mixed with its lactone, as an amorphous substance; in p. 125°,  $\lceil \alpha \rceil_D - 94$  3°. It is hydrolysed to d-galactonic acid and rhamnose.

This behaviour points to the two rhamnose residues being united in the trisaccharide, but this disaccharide has not been isolated. Rhamninose

is not fermentable, and enzymes are without The octacetate has m p. 95°, [a]<sub>p</sub>-31°. action

Gentianose C<sub>18</sub>H<sub>32</sub>O<sub>16</sub> is found in the roots of a number of gentians, from which it is prepared by extracting the fresh roots with 95 p c alcohol It crystallises in colourless plates, m.p.  $209^{\circ}$ – $210^{\circ}$ , tastes faintly sweet, and has  $[a]_{\rm D}+31\cdot2^{\circ}$  to  $+33\cdot4^{\circ}$ .

It does not reduce Fehling's solution, but is hydrolysed by acids to lævulose and 2 molecules of dextrose, the final product having  $[a]_D-20$  2°. The enzyme invertase hydrolyses it to levulose and the disacchande gentiobiose, that of Aspergillus niger converts it into dextrose and sucrose.

Raffinose (also termed melitose, gossypose, melitriose) C<sub>18</sub>H<sub>12</sub>O<sub>16</sub> was first discovered by Johnston in 1843, in the manna from Eucalyptus mannifera, found in Tasmania. It is often found in considerable amount in the sugar beet, where it was discovered by Loiseau, Ritthausen found it in cotton-seed cake, it is also present in wheat and in oats To prepare raffinose from molasses, strontium oxide is added until a molecule is present for every molecule of sucrose After some hours, the strontium saccharate formed is separated by filtration and the liquid heated with excess of strontia, whereby the raftmose distrontionate is precipitated. The raffinose distrontionate is precipitated strontia compound is decomposed by carbon dioxide, the solution concentrated, and the process repeated to remove most of the sucrose The syrup finally obtained is dissolved in hot alcohol, the product which separates on cooling is kept under alcohol in a closed vessel, when raffinose slowly crystallises

According to Hudson and Harding (J Amer Chem Soc 1914, 36, 2110), cotton-seed meal is extracted with water, and, after purification, the solution is evaporated and barium hydrate added. The barium raffinate is powdered and washed with methyl alcohol The barium compound is suspended in water and decomposed with the exact amount of 50 pc phosphoric acid. The filtrate is completely freed from barium by sulphuric acid, and concentrated in a vacuum, seeded with inflinose hydrate and left to crystallise The yield is 4-5 pc of the weight of cotton-seed meal employed

Raffinose forms small needles, soluble in 6 parts of water at 16°, it is less soluble in ethyl alcohol than sucrose It is difficult to recognise when it crystallises with sucrose The hydrate melts at 80°, the anhydrous forms at 118°-119° The optical rotatory power [a]<sub>D</sub> is +104° without muta-rotation It has no reducing action, and behaves exactly as sucrose Dilute mineral acids hydrolyse it to levulose and melibose strong acids yield a molecule each of lævulose, dextrose, and galactose Invertase converts it into lævulose and melibiose, emulsin hydrolyses it to sucrose and galactose Accordingly, the formula is established as.

$$\begin{array}{c} C_6H_{11}O_5 - O - C_6H_{10}O_4 - O - C_6H_{11}O_5 \\ \text{Lee vulose} & \underline{Dextrose} & \underline{\textbf{Melbiose}} \end{array}$$

The undeca-acetyl derivative has mp 100°,  $[\alpha]_D + 92^\circ$ 

closely related sugars may be effected by means of selected enzymes For details of the method, see Davis (J Soc Chem Ind 1915, 35, 201)

Melezitose (melicitose) C<sub>18</sub>H<sub>32</sub>O<sub>16</sub>'2H<sub>2</sub>O, is

found in Briancon manna, which is obtained as an exudation from the young twigs of the larch (Abies tarix; Fi Mélèze) The manna from the Douglas fir consists mainly of melezitose (Hudson and Sherwood, J. Amer. Chem. Soc 1918, 40, 1456) It was investigated by Berthelot (Ann (him Phys [3] 55, 282) and by Alekhine (ibid [6] 18, 532). It is found also in turanibin or terenjabine, an exudation from Alhagi maurorum, growing in Afghanistan, Persia, and in the deserts of the East, and used in Northern India as a laxative (Villiers, ibid. [5] 12, 43) This substance is a brown, semisolid mass, of a slightly sweet taste, due mainly to the presence of dextrose. To obtain melezitose from this product it is treated with four times its weight of lukewaim water, and the liquid passed through a sieve to separate husks, leaves, &c, and after standing to allow of the deposition of earthy matter, it is evaporated to half its bulk. On standing for a few days, the greater part of the melezitose crystallises out The crystals are redissolved in twice their weight of hot water, the solution heated on the waterbath, diluted with its own volume of alcohol, heated to boiling to separate carthy and coagulable matter, and filtered whilst hot On cooling, melezitose separates out and may be obtained pure by two or three recrystallisations It forms large rhombohedral prisms

 $C_{18}H_{32}O_{16}, 2H_{2}O$ 

which effloresce in an and become opaque, they lose the whole of their water at 110°. Dehydrated melezitose has mp 148°-150°, 100 pts of water dissolve of anhydrous melezitose 26.8 pts at  $17.5^{\circ}$ , 34.4 pts at  $25^{\circ}$ , 75.6 pts at  $100^{\circ}$ , sparingly soluble in alcohol, insoluble in ether. The rotatory power is  $[a]_D + 88.5^{\circ}$ . Melezitose yields no crystalline compounds with alkaline chlorides. On boiling with dilute sulphuric acid it yields turanose and dextrose, the iotation falling to +63°. It has no action on an alkaline solution of copper, and is unchanged by diastase or yeast - Nitric acid transforms it into oxalic acid without the intermediate formation of mucic acid. It does not interact The undeca-acetate with phenyl hydrazine  $C_{18}\Pi_{21}O_{16}(OC_2H_3)_{11}$  crystallises in shining monoclinic prisms, m p  $170^{\circ}$ ,  $[a]_{D}^{20} + 110 4^{\circ}$ .

Stachyose (Mannotetrose, Lupcose) C24H42O21 was discovered by Schulze and Planta in the tubers of Stachys tubifera, and thought to be a trisaccharide. Tanret obtained it from ash manna, and termed it mannotetrose It has also been found in the twigs of white jasmine and in the subterranean parts of Lamium album. It constitutes from 60-75 p c. of the dry matter of the stachys tubers The tetrahydrate crystal lises in lustrous hard doubly refractive colourless plates (a b c=1.0512.1.0.4213,  $\gamma=90^{\circ} 46'$ ). It tastes quite sweet and dissolves at 13° in 0.75 part of water. The anhydride has m.p.  $167^{\circ}$ – $170^{\circ}$ ,  $[a]_{D}+148^{\circ}$ , without muta-rotation; the hydrate has [a]<sub>D</sub>+133°.

Stachyose is not acted on by Fehling's solu-The analysis of rafinose in admixture with tion or by alkalis. Acetic acid hydrolyses it

Sulphuric acid to lævulose and mannotriose. converts it into 4 monosaccharides, viz.: 1 molecule lavulose, 1 molecule dextrose, 2 molecules galactose. By the action of nitric acid, about 38 pc of mucic acid is formed Invertase hydrolyses it to levulose and mannotriose, which latter is slowly attacked by the emulsin of almonds or of Aspergillus niger

According to recent work of Schulze, stachyose is probably identical with the carbohydrate lupeose, present in Lupinus luteus and angustifolius, as lupeose has  $[a]_{D}+148^{\circ}$ , and gives the

same products on hydrolysis

Neuberg (Brochem Zeitsch 1910, 24, 173) prepares it by pressing the juice from the tubers, precipitating impurities with mercuric acetate, removal of the metal by hydrogen sulphide, neutralisation with ammonia, and concentration to a syrup, which is precipitated with alcohol The precipitate is dissolved in water, impurities precipitated with phosphotungstic acid, and the filtrate concentrated Barium hydroxide and alcohol are added alternatively After 24 hours, the barrum salt is collected, washed with alcohol, and decomposed by carbon dioxide. Reducing sugars are removed by this treatment and the stachyose readily crystallises

Polyamyloses have been obtained from potato starch paste by the action of Bacillus Macerans (Schardinger, Chem Soc Absti 1912, i 181, Pringsheim and Langhans, Ber 1912, 45, 2533) Tetra-amylose  $(C_6H_{10}O_5)_4$  or a-dextrin crystallises in colourless hexagonal plates,  $[\alpha]_D + 128^\circ$ , hexa-amylose or  $\beta$ -dextrin forms rhombic crystals,  $\lceil \alpha \rceil_D + 136^\circ$ On acetylation hydrolysis of the dextrins takes place, and from the acetyl derivatives formed diamylose and triamylose were obtained These crystallise in needles, and do not reduce Fehling's solution Rice starch gives similar definite polyamyloses on degradation (Pringsheim, Ber 1914, 47, 2565)

## Polysaccharides.

Glycogen  $(C_6H_{10}O_5)n$ , the reserve carbohydrate of the animal organism in which it appears to take the place of statch, is a regular constituent of all developing cells It is present in the liver up to 10 p c and in muscle

Preparation -Liver is finely minced and thrown into boiling water acidified with acetic The coagulated proteins are filtered off, and the remaining proteins precipitated from the filtrate with trichloracetic acid or potassium mercuric iodide (Brucke's reagent) Glycogen is precipitated from the filtrate with alcohol

Fresh finely minced liver is extracted for 2 hours with boiling 60 p c potassium hydroxide An equal volume of 95 pc alcohol is added to the clear filtrate, containing 15 pc KOH, and the precipitated glycogen washed with a mixture of 15 pc KOH and 2 vols of 95 pc alcohol.

It is purified in either case by solution and reprecipitation with alcohol, and obtained as an amorphous snow-white powder [a]<sub>p</sub>+191°, soluble in cold water, giving an opalescent solution. It is not fermentable, does not reduce Fehling's solution, and is not acted on by alkali, even by concentrated solutions at the boiling-With iodine it gives a brown-red colouration. Acids hydrolyse it ultimately to dextrose, but dextrins and maltose are formed as intermediate products Diastase derived from either plants or animals also converts it into dextrins and maltose (see Tebb, Journ. of Physiol 1898, 22, 423)

Glycogen may be obtained from yeast free from nitrogen, yeast-gum, and ash (Harden and Young, Chem Soc Trans 1912, 101, 1928) The crude preparation from yeast is freed from nitrogen and ash by repeated solution in water and reprecipitating with alcohol, the yeast-gum is removed by dissolving the crude glycogen in water and saturating with ammonium sulphate The last traces of ash are removed several times by several reprecipitations from water by alcohol

To estimate glycogen, the tissue is minced and boiled 2-3 hours with 30 pc potassium hydroxide The solution is diluted, filtered, and precipitated with alcohol The glycogen is again dissolved in dilute alkali and precipitated with alcohol Finally it is dissolved in water and estimated by hydrolysis with acids into dextrose (1 part = 0 927 part glycogen) or with the polarimeter

A 5 pc solution of sterilised glycogen treated with a potato culture of Bacillus macerans at 37° C, gave two crystalline cyclic polysaccharides (dextrin-\$\beta\$- or \$\beta\$-hexa-amylose (25 p c) and dextrin-a- or tetra-amylose (75 p c)) See Pringsheim and Lichtenstein, Ber 1916, 49,

Inulin. Inulin is widely distributed as a reserve material in plants having tubers or tuberous or fleshy roots, particularly in the antumn in dahlia tubers, Jerusilem artichoke chicory, garlie, onions, and other plants and bulbs

To prepare it, a mash is made of the ripe tubers, a little calcium carbonate is added, and the mixture extracted with boiling water filtrate is frozen and the sediment which separates dissolved in hot water and again frozen. Tanret advises precipitation with barium hydroxide, decomposition of this precipitate with carbon dioxide and subsequent precipitation with 95 p c. alcohol

Inulin, precipitated by alcohol, is a compact powder, resembling starch colourless molecular composition is uncertain, as the ordinary methods do not yield trustworthy results Kiliani gives  $(C_6H_{10}O_5)_6, H_2O$ , Brown and Morris,  $(C_6H_{10}O_5)_{12}, 2H_2O$ , Dull,  $(C_6H_{10}O_5)_{18}, H_2O$ , Tantet,  $(C_6H_{10}O_5)_{10}, 5H_2O$  It melts at 178°, having  $[a]_D-38^\circ$  to  $-40^\circ$ , sp gr In cold water it is sparingly soluble, but very soluble in hot water, and readily forms supersaturated solutions. It is precipitated by alcohol, when the percentage of alcohol in the liquid reaches 65.

The barium salt C<sub>36</sub>H<sub>62</sub>O<sub>31</sub>·3BaO (Tanret, Compt rend 116, 415) is insoluble

Inulin is hydrolysed by boiling the aqueous solution under pressure, by dilute acids, and also by the enzyme mulase, discovered by Reynolds Green, which is usually present in the same plant when in the germinating condition, but mert in the resting stage. In every case, levulose is the sole product of hydrolysis. Yeasts are without action

A number of products are described as

Levulins and Levulans, which probably represent polymerides of Levulose of lower molecular weight than inulin

Manna is the dried saccharine exudation from the stem of the flowering ash Frazinus ornus and F. rotundifolia, small trees cultivated for the purpose in Sicily A vertical series of oblique incisions is made in the bark when the trees are about 10 years old, the nuce slowly exudes and either dries on the stem (flake manna) or in wet seasons drops from the trunk, where it is caught upon tiles of cactus leaves, yielding an inferior variety. Flake manna is obtained in commerce in brittle stalactitic pieces, about 4-6 inches long and I inch wide It is yellowishwhite in colour, has a slight agreeable odour and a sweet taste It is used as a gentle laxative for infants and children

It consists principally of mannitol (70-80 p.c.) other constituents are mannotetrose (12-16 p.c.), mannotriose (6-16 p.c.) which is formed from mannotetrose, and small quantities of hexoses

The term is not restricted to the ash, and a number of saccharine exudations of varying origin and composition are classed as 'mannas' Amongst these are the Persian and Turkestan manna, derived from Alhagi mauroium of camelorum, the tamarisk manna, also of Persian origin, from the Tamaric gallica, oak manna, procured from Quercus valonia and Quercus persicus in Kuidistan, Australian manna, Eucalyptus viminalis, Briançon manna, from the larch, Larre europæa in Southern France, Astragalus manna, from various species of astragalus in Persia

Authorities -E von Lippmann, Die Chemie der Zuckerarten, 3rd ed 1904, L Maquenne, Les Sucres et leurs principaux dérivés, Paus, 1900; E Frankland Armstrong, The Simple Carbohydrates, London, 1919, Fischer, Untersuchungen über Kohlenhydrate, 1884-1908, Berlin, 1909 EFA

CARBOLIC ACID Phenol C. H. OH
Occurrence and Formation — Carbolic acid occurs in small quantities in castoreum (Wohler, Annalen, 67, 360), in urine (Stadeler, ibid 77, 18), and is a constant product of the putiefaction of albumen (Baumann, Ber 10, 685) formed when organic substances are strongly heated, and is contained in the tars obtained by the dry distillation of bones, wood (Duclos, Annalen, 109, 163), shale (brown coal), and coal (Runge, Pogg Ann 31, 69, 32, 308; Laurent, Ann Chim Phys [3] 3, 195)

The tar produced in gas manufacture was until the late war the chief source of carbolic Owing to the demand for carbolic acid as a disinfectant and for the manufacture of dyes and explosives, it has become usual, in tar distillation, to collect a special fraction, the 'carbolic oil' containing as much carbolic acid as possible before collecting the 'creosote oil,' which contains the other phenolic constituents of coal tar The 'carbolic oil' begins to come over when the specific gravity of the distillate attains that of water According to Watson Smith (Chem Soc Trans 1886, 21), ordinary Lancashire coal tar yields about 5 p.c by volume of crude phenols, containing 65 p c. by volume of carbolic acid crystallisable at ordinary temperatures

('oke ovens are now constructed so that the tar produced during the coking of coal can be collected, the following data, having reference to the percentage of carbolic acid in such tais, are given by Lunge (Coal Tar and Ammonia, ed. 1909), which has been largely drawn upon in the compilation and revision of this article. he says, The tar from Hussener's modification of the Carvès oven gave 1 37 p c of pure carbolic acid, the tar from the Simon-Carvès oven gave 0.05 p e. of crude carbolic acid, and similar ovens working with another kind of coal and at higher temperature gave 0 305 pe of crude acid The tar collected from blast furnaces, working with coal (raw) and also that obtained from Mond and Duft producers, contains a high percentage of phenohe constituents, but the quantity of carbolic acid present is very small?

Carbolic acid can be obtained by fusing potassium benzenesulphonate with caustic potash, the yield is proportional to the temperature and quantity of alkali employed, and is at best (96 23 p c of that theoretically possible), when I mol prop of the former is fused with 6 mol props of the latter at 252° Caustic soda cannot be employed instead of potash, since only a poor yield is obtained by its use (Degener, 7 pi Chem [2] 17, 394

Carbolic acid can also be obtained by heating the diazo-compounds of benzene with water

Preparation --- Carbolic acid is almost exclusively obtained from coal tar, and is worked up either from the special fraction known as carbolic oil' or from the oils intermediate in specific gravity (sp gr = 1.000-1.020) between the light and heavy oils, that is, distilling between 170° and 230°. The acid is present also in the crossote oils, distilling between 240° and 270°.

The preparation of carbolic acid from coal tar is effected by washing the oils obtained on distilling the tar with a solution of caustic soda, sp gr 1075-1100, when the tar acids are dissolved as sodium compounds and form a heavy solution upon which the now neutral oils float. It is not advisable to use a stronger solution of caustic soda, as in that case a considerable quantity of naphthalene would also be dissolved. If it is desired to extract carbolic acid only, without any of the higher homologues, the oils are often washed fractionally For example, a quantity of caustic soda solution more than enough to extract all the carbolic acid but insufficient to take up all the cresylic acid, is employed, and the phenate of soda solution drawn off is used to wash another portion of oil when the cresylate of soda is decomposed and the cresylic acid is replaced by carbolic acid, and a solution consisting almost entirely of carbolate of soda is obtained

Another method, suggested by Davis, is to employ, for the first wash, only one-third of the quantity of caustic soda required to extract all the tar acids when carbolic acid only is extracted. In many works, however, the whole of the tar acids contained in the light oil, carbolic oil, and creosote oil fractions are extracted, and after separating the tar acids in one of the ways about to be described, the mixture of carbolic and cresylic acids obtained is separated by fractional distillation. The phenate or carbolate of soda, drawn off from the oil is, in many c ses, first purified by blowing steam through it. This

carries away naphthalene, neutral oils, and pyridine bases, and the blowing with steam is continued until the water condensing from the escaping steam ceases to have a milky appearance. The purified phenate of soda is then treated with an acid to decompose it and set free the tar acids which float on the surface and are either skimmed off or are separated in an apparatus similar to a Florentine receiver.

Formerly the decomposition was almost always effected by sulphuric or hydrochloric acid, in which case the soda was lost as sulphate or chloride, which it did not pay to recover. The more common practice to-day, however, is to use carbon dioxide to effect the decomposition. If this is used under pressure, complete decomposition is said to be effected, but more generally the process is completed by the addition of a small quantity of sulphuric acid, this is the more necessary, as both carbolic acid and carbolate of soda are mutually soluble in each other.

The separated solution of sodium carbonate, which contains about 1 pe of carbolic acid, is recausticised with lime and is used over again to wash another quantity of oil A twofold saving is thus effected, in that the loss of the soda is avoided and also the carbolic acid which remained dissolved in the sodium sulphate of chloride solution, and was run to waste, is now recovered, masmuch as it goes forward with the regenerated caustic soda and is regained in the next washing operation. The clude carbolic thus obtained contains, besides phenol (carbolic acid), about 14 to 15 p.c. of water and variable quantities of eresplic acid. It occurs in commerce in three qualities, known as 75 s, 60's, and 50's crude carbolic acid, and its value is determined by 'Lowe's' test This is performed as follows 100 e e of the crude tar acid is slowly distilled in an 8-oz glass retort, and the receiver is changed when 10 e.e. of oil have come over, these 10 ce are accompanied by a varying amount of water, and by reading the quantity of water obtained, the percentage of water is ascertained The distillation is continued until 621 c.c. have collected in the graduated tube which is used as a receiver, the distillation is The 621 cc are then cooled, and then stopped a minute crystal of pure phenol is dropped into the tube, and the cooling continued until the contents begin to crystallise. The temperature is noted when the crystallisation appears to spread through the tube, and this is the measure of the quality of the carbolic acid

The preparation of pure carbohe acid from the crude article is always commenced by a distillation in wrought-iron stills, formerly without a column, but at the present day fractionating columns are almost universally employed. The water comes over first and then the carbohe acid, which is collected apart, so long as it crystallises on cooling. Some uncrystallisable acid comes over next, and the distillation is then stopped and the residue is mostly pitch.

In some cases, a little strong sulphuric acid and potassium dichromate is added to the contents of the still. The condensing worm must be made of zinc, silver, or stoneware. The distillate is allowed to cool and crystallise, and the crystals are drained from the liquid portion,

either on a drainer or in a centrifugal machine. The liquid portion is either sold as liquid carbolic acid or is worked up again with the next batch. The drained crystals are treated with a small quantity of concentrated sulphuric acid and potassium dichromate and redistilled, when pure' crystallised carbolic acid of commerce is obtained. In some cases the separation of the last traces of cresylic acid is effected by adding a small quantity of water, and the mixture is cooled, when a hydrate of carbolic acid crystallises out; this is separated from the liquid portion, which contains the cresylic acid and the crystals are redistilled Water comes over first, and then the boiling-point rises and pure carbolic acid distils over For medicinal purposes, a final distillation in glass retorts is performed

Properties —Pure carbolic acid crystallises in long, colourless needles, has a characteristic odour, melts at 42.5° or 43° and boils at 178.5° (Choay, Compt rend 118, 1211), Lunge (Coal Tar and Ammonia, 1909 ed 210), gives m.p. 42.2° and b.p. 184° under 760 mm. pressure. Ordinary pure carbolic acid of commerce, which contains traces of cresols, melts at a somewhat lower temperature and boils at 182° to 184°. The specific gravity of carbolic acid at 18° is 1.065 (Laurent); its expansion for temperature to at 760 mm. pressure is stated by H. Kopp as follows —

 $abla t = 1 + 0.0006744t + 0.000001721t^2 \\
-0.00000000050408t^3$ 

The presence of small quantities of impunities such as water, naphthalene, or pyridine, materially lowers the melting-point. The red colour of ordinary commercial acid seems to be induced by the presence of minute traces of metals, particularly lead (Meyke, Ber 16, 2513, of however, Ebell, abid 17, Referate 69, Hager, abid. 18, Referate 111, Yvon, Pharm. J Trans 1881, 1051, Richardson, J Soc Chem. Ind 12, 415, Bach, Mon Ser (A), 8, 508, Kraemer and Spilker, Ber 1890, 648) (Carbolic acid is a deliquescent substance, and in damp air forms a hydrate ('6H5 OH, H2O, which melts at 17 2° (Allen, Analyst, 3, 319). At the same time, however, it is not very readily soluble in water, 100 parts of water dissolving 4 83 parts at 11°; 5 36 parts at 35°, 6 19 parts at  $45^{\circ}$ , 7 33 parts at  $58^{\circ}$ , 11 83 parts at  $77^{\circ}$ , and at 84° both liquids mix in all proportions, whilst conversely, 100 parts of phenol dissolve 23 3 parts of water at 9°, 26 75 parts at 32°; 31 99 parts at 53°; and 40 72 parts at 71° (Alexejeff, Ber. 10, 410) According to Hamberg (*ibid* 4, 751), however, it dissolves in 15 parts of water at 16°-17°. It is soluble in all proportions in alcohol, ether, benzene, glacial acetic acid, glycerol, olive oil, chloroform, carbon disulphide, &c. The aqueous solution becomes colouted violet by ferric chloride and is without action on litmus According to Kramers, a mixture of benzene, toluene, xylene, naphthalene, anthracene, and phenanthrene, is obtained when the vapour of carbolic acid is passed through a red-hot tube (Annalen, 189, 129) Two isomeric mononitrophenols are obtained by the action of dilute nitric acid (sp gr 1.34) (Fritzsche, *ibid.* 110, 150); and at a lower temperature, the para- and at higher temperature

the ortho-derivative appear to be chiefly formed (Goldstein, Ber 11, 1943) By the further action of nitric acid, dinitrophenol (Kolbe, 4, 147, 67), and trinitrophenol (pierie acid) (Schmitt

and Glutz, ibid. 2, 52), result

Chlorine (Laurent, Annalen, 23, 60, 43, 209, Faust and Muller, ibid 173, 303, Benedikt, Monatsh 4, 233, Benedikt and Schmidt, ibid. 4, 606) and bromine (Korner, Annalen, 137, 200, 205, 208, 209, 210, Hubner and Brenken, Ber 6, 171) convert carbolic acid at the ordinary temperatures into mono-, di-, and trisubstitution derivatives, and at higher temperatures or in the presence of halogen carriers, such as antimony pentachloride, &c, into tetra- and penta- derivatives The nitro-, chloro-, and bromo- derivatives of carbolic acid are fairly strong acids, and the acid character increases with the number of nitro- groups or chlorine or bromine atoms introduced into the molecule Iodine yields mono- and di- derivatives in the presence of mercury (Hlasiwetz and Weselsky, Ber 2, 524) or rodic acid (Korner, Annalen, 137, 213) Sulphuric acid converts carbolic acid into two isomeric monosulphonic acids (Kekulé, Zeitsch f Chem [2] 3, 107), of which the orthoacid is the chief product at the ordinary and the para- acid at higher temperatures When heated with ammonium zinc chloride at 280°-300°. carbolic acid yields aniline, together with diphenylamine and phenyl ether (Merz and Weith, Ber 13, 1299) When fused with caustic potash, salicylic acid, metahydroxy-benzoic acid and two isomeric diphenols are formed (Baith and Schreder, ibid 11, 1332), whilst fusion with caustic soda results in the formation of pyrocatechol (catechin), resorcinol (resorcin), and phloroglucol (phloroglucin) (*ibid* 12, 417). The behaviour of sodium and potassium phenates (carbolates), when heated in a current of carbon dioxide, has been studied by Kolbe (J. pr. Chem. [2] 10, 89, of also Schmitt, J. pr. Chem. [2] 31, 410, D R P 29939, June 24, 1884), with sodium phenate, the reaction commences below 100°, is most rapid and complete about 180°. and continues up to the temperature of the decomposition of sodium salicylate with the formation of that compound as sole product, but with potassium phenate, salicylate is formed only at temperatures below 150°, whilst at higher temperatures the isomeric potassium parahydroxy-benzoate constitutes almost the entire product, in these reactions, one half of the phenol is recovered. When carbolic acid is heated with phthalic anhydride and a dehydrating agent, such as zinc chloride or sulphuric acid, it yields phenolphthalein (Baeyer, Ber 9, 1230, Annalen, 202, 68)

If the acid is heated with oxelic acid and sulphuric acid, it is converted into coralline (Zulkowsky, Annalen, 194, 119, 202, 184), from which pure aurine can be extracted by suitable methods (Dale and Schoilemmer, ibid. 196, 77), whilst benzaurine results from heating carbolic acid with benzotrichloride (Doebner-Ber 12, 1462)

Reactions -(1) In aqueous solution, carbolic acid gives a violet colour with ferric chloride; this, however, is neither developed in very dilute solutions (Sarauw, Ber 15, 46) nor in the presence of alcohol (Hesse, Annalen, 182, 161); limit of sensitiveness, 1 in 2000 (Polacci, Ber

7, 360) (2) The aqueous solution, on treatment with 1 vol. of ammonia and then with a few drops of an aqueous solution of bleaching powder (1 part in 20 parts of water), gives either at once or on standing a blue colouration; limit of sensitiveness, 1 in 4000 (Salkowski, Zeitsch. anal Chem 11, 316). (3) Bromine water, added to an aqueous solution of carbolic acid, gives either at once or on standing a yellowishwhite flocculent precipitate of tribromophenol bromide (Landolt, Ber. 4, 770); limit of sensitiveness, 1 in 43,700 (ibid ), 1 in 80,000 (Lunge) (1) A solution of carbolic acid assumes a deepred colour when boiled with one-third to one-half its bulk of Millon's reagent (a 10-15 p c. solution of mercurous nitrate containing nitrous acid), limit of sensitiveness, reaction distinct with 1 in 60,000, and still appreciable with 1 in 200,000 Salicylic acid gives a similar reaction (Plugge, Zeitsch anal Chem 11, 173, Almen, J. 1878, 1079)

Quantitative Estimation —Carbolic acid occurs in commerce in different qualities, as ciude acid, as liquid acid, and as crystallised acid of varying degrees of purity The percentage of phenols in crude carbolic acid can be approximately determined by shaking it with twice its volume of 10 pc soda ley added gradually, the separation of the oily and aqueous layers becomes more accurate if a known quantity of petroleum spirit equal in volume to that of the layer of indifferent and resmous substances, is added, and the amount added afterwards deducted. phenols are estimated in a portion of the aqueous layer by treatment with hydrochloric acid and subsequent addition of salt to ensure a complete separation. Such a correction is, however, hardly called for, since the phenols will dissolve about as much water as the water will dissolve phenols (Beckurts, Arch Pharm [3] 24, 572). Beckurts (*ibid* [3] 24, 580) also states that Koppeschaar's method (*v infra*) gives satisfactory results for testing liquid carbolic acid when the specimen is free from cresols thelaz (Bull Soc Chim 42, 574) tests measured samples of crude or liquid carbolic acid in tubes with water, with sulphune acid (1 to 1), and with soda solution (1 part soda ley (sp. gr. 138) to 9 parts of water), and finally fractionates a fourth sample

The exact quantitative estimation of carbolic acid in the pure product is always made by precipitating it with biomine. The composition of the precipitate was believed to be tribromophenol (Landolt) until it was ascertained by Benedikt that under certain conditions it was partially composed of tribromphenol bromide (cf Weinreb and Bondi, Monatsh 6, 506). Koppeschaar's method (Zeitsch anal Chem 15, 233), the one usually employed, requires the following solutions, (a) solution of sodium thiosulphate equivalent to a solution of iodine containing 5 pc. of rodine, (b) solution of starch, (c) bromine water (titiated with pure carbolic acid), or preferably a solution of bromine in caustic soda prepared by adding an excess of bromine to the soda and subsequently removing the excess either by boiling (Allen, J. Soc. Chem. Ind 1884, 64) or by evaporating the solution to dryness and again dissolving in water; (d) solution of potassium iodide containing 125 grams in the litre The process consists in treating 25 c.c.

CARBON 57

of the aqueous solution of carbolic acid (4 grams in the litre) with 100 c c, either of the solution of bromate and bromide with 5 c c, of concentrated hydrochloric acid to liberate the bromine, or of bromine water in a stoppered bottle, which is then well shaken, allowed to remain for 15 minutes, treated with 10 c c of potassium iodide solution, again shaken, and titrated with thio-sulphate. The reactions involved are the following —

(Weinreb and Bondi,  $l\,\epsilon$ ), so that, as Beckurts points out (lc infra), the assumption made by Koppeschaar in the preceding method, that 6 atom, props of bromine enter into combination with I mol prop of phenol, is in practice correct Beckurts (Arch Pharm [3] 24, 562) gives the following as the best mode of estimating carbolic acid. The solutions employed are (a) 1120 normal potassium bromide (5 939) grams in the litre): (b) centinormal potassium bromate (1 666 grams in the litre), (c) potassium iodide solution containing 125 grams in the litie, (d) decinormal sodium thiosulphate (24 8 grams of Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>,5H<sub>2</sub>O in the litre) titration, 25 to 30 c c of the phenol solution (1 m 1000) are treated with 50 c.c. each of the potassium bromate and bromide solutions, shaken with 5 cc of concentrated sulphuic acid, allowed to remain 15 minutes, treated with 10 cc of the potassium iodide solution, and finally titrated with thiosulphate to estimate the amount of rodine liberated. The calculation is simple: from the 50 cc each of bromate and bromide solution, 0 2397 gram of bromide is liberated by the sulphuric acid, and this is capable of converting 0 0469 gram of carbolic acid into tubromophenol, I ce of the decinormal thiosulphate is equivalent to 0 008 gram of bromine, a quantity capable of converting 0 00156 gram carbolic acid into tribromomultiplying now 0.00156 by the number of cc of thiosulphate used, and subtracting the product from 0.0469, gives the weight in grains of phenol in the quantity of solution originally taken This process is accurate whenever solutions of pure carbolic acid, or mixtures from which the pure acid can be separated, are to be tested, but it fails in all cases (eq crude carbolic acid) when other phenols, particularly cresols, are also present Methods for the estimation of carbolic acid have also been proposed by Waller (Chem. News, 43, 152), Degener (J. pr. Chem. [2] 17, 390), and Chandelon (J. Soc. Chem. Ind. 1882, 203): but these are maccurate (Beckurts) Other methods have been proposed by Moeik (Chem Zenti Ind 1917, 36, 842; idem 1918, 265 T); and A biological method Petrie (idem 1919, 132 T) for the determination of phenol has been proposed by Blyth and Goodban (J. Soc Chem. Ind. 1907, 632), and an iodometric method by Skirrow (ibid 1908, 58); and Wake and Inglis have investigated the iodine values of the phenols (*ibid* 1908, 315) A method has been devised by Allen for determining phenols in carbolic soap (Analyst, 1886, 103)

Uses.—Carbolic acid has powerful antiseptic properties and is used on the large scale as a disinfectant. Large quantities of carbolic acid are also employed in the manufacture of salicylic acid, whilst in the colour industry, a considerable demand for the acid exists, masmuch as it is the source of pieric acid and coralline, and it is used in the preparation of some azo- colours has, of late years, been very largely used for the 'Lyddpreparation of modern high explosives ite; and 'melinite,' consisting very largely of piene acid and picrates, although trinitrotoluene appears now to be replacing pieric acid—Phenol forms condensation products with formaldehyde which are bodies of resinous appearance and properties, and which are proposed as substitutes for natural gums and shellac

Compounds with Metals —Potassium phenate  $C_6H_5$  OK, formed by dissolving potassium in earbolic acid (Hartmann, J. pr Chem [2] 16, 36), or by heating carbolic acid with caustic potash (Baumann, Ber. 10, 686), crystallises in slender white needles, readily soluble in water, alcohol, and ether Sodium phenate can be prepared by similar methods and may be used in the manufacture of saheyhe acid and as a disinfectant Compounds with barium (Laurent) and lead (Calvert, Zeitsch Chem 1865, 531) have also been described. W. H. C.

CARBOLINEUM. A preparation of crude carbolic acid Used as an antiseptic and preservative

CARBON. Sym. C At wt 12 Carbon bols at 3600° (Violle, Compt rend 1892, 115, 1273, 1895, 120, 868) Carbon occurs in nature in the free state, and very abundantly in combination, notably in the form of carbonates, and as an essential constituent of organic bodies. In the free state it is a solid, without taste or smell, exhibiting great diversity in the physical characteristics of its three allotropic forms—diamond, graphite, and charcoal

The diamond, up to the time of Bergman, was supposed to be a kind of rock-crystal, although Newton regarded it as probably an unctuous substance coagulated. It was shown to be combustible by the members of the Academy del Cimento in 1694, and Lavoisier proved that the sole product of its combustion was earbon dioxide He had previously ascertained that this gas was a compound of oxygen and an element to which he gave the name of carbone, contained in coal and wood Graphite, as its synonyms, blacklead and plumbago (from the Italian grafio prombino-the writing lead), imply, was long considered to be a kind of lead, or as related to antimony, Scheele regarded it as a compound of iron and carbon, Kastner Carbon proved that it was essentially carbon combines directly with hydrogen at 1100°-1200°, forming hydrocarbons (Bone and Jerdan, Chem. Soc Proc 1901, 162, Bone and Coward, *ibid* Trans 1908, 1975; 1910, 1219, Proc 1908, 222, Pring and Hutton, Trans 1906, 1591, Pring, ibid. 1910, 498) At high temperatures, such as the electric furnace, it is dissolved by the alkaline earth carbides and by rhodium, iridium, palladium, and platinum (Kahn, Compt rend. 1906, 143, 49; 1907, 144, 197, Moissan, ibid. 122, 1479). At the temperature of the electric aic, carbon reduces alumina (Moissan, ibid. 1894, 119, 935).

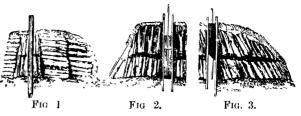

58 CARBON.

Manufacture of Wood Charcoal —The earliest | meiler' (Figs. 2 and 3) Both are distributed in plan of coaling wood, as the manufacture of much the same way.

charcoal was termed and is still called, is carried on as follows. A piece of ground is levelled at some convenent spot in the forest, which is termed the 'hearth' or 'earth'. In the centre of this a thick pole or bundle of brushwood is placed, around which the wood is arranged, some of the pieces being laid horizontally and others set up at an inclination, or the wood may be placed.

altogether at any steep angle, sloping outwards from the centre to form a flattened cone, which, when complete, is usually called a heap, the object, whichever way the wood is placed, is to obtain a free circulation of air under the heap to communicate with the chimney in the centre, which is formed by then withdrawing the centre pole or bundle of brushwood The large wood should, if convenient, be at the bottom of the heap, and the outside packed as close as possible, the heap is then covered with small brushwood, and afterwards with turt, or the material most impervious to air which can be conveniently obtained. A fire is lighted in the centre chimney, and by leaving openings in the outside covering at the bottom of the heap, the fire soon extends, and can be guided to any part by making temporary openings to admit the air. When the heap is sufficiently fired, all the openings are closed, and lastly the chimney itself. The fire will always extend most rapidly on the side facing or towards the wind, and great care must be taken to watch and check this, by keeping the covering on that side in good order charcoal burner must always be careful to spread the fire as evenly as possible through the heap, and after it is coaled to stop it down carefully, he can always accelerate the process in any part of the heap, if well built, by opening the outside to admit air freely, but if he finds this does not act, from any fault in setting the wood, he had better open a hole with a bar at the place required, and light a fire in the hole, this will soon communicate with the main fire in the heap As soon as the smoke and white flame cease to escape at the vents, the whole heap must be closed from the air as carefully as possible until the charcoal is quite cooled, and is ready to draw. The fire must never burn too fast, the slower the process, if the fire is steady and regular, the better the yield of charcoal Hard close-grained woods take a longer time to coal than soft open-grained woods, and should be placed in the heap accordingly These technical instructions, handed down in the forests for ages as secrets from father to son amongst the 'coalliers' in every country in Europe, are the results of long practical experience, and strictly accord with the true principles on which the process is based

To carbonise wood under a movable covering, the plan of meller, or heaps, is employed in Germany. The wood is arranged either in horizontal layers or in nearly vertical ones with a slight slope, so as to form conical rounded heaps of different sizes. The former are called 'lying meller' (Fig. 1); the latter, 'standing

In districts where the wood can be transported by means of rivers or mountain slides, a dry flat space must be pitched upon (screened from storms and floods), which may be walled round, having a slight declivity made in the ground towards the centre (v Fig 4). Into this space the tarry acid will partially fall, and may be conducted outwards through a covered gutter beneath into a covered tank. The mouth of the tank must be shut during the coking with an

Fig. 4 represents a walled meder station a, the station, b, the gutter, c, the tank, which is covered with the slab d, e, a slab which serves to keep the gutter clear of coals. The cover of the heaps is formed of earth, sand,

iron or stone slab, luted with clay A square

iron plate is placed over the inner orifice of the

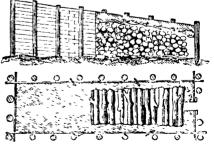

gutter to prevent it being choked with coal ashes

Fig 4

ashes, or such other matter as may be most readily found in the woods. They should be kindled in the centre. From 6 days to 4 weeks may be required for charing a heap, according to its size, haid wood requiring more time, and the slower the process the better and greater is the product, generally speaking.

Chairing of wood in mounds (haufe or liegende worke) (Figs 5 and 6) differs from that in the meder, because the wood in the haufe is successively charted, and the charcoal

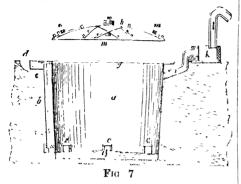

Figs 5 and 6

is raked out little by little. The product is said to be greater in this way, and also better. Uncleft billets, 6 or 8 feet long, being laid over each other, are covered with ashes, and then

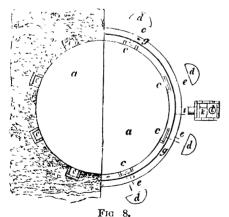

CARBON 59

carbonised The station is sometimes horizontal and sometimes made to slope. The length may be 24 feet, the breadth 8 feet, and the wood is laid crosswise. Piles are set perpendicularly to support a roof made of boughs and leaves covered with ashes. Pipes are occasionally laid within the upper parts of the mounds, which serve to catch and carry off some of the liquid.

Fig. 7 is a vertical section, and Fig 8 a half bird's-eye view and half cross-section at the

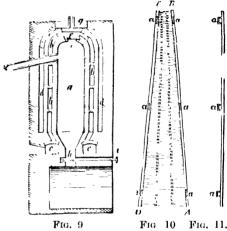

height of the pit bottom, of Chabeaussière's kiln for making wood charcoal a is the oven, b, vertical air-pipes, c, c, horizontal flues for admitting air to the kilns, d, d, small pits which communicate by short horizontal pipes, c, e, with the vertical ones, f, the sole of the kiln, a circle of buckwork upon which the cover or hood h reposes, i, a pipe which leads to the cistem k;

l, the pipe destined for earrying off the gaseous matter; m, m, holes in the iron cover of hd

The distribution of the wood is like that in the horizontal meiler or heaps; it is kindled in the central vertical canal with buining fuel, and the lid is covered with a few inches of earth At the beginning of the operation all the draught flues are left open, but they are progressively closed as occasion requires. In 8 kilns of this kind 500 decasters of oak wood are carbonised, from which 15,000 hectolitres of charcoal are obtained, equal to 64,000 lbs. French, being about 25 p.c., besides tar and 3000 velts of wood vinegar of from 2° to 3° Baumé.

At Crouy-upon-the-Ourcq, near Meaux, there is a well-constructed kiln for making turf-chai-It resembles most nearly a tar kiln. In Fig 9, a is the cylindrical coking place whose surrounding walls are heated by the flame which passes through the intermediate space b. The place itself is divided by partitions of fire tiles into three stages, through the apertures in which the flames of the fire, c, c, rise, and heat the exterior of the coking apartment In order to confine the heat, there is in the enclosing walls of the outer kiln a cylindrical hollow space, d, where the air is kept stagnant Through the apertures left in the upper end at e, the turf is introduced; they are then shut with an iron plate, f, which is covered with ashes or sand The fireplace opens above this aperture, and its outlet is provided with a movable iron cover,  $q_i$ in which there is a small hole for the issue of the gases. The sole of the kiln consists of a cast-iron slab, h, which may be raised by means of a hook, i, upon it. This is drawn back after the carbonisation is completed, whereby the charcoal falls from the coking space into a

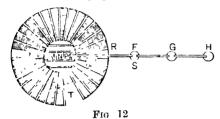

subjacent vault. The volatile products are carried off by the pipe k, and led into the condensing cistern, the gases escaping to the fire-place, where they are burned. The iron slab is protected from the corrosion of the acid vapours by a layer of coal ashes.

Charcoal obtained by the action of a rapid fire in close vessels is not so solid and so good a fuel as that which is made in the ancient way by the slow calcination of pyramidal piles covered with earth. According to Juon (Stahl and Eisen, 1904, 24, 1230), this is due merely to the difference in temperature of the two processes, the higher temperature used in the heapmade carbon increasing the carbon content One of the most economical ovens for making wood charcoal is that invented by M Foucauld, To construct which he calls a shroud or abri one of these, 30 feet in diameter at the base, 10 feet at its summit, and from 8 to 9 feet high, he forms, with wood 2 inches square, a frame 12 feet long, 3 feet broad at one end, and 1 foot at the other end.

The Figs. 10 and 11 will explain the

construction. The uprights, A, B, and C, D, of this frame are furnished with three pairs of wooden handles, a, a, a, by means of which they can be joined together, by passing through two contiguous handles a wooden fork, the frame being previously provided with props, as shown in Fig. 11, and covered with loam mixed with grass A flat cover of 10 feet diameter, made of planks well joined, and secured by four crossbars, is mounted with two trap doors, M, N (Fig. 12), for giving egress to the smoke at the

commencement of the operation, a triangular hole, P, cut out in the cover, receives the end of the conduit, Q, R, s (Figs. 12 and 13), of wood formed of three deals destined to convey the gases and condensed liquids into the casks F, G, H

Lastly, a door, r, which may be opened and shut at pleasure, permits the operator to inspect the state of the fire—The charcoal calcined by this abri has been found of superior quality

When it is wished to change the place where the abri is erected, and to transport it to a store of new-felled timber, the frame is taken down, after beating off the clay which covers it, the joints are then cut by a saw, as well as the ends of the fork which fixed the frames to one another. This process is economical in use and simple and cheap in construction, since all the pieces of the apparatus are easily moved about, and may be readily mounted in the forests. For obtaining a compact charcoal for the use of artisans, this mixed process of Foucauld is said to be preferable to either the close iron cylinder or the pile.

The fierce process for the production of charcoal, in which the wood is heated in brick kilns shaped like a bee-hive, of 32 feet diameter and 16 feet high in the centre, by means of the combustion of the permanent gases produced during a previous process, is said to produce a far higher percentage of charcoal and to involve a smaller loss of by-products (Dudley, J. Anal and Appl. Chem. May, 1891; Armour, Bowers, J. Soc. Chem. Ind. 1892, 152)

The charcoal made at Ontano from the local wood is of excellent quality for blast-furnace use. The wood is here heated in half-iron cylinder retorts, set honzontally and about 9 feet long and 4 feet high. The retorts are charged once a day, and are heated underneath by the tar produced mixed with the waste from the charcoal. The distillate is condensed by

straight condensers, one of which is attached to each retort (Goodwin, J. Soc Chem. Ind. 1902, 743)

In other processes wood is carbonised by superheated steam (Elfetrom, Proc Inst Civil Eng 1906, 164, 60, Zwilliger, J Soc. Chem Ind 1891, 129).

According to Rubands (J. Soc Chem. Ind. 1902, 1466), a hygienic and antiseptic wood charcoal is obtained by heating a mixture of aromatic plants, such as jumper, thyme, broom, &c., in an oven until the cresols begin to come off. The mass is then thrown into sheet-iron boxes, sealed to prevent combustion, and allowed to cool, the empyreumatic matters thus being reabsorbed

A large number of improvements in the apparatus employed for obtaining wood charcoal have been proposed (Jones, Eng Pat 1485, 1894, J Soc Chem Ind 1895, 24; Wise Waworth, Eng Pat 10522, 1897, ibid 1899, 128, Schenk, Eng Pat 23085, ibid. 1900, 321, Burey, ibid 1902, 909; Mourlot, ibid 1902, 1448; Blacher, Chem Ind 23, 508)

Chaicoal is also prepared from sawdust, wood, chips, and peat. The raw material is fed and pressed into and through heated retoits in a continuous stream, and comes out at the other end of the furnace as hard chaicoal. The retorts are provided with pipes for drawing off the by-products (Heidonstam, J. Soc. Chem. Ind. 1898, 445). Many other methods of converting peat into charcoal have been described (Rose, ibid. 1896, 643, Eng. Pat. 17568, 1895, Calmont, ibid. 1892, 257, Eng. Pat. 3978, Cohrab. ibid. 1893, 437, 1897, 1006, Eng. Pat. 3619, 1892, Jurgensen and Bauschlicker, Chem. Zeit. 1901, 25, 635, Stauber, J. Soc. Chem. Ind. 1906, 685; Jurgensen, ibid. 1907, 685)

For blast-furnace work, peat charcoal and that obtained from birchwood is the best

According to Maubér (*ibid* 1890, 881), charcoal is also produced from the by-products in the manufacture of spirits from grains and cereals Charcoal suitable for use as filters, respirators, and as wick for candles, can be prepared by placing vegetable fibres, such as cotton, cotton fabric or waste threads into drums, which are placed one by one into an inclined furnace, down which they roll to the lower end, which is provided with an exit door When no more gases are given off, the drums are withdrawn and the charcoal washed with water (Cooper, J. Soc Chem Ind 1902, 421)

For making gunpowder charcoal the lighter woods, such as the willow, dogwood, and alder, answer best, and in their carbonisation care should be taken to let the vapours freely escape, especially towards the end of the operation, for when they are reabsorbed, they greatly impair the combustibility of the charcoal (Taylor and Challon, ibid 1890, 106

The charcoal of some woods contains silica, and is therefore used for polishing metals. Being a bad conductor of heat, charcoal is employed sometimes in powder to encase small furnaces and steam-pipes. It is not affected by water, and hence the extremities of stakes driven into moist ground are not liable to decomposition. In like manner casks when charred inside preserve water much better than common

casks, because they furnish no soluble matter for termentation or for food to animalcules.

For making crayons of charcoal the willow is the best wood that can be employed, as the softness is uniform in all its parts The durability of charcoal may be seen in several of our old churchyards, where the letters made with lampblack are still perfect, though the white lead with which the body of the stones was painted is entirely destroyed. This property of carbon is shown, however, in a more striking manner by the writings that were found in the ruins of Herculaneum, which have retained their original blackness for two thousand years. The ancients wrote with mk made from ground charcoal.

If it be required to purify any carbonaceous matter to render it fitter for delicate pigments, this may be done by first calcining it in a close vessel, and then lixiviating it in water slightly

acidulated by nitric acid.

The incorruptibility of charcoal was well known to the ancients, and they availed themselves of this property upon all important occasions.

Some years ago a quantity of oak stakes were found in the bed of the Thames, in the very spot where Tacitus says that the Britons fixed a vast number of such stakes to prevent the passage of Julius Cæsai and his army These stakes were chaired to a considerable depth, had retained their form completely, and were firm at the heart

Desmond found that wood charcoal, when submitted to a high temperature out of contact with air, evolved a considerable quantity of gas consisting of 9:14 p.c.  $CO_2$ , 18 08 p.c. CO, 49 11 p.c.  $H_2$ , 16:04 p.c.  $CII_4$ , 0-26 p.c.  $O_2$ , and 737 pc. N<sub>2</sub>, its antiseptic properties being superior to carbon monoxide (Compt. rend 1894, 119, 733).

Most of the houses in Venice stand upon piles of wood, which have all been previously charied for their preservation In this country estates were formerly marked out by charred stakes driven to a considerable depth into the ground These are occasionally found, and usually the charred portions are quite perfect, although every other part is decayed (r Wood, DESTRUCTIVE DISTILLATION OF).

Wood charcoal possesses in a remarkable degree the power of absorbing gases in its poies, and in many cases of determining their combi-This power increases with its density As ordinary charcoal contains atmospheric air in its pores, it must for this purpose be prepared by heating it to redness in a close vessel, and cooling over mercury. The following table shows the absorptive power of Saussure boxwood charcoal of sp gr 157 for different gases.—

Ammonia gas .	. {	0 vols.
Hydrochloric acid gas	. 8	5 ,,
Sulphur dioxide	(	5,,
Hydrosulphuric acid	5	5 ,,
Nitrous exide	4	.0 ,,
Carbon dioxide .	3	5 ,,
Ethylene .	3	5 ,,
Carbon monoxide .		9.42 vols.
Oxygen		9.25 ,,
Nitrogen		6.5 4 .,
Hydrogen .		1.25 ,,

cocoa-nut has still greater absorptive properties, absorbing, according to Hunter,

Ammonia	. 171 7 vols
Carbon dioxide	677,
Carbon monoxide	21 2 ,,
Oxygen .	179,

In consequence of this absorption of gases in the pores of charcoal, their chemical activity is greatly increased When a piece of charcoal which has absorbed a considerable quantity of sulphuretted hydrogen is introduced into oxygen, a violent reaction immediately takes place, water and sulphur dioxide being set free. If air be employed instead of oxygen, sulphur is deposited.

This property is utilised in the removal of feetid and bad-smelling gases from rooms, and in the sweetening of bad-smelling liquids and of clothes For this purpose charcoal of average porosity is found to be the most efficient, and it should be in moderate-sized pieces, its absorbent power being greater in this state than when

in fine powder or in very large pieces

Potassium and sodium alloy absorbs chaicoal, and the suspension so obtained has a variety of uses, and constitutes an intermediate product in a variety of processes such as the production of potassium cyanide and so forth (Weintraub, J Soc Chem Ind 1909, 791)

When charcoal is boiled in a solution of platinum tetrachloride, it becomes impregnated with platinum, and is known as platinised charcoal. This substance possesses in a greatly increased degree the power of inducing chemical combination

Charcoal containing 2 p c of platinum causes oxygen and hydrogen to unite completely in about a quarter of an hour, the rapidity increasing with the percentage of platinum, charcoal containing a larger quantity of platinum acting like platinum sponge Platinised charcoal may be applied to the preparation of air-filters and respirators, and also as a mild caustic (Stenhouse, Chem Soc Trans 8, 105).

Charcoal is readily oxidised by dilute aqueous solutions of calcium hypochlorite, and potassium chlorate, especially in presence of osmium tetroxide, forming carbon dioxide, carbon monoxide, mellogen, and mellitic acid.

A further property of charcoal is its power of depriving most coloured liquids of then colouring matters, by absorbing them within its The colouring of red wine, cochineal, madder, or indigo, can thus be removed from solutions

This property was discovered in 1790 by Lowitz, and is made use of on the large scale in several industrial operations, particularly in the process of refining sugar. It is most strikingly possessed by bone-black or animal charcoal Charcoal of great decolourising power can be obtained by the dry distillation of birchwood or other substances containing carbon mixed with calcium or magnesium chloride, without access of air. The charcoal so obtained is washed with water, then with hydrochloric acid, and then again with water (Osticjho, J Soc Chem Ind 1900, 1099, 1902, 58) Chaicoal of higher decolourising power is

obtained from blood, horns, hoofs, clippings of hides, glue, &c, in contact with pearl-ash. Charcoal obtained from the shell of the good decolourising charcoal is also obtained by

carbonising vegetable matters mixed with chalk, calcined flints, or other earthy substances.

According to Halse (J. Soc Chem. Ind. 1903, 504), charcoal, especially applicable for use in decolourising and purifying saccharine and other liquids, and which can be used in acid solutions, is obtained by heating wood or a similar material with sulphuric acid to a temperature not exceeding 200°. The charted mass is then washed and dried, and, when spent, it can be revivified by treatment with a smaller amount of sulphuric acid.

Charcoal also precipitates or absorbs certain substances from solution, notably iodine, lime, and its salts (being used for the purification of highly calcarcous waters), lead salts and most metallic subsalts, besides many organic substances, as the bitter principles of hop, gentian, and aloc, tannin, alkaloids and resins, from their alcoholic solution (de Connick, Compt. rend. 130, 1627. Laval, Pharm. J. 1900, 65, 213., Malmegac, J. Pharm. Chim. 1900, 12, 5; Davis, Chem. Soc. Trans. 1907, 1666).

Crude alcohol is occasionally allowed to remain for some time in contact with charcoal

Carbon is used for the reduction of metals from their ores, and in the manufacture of glass for the reduction of alkaline sulphates.

Porous carbon can also be used with advantage in electrolytic cells (Lob. Zeit. f. Elect. Chem 1896, 3, 185) When used as an anode in strong hot sulphuric and other acids, which give off oxygen at the anode, carbon is dissolved, and this property can be used for depositing carbon on suitable cathodes (Coehn, J. Soc. Chem. Ind 1897, 1445)

(For the treatment of carbon articles before use, compare Thomson Houston, *ibid* 1905, 1230, Eng Pat 28062, 1904; Acheson U.S. Pat 74918, 1904)

Gas-carbon (clance coal) is a very dense form of carbon, deposited in the upper part of the retorts in the manufacture of coal gas and in blast furnaces. It often exhibits the lustre and sonority of a metal, is very hard, and a good conductor of heat and electricity. It is used to form the negative element in a Bunsen battery.

Materials used for manufacture of carbon electrodes are coke, hard and soft pitch, coal tar, and petroleum oil, in some cases, to obtain electrodes of better mechanical wearing power, a small portion of the coke is replaced by soot. The proportions of the various substances depend on the kind of electrode required Roush (J. Ind. Eng. Chem. 1909, 1, 286, Lake, J. Soc. Chem. Ind. 1900, 1001, Cooper, Shrewsbury and Marshall, ibid. 1896, 25, Starts, ibid. 1906, 544, U.S. Pat. 819606, 1906).

According to Nieweth (J Soc Chem Ind 1894, 1200), carbons of less resistance and greater flummating power when used in arc lamps, can be obtained by mixing the carbon with aluminous earths, magnesia, or other metalliferous minerals before moulding, after which process it is heated by means of an electric current. The carbon, when being heated, is supported in a holding sleeve of non-conducting material to prevent warping. Castner (J. Soc. Chem. Ind. 1894, 1067; Acheson, ibid. 1894, 407) adds 10 p.c. carbide of silicon to the carbon used for arc lamps; Rivers (ibid. 1906, 483; Kuffrath, ibid. 1907, 1903; Smith, J. Cennard, J. Soc. 300) adds yttrium salts. Langville (ibid. 1892, ibid. 1902, 1084).

935) describes a process for obtaining carbon for electrical purposes from paper pulp (Eng. Pat. 13847, 1892).

Carbon filaments are also prepared for use in meandescent lamps and electric lamps (Thomson Houston, J Soc. Chem. Ind 1905, 62; Pring and Fielding, Chem Soc Trans 1909, 1497, Chatelier and Wolagdine, Compt rend. 1909, 148, 1715, Howell, Electrician, 1905, 55, 588; Levis, J Soc Chem Ind 1905, 721, 882, Eng Pat 6959, 1904)

Graphte is formed in the manufacture of carborundum  $(q\ v)$ , and its production on a commercial scale has been established by Acheson (US Pat 568523). It is used to form lamp carbons, crucibles, electrodes, &c For the lower qualities of graphite articles anthracite may be employed, for the finer kinds, and for the manufacture of lubricating graphite, petroleum coke mixed with a catalytic oxide is used. For a discussion of the properties, mode of formation, and structure of graphitic carbon, v Kohlschutter, Zeitsch anorg. Chem. 1919, 105, 35

Lampblack is prepared on the large scale by burning fat, oil, resin, tar, &c, with an imperfect supply of air, either in a brick furnace or in cast-iron chambers.

The resulting dense black smoke is conducted into large chambers, where, on account of the extremely sluggish draught, it is allowed to roll about until the particles gradually coalesce into masses which after some time tall on the floor as soot. The condensation of the particles may be greatly facilitated by sending a current of electricity through the atmosphere of smoke, or else it can be agitated by mechanical means (Irvine, J. Soc. Chem. Ind. 1890, 1110)

For an account of the history and development of the lampblack and carbon-black industry, see Cabot, 8th Int. Cong Appl Chem 1912, Ve, 12-13

When commercial lampblack is strongly heated, a large amount of empyreumatic matter is given off, which condenses into a brown greasy mass consisting of chrysene, pyrene, capnomat, &c This causes ordinary lampblack to cohere when pressed. After calcination it loses this property.

Cressote or other suitable carbonaceous fucl is burnt in a furnace with an adjustable an supply, and the products of combustion are sent through a cooler, where by-products are condensed in centrifugal separators, the carbon deposited being collected in underlying receivers (Adam, J. Soc. Chem. Ind. 1907, 701, Eng. Pat. 13301, 1900)

An arrangement of lamps for the preparation of an especially fine quality of lampblack from waste fat and mineral oils is described in Payen-Paul, 64, 65.

Numerous improvements in the apparatus for the production of lampblack have been described (Wegelin, J. Soc. Chem. Ind. 1898, 747, 1899, 925, 1900, 56; 1902 1022; 1903, 1190, 1908, 81, 579, Fr. Pat. 380983, 1907; Irvine, J. Soc. Chem. Ind. 1890, 1110; Sanders, ibid. 1900, 753; Lembdner, ibid. 1903, 1238; U.S. Pat. 741726, 1903; Smith, J. Soc. Chem. Ind. 1909, 430; Meiser, ibid. 1908, 1212; D. R. P. 203711; Lennard, J. Soc. Chem. Ind. 1899, 1009: Ogilvy, ibid. 1902, 1084).

Carbon has also been obtained direct from smoke (Ward, bud. 1897, 902) livine (bud 1894, 532) obtains lampblack by spraying tars or oils rich in carbon over incandescent coke, mixing the gases so produced with air and steam, and burning them with a limited supply of air.

Lampblack, carbon black, also sometimes spoken of as gasblack, hydrocarbon black, jetblack, and so forth, is used in the production of printer's ink, paints, immeral-black, stove polish, shoe leather, rubber goods, fertilisers, colouring cement, mortal pulp, and artificial stone, harness oil, stenciling, &c. It varies in composition and properties with the material and method used in its production. When produced from the natural gas in American oil wells, the carbon-black differs from ordinary lampblack, by mixing with water on being shaken with it, ordinary lampblack will not do this. It is also quite different in appearance from lampblack obtained from oils, having a fine velvet-like gloss

(See description of figure and apparatus for manufacture, Cabot, J. Soc. Chem. Ind. 1894, 130. Cf. also Purtle and Rowlands, ibid. 1908, 234; U.S. Pat. 877596, 1908, Prosch, J. Soc. Chem. Ind. 1903, 640, Buller, Min. and Eng. World, Oct. 28, 1911.)

A good lampblack, said to be superior to the best American blacks, is also obtained by sparking a mixture of hydrocarbons under pressure and with or without admixture of carbon disormon-oxide (Koppers, J. Soc. Chem. Ind. 1906, 13; Machtolf, ibid. 894, 1909, 482, 1050, D. R. P. 207520, 1907, Gollwert, J. Soc. Chem. Ind. 1909, 1050). According to Frank (ibid. 1900, 545, 1905, 29, 1044), the carbon, at the moment of liberation, is readily taken up by metals, it can thus be made to pass into silver, imparting to the latter the appearance of so-called oxidised silver.

According to Peters, lampblack suitable for use in the preparation of paints, can also be obtained by heating the waste carbons from aic lamps to 1200°-1400°, and then allowing the mass to cool slowly (see also Acceptane black)

Colloidal carbon. By the careful addition of sugar to concentrated sulphune acid, filtering and dialysing the liquid, a clear black stable solution of colloidal carbon may be obtained (Sabbatam, Kolloid-Zeitsch 1914, 14, 29).

Carbon monoxide, carbonous of carbonuc orde; forma anhydrade (O, sp gr 0 96716 (Raylengh), 0 96702 (Leduc) (arr = 1) V D 14 (-186°) (Wroblewski, Compt rend 98, 982) S H p 0 2346 S H v 0 16844 (Wredemann, Pogg Ann 157, 1) C E 0 003667 (Regnault) S (6°) 0 0287, (9°) 0 0269; (18 5°), 0 02315 (Bunsen) S alcohol (2°) 0 20356; (13°) 0 20416, (16°) 0 20566, (24°) 0 20452 (Bunsen),  $\mu_{\rm c} = 1~000301$ ;  $\mu_{\rm g} = 1~00035$ ;  $\mu_{\rm u} = 1~00030$  (Croullebois, Ann Chim Phys [4] 20, 136) Does not exactly obey Boyle's law, PV/P<sub>1</sub>V<sub>1</sub> = 1 00293 (Regnault) Its critical temperature is  $-138~7\pm0$  1, and the corresponding pressure  $34~6\pm1$  atmospheres, critical density 0 3110 It boils at  $-190^\circ$ 

Discovered by Lassonne, and independently by Priestley. Composition first established by Clement and Desormes.

Carbon monoxide is present in coal- and water-gas, from both of which it is sometimes

obtained industrially (Williams, J. Soc Chem. Ind 1891, 270, Claus, ibid 1890, 170)

Produced by the oxidation of charcoal at high temperatures (if Johnson and McIntosh, Trans Roy Soe Canada, 1913, 7, m 161) By the reduction of carbon dioxide by means of hydrogen, carbon, metals, &c, at a red heat, or over carbon made incandescent electrically and coated with a bad conducting material (Engels, J Soc Chem Ind 1901, 350) On the rate of reduction of carbon dioxide by carbon, see Rhead and Wheeler (Chem. Soc. Trans. 1912, 101, 831, which contains a number of references to previous work on the subject) In the reduction of metallic oxides by charcoal or coke By the dry distillation of many organic compounds, and together with hydrogen and carbon dioxide when steam is passed over red hot charcoal. By passing electric sparks through charcoal By passing electric sparks through carbon dioxide (Buff and Hofmann, Annalen, 113, 140) or by heating carbon dioxide to  $1300^{\circ}$ (Deville, Compt rend 59, 873) By heating dehydrated oxalie acid, or by heating dry alkaline formates and acetates with formic acid (Loim, ibid 82, 750). By heating an oxalate or formate or these acids with concentrated sulphuric acid

Carbon monoxide is also produced in considerable quantities from various explosives, such as mellinite, gun cotton, &c. It is evolved by an alkaline pyrogallol solution during the absorption of oxygen, unless a large excess of potash is employed (Clowes, Chem. Soc. Proc. 1895, 200)

Prepared by the decomposition of (i) oxalic or formic acid, (2) potassium ferrocyanide, or (3) potassium cyanide, by concentrated sulphuric acid (Boudouard, Compt. rend. 1899, 128, 98, 307, 822, Wade and Panting, Chem. Soc. Trans. 1898, 257)

$$\begin{array}{l} \text{(1)} \ \ (^{1}_{2}\text{H}_{2}\text{O}_{4} = (^{1}\text{O} + (^{1}\text{O}_{2} + \text{H}_{2}\text{O} \\ \text{(2)} \ \ (^{1}\text{H}_{2}\text{O}_{2} = (^{1}\text{O} + \text{H}_{2}\text{O} \\ \text{(3)} \ \ \text{K}_{4}\text{Fe}((^{1}\text{N})_{6} + 6\text{H}_{2}\text{SO}_{4} + 6\text{H}_{2}\text{O} \\ -6(^{1}\text{O} + 2\text{K}_{2}\text{SO}_{4} + 3(\text{NH}_{4})_{2}\text{SO}_{4} + \text{FeSO}_{4} \\ \end{array}$$

In the first case the gas is mixed with carbon dioxide, which must be removed by passing through potash or lime-water. In the last reaction it is free from carbon dioxide if the temperature does not exceed 200°, but above this point this gas and sulphur dioxide are produced by the reducing action of carbon monoxide upon sulphuric acid

$$H_2SO_1+CO-CO_2+SO_2+H_2O$$

It is hable also to contain a small quantity of hydrocyanic acid vapour

Dry calcium oxalate or barium oxalate is mixed with about  $\frac{1}{10}$  dry lime, and strongly heated, the gas passed through lime and dried  $\mathrm{CaC}_2\mathrm{O}_4 = \mathrm{CaC}_2\mathrm{I}_4 + \mathrm{CO}_2$ , any carbon droxide formed being absorbed by the lime Carbon monoxide is evolved in the manufacture of carbides, and is collected and stored. It is also produced in the decomposition of sugars

Carbon monoxide is manufactured practically pure by bringing a mixture of oxygen and carbon dioxide in contact with incandescent graphite, coke, anthracite, &c. As thus obtained, it may be used for the manufacture of special steels, the reduction of refractory oxides, the treatment of iron ores in the blast furnace, and for other

purposes (Loiseau, J Soc. Chem Ind 1908, 1112; Pat. 390673, 1908). Carbon monoxide passed over heated sodium or potassium hydroxide, soda lime, or calcium hydroxide, yields a formate and hydrogen, together with methane and ethylene. Carbon monoxide may be converted into hydrogen and hydrocarbons to the extent of 995 pc. by passage over hot lime several times, and it is suggested that in this way illuminating gas might be freed from this toxic constituent (Vignon, Bull Soc chim 1911, [iv.] 9, 18).

Properties - Colourless gas of metallic odour and taste, combustible, non-supporter of combustion. Absorbed by carbon, by several metals, and by a solution of cuprous chloride in hydrochloric acid or ammonia It acts as an energetic reducer It is a highly poisonous gas, producing giddiness, and ultimately asphyxia when inhaled 0 43 pc in air is fatal to man (Mosso, J Gas Lighting, 1902, 80, 1334), 0.2 pc. is also poisonous if breathed for any

When carbon monoxide is passed over dry silver oxide, the latter is reduced thus.  $CO + Ag_2O$ = Ag<sub>2</sub>+CO<sub>2</sub>. Ammoniacal silver oxide is also reduced, and the reaction may be employed for the detection of small quantities of carbon monoxide in air (Dejust, Compt. rend. 1905, 140, 1250; Berthelot, *ibid.* 1891, 112, 597; Habermann, Zeitsch. angew. Chem. 1892, 324) It reduces Barreswil's (Fehling's) solution, and in contact with metallic copper moistened with aqueous potassium hydroxide is rapidly oxidised when mixed with air The copper is converted into a peroxide, Cu<sub>2</sub>O<sub>3</sub> or CuO<sub>2</sub>, which is the active oxidising agent The rate of oxidation is increased when the copper surface is coated with iridium

0 02 pc carbon monoxide may be detected by the decolouration of a mixture of silver nitrate, and weak permanganate solution aciditied with nitric acid (Merwet, Compt. rend 1897,

According to Grehant (ibid 1891, 113, 289; 114, 309), 1 part of carbon monoxide may be detected in 10,000 parts of air, by aspirating the air through dog's blood, and testing the respiratory capacity of the blood before and after the experiment. When the air is passed under a pressure of 5 atmospheres, the test becomes still more delicate. It can also be detected by passing the gas through palladium chloride, when a metallic precipitate is formed and the colour indicates the quantity present 30000 to 300000 carbon monoxide can be detected in the atmo sphere by passing several litres of the suspected air through rodic acid, when the following reaction occurs .-

$$5CO + 2HIO_3 = 5CO_2 + H_2O + I_2$$

The iodine is absorbed in chloroform or carbon disulphide, when the relative tint indicates the quantity of carbon monoxide, or else the carbon dioxide is absorbed by standard potash solution and the carbon monoxide calculated (Gautier, Compt. rend. 1898, 126, 793, 871, 931, 1299; St Martin, Compt. rend. 14, 1036; Kinnicutt and Sandford, J Amer Chem. Soc 1900, 22, 14, Fillanger, Chem Zeit. 1903, 27, Rep. 126; Levy and Pécoul, Compt. rend. 1905, 140, 98; Fr. Pat. 349714, 1904; 142162, 1906; Morgan

and McWhorter, J Amer. Chem. Soc. 1906, 29, 1589; Goutal, Ann. Chim. anal. 1910, 15; Graham and Winmill, Chem. Soc. Trans. 1914, 105, 1996; Sinnatt and Cramer, Analyst, 1914, 163; Frobose, Zeitsch. anal. Chem 1915, 54, 1; Graham. J Soc Chem. Ind. 1919, 10 T.).

Carbon monoxide is oxidised quantitatively to carbon dioxide by passing it over yellow mercuric oxide heated to 100° (Moser and Schmid, Zeitsch anal Chem. 1914, 53, 217); Clowes recommends the flame cap test as an accurate and rapid method for detecting carbon monoxide (Brit Assoc Report, Chem Zeit. 1896), whilst to detect the presence of carbon monoxide in mines, Haldane and also Herman (J Soc Chem Ind. 1896, 854) recommend the use of mice, which are very rapidly affected by small quantities of carbon monoxide. For a method of determining small quantities of carbon monoxide in hydrogen as used for ammonia synthesis, see E K Rideal and Taylor, Analyst, 1919, 89

According to Leblane (Ann Chim. Phys. [3] 5, 223), it is chiefly the presence of this gas that causes the poisonous action of air in which charcoal has been burnt. The gases from a charcoal fire may contain up to 18 p c of carbon monoxide, those from a petrol engine 7.32 p c (in these gases the quantity of carbon monoxide exceeds that of the carbon dioxide), whilst the combustion products from gas-heaters contain from 1 part in 15,000 to 03 pc, according to the supply of air to the burner. A small proportion of carbon monoxide in a dusty atmosphere constitutes a dangerously explosive mixture. It combines with the red colouring matter of the blood-forming carboxyh@moglobin, and may be recognised by its absorption spectrum, which is almost identical with that of oxygenated blood, and is characterised by two bands between D and E. On the addition of ammonium sulphide, these disappear in the case of oxygenated blood, and the spectrum shows one band midway between D and E, but remains unchanged if carbon monoxide is present (Vogel, Ber. 11, 235; Hoppe-Seyler, Zeitsch anal Chem 3, 439, also Preyer, J 1867, 802; Nawrocki, J 16, 640, Gréhaut, Lindel Chem 1, 1868, 1864, July 1868, 1864, 1864, July 1868, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 1864, 18 Compt rend 87, 193; St Martin, ibid 1892, 1 4, 1006) According to Nicloux (ibid. 1898, 126, 1526, 1595), carbon monoxide is a normal constituent of dog's blood, but this has been denied by Buckmaster and Gardner (Proc. Roy. Soc. B, 1909, 81, 515). Carbon monoxide burns ordinarily with a blue flame, which, by previous heating, becomes red, generating carbon dioxide. The temperature of its flame in air is about 1400° (Valerius, J. 1874, 58). According to Wieland (Ber. 1912, 45, 679), formic acid is an intermediate product in the combustion of carbon monoxide, and can be detected by allowing the flame to play upon ice. When dry it is not changed by the electric current nor by ignited platinum wire, but when standing over water it is decomposed by a glowing platinum spiral (Buff and Hofmann, Chem. Soc. Trans. 1860, 12, 273). When not absolutely dry, it may be exploded with oxygen by the electric spark or by platinum wire heated to 300° or by spongy platnum at ordinary temperatures. 2 vols. CO unite with 'vol. O, forming 2 vols. CO<sub>2</sub>

Dixon (Phil. Trans 1884, 617) has shown that no action takes place when a spark is passed into a mixture of perfectly dry carbon monoxide and oxygen, but that a mere trace of moisture renders the mixture explosive The combination takes place very slowly in presence of small quantities of steam, and increases in rapidity with the quantity of steam present. Probable reactions:

$$\substack{ 2\text{CO} + 2\text{H}_2\text{O} - 2\text{CO}_2 + 2\text{H}_2 \\ 2\text{H}_2 + \text{O}_2 = 2\text{H}_2\text{O} }$$

Hence the steam acts as a carrier of oxygen to carbon monoxde (v Dixon, Chem. Soc Trans.

Small quantities of other gases than steam were tried. if the gas contained hydrogen, explosion occurred, if the gas contained no hydrogen, no explosion occurred. When a mixture of carbon monoxide and steam is heated to about 600°, a portion of the carbon monoxide is oxidised. If the carbon dioxide is removed as it is formed, the whole may be oxidised Meyer's experiments (Ber 19, 1099) seem to prove that a dry mixture of carbon monoxide and oxygen can be exploded if a very strong spark is used, and a sufficiently high temperature then obtained, and if the gases are under considerable pressure When sparks from an induction coil are passed through a mixture of carbon monoxide and steam, carbon dioxide, a little formic acid, and sometimes carbon, are formed (Dixon, Chem. Soc. Trans 49, 94) When to a mixture of dry carbon monoxide and hydrogen, oxygen insufficient for complete combustion is added, and the mixture exploded by the spark, carbon dioxide and steam are formed in a ratio dependent upon the shape of the vessel and the pressure up to a certain limit, called the 'critical pressure.' Above this pressure the ratio of the formation of carbon dioxide and water is independent of the shape of the vessel. The critical pressure becomes lower the larger the quantity of oxygen The ratio CO+H<sub>2</sub>O.CO<sub>2</sub>+H<sub>2</sub> remains constant so long as the vol. of the hydrogen is more than twice that of the oxygen, provided no steam condenses, and the pressure is above When the vol of hydrogen the critical pressure is less than twice the vol of oxygen, the above The presence of an mert ratio diminishes gas increases the formation of carbon dioxide and diminishes that of water, hence it lowers the value of the ratio  ${\rm CO} + {\rm H_2O} \cdot {\rm CO}_2 + {\rm H}_2$ . This ratio is called the 'coefficient of affinity' of the reaction (Dixon, Phil Trans. 1884, 617; Chem. Soc Trans. 49, 94). According to Brodie, when carbon monoxide and hydrogen are submitted to the action of the silent discharge, marsh gas is formed by synthesis, when pure and dry carbon monoxide is circulated through the induction tube, it is decomposed, carbon dioxide being formed together with other 'oxy-carbons' of the formulæ C<sub>4</sub>O<sub>3</sub> and C<sub>5</sub>O<sub>4</sub> (Brodie, Proc Roy Soc 21, 245).

Carbon monoxide is converted into carbon dioxide under the influence of nascent oxygen from chromic acid (Ludwig, Annalen, 142, 47), but not by ozone, either in diffused daylight or in direct sunshine (Remsen and Southwark, Amer. J Sci [3] 11, 136) It is likewise oxidised by palladium charged with hydrogen in presence of oxygen and water (Traube, Ber. 15, 2325, 2854; 16, 123; Remsen and Keiser, ibid. 17, Vol. II.-T.

83; Wieland, Ber. 1912, 45, 679); by mixing with oxygen and passing over platinum black; by nitric oxide (Hasenbach, J, pr. Chem [2] 4, 1), by heating with metallic oxides and with 'activated' many oxysalts Adsorbed on platinum it is rapidly converted into carbon dioxide in contact with oxygen.

When passed over finely divided metals, such as nickel, cobalt, or iron, the quantity of carbon dioxide formed depends on the temperature and the metal (Zimmermann, Ber. 1903, 36, 1231, Sabatier and Senderens, Bull Soc chim 1903, 29, 294, Berthelot, Compt rend 1891, 112, Van Breakedensen and Horst, Rec trav. 594 chim 19, 27, Smits and Wolff, Zeitsch. physikal. Chem 1903, 45, 199, Charpy, Compt rend. 1903, 137, 120; Boudouard, *ibid* 1899, 128, In some cases a volatile carbonyl compound is formed of the type M(CO)4 (Lange and Quincke, Chem Soc Proc 1890, 112, 1891, 117, Wartha, Chem Zeit 1891, 15, 915, Garnier, Compt rend 1891, 113, 189, Gautz, Bull Soc chim 1892, 13, 278, Bertholet, 1892, Accord-431, 434, Sabatier and Senderens, lc.) ing to Gautz (Compt rend 1892, 114, 115), at 400° carbon monoxide reacts with manganese and iron, thus. CO+Mn=MnO+C. Carbon monoxide passes through cast and wrought iron when heated to redness, and, according to Sieverts and Krumbhaai (Ber. 1910, 43, 893), it dissolves in nickel and cobalt, but not in copper

Minute quantities of carbon monoxide reduce gold chloride, and also gold, silver, and mercury oxides (Fay and Secker, J. Amer Chem Soc. 1903, 25, 641) Brunck (Zeitsch angew Chem. 1912, 25, 2479) has proposed to employ its reducing action on palladium chloride (sodiumpalladous chloride) as a method of estimating

small quantities of carbon monoxide

When an electric spark is sent through a mixture of ammonia and carbon monovide, ammonium cyanate is chiefly formed (Northall Laurie, Chem Soc Trans 1905, 433)

Pure carbon monoxide forms a colourless transparent liquid under 200-300 atmospheres at-139°, and solidifies to a snowy mass in vacuo at  $-211^{\circ}$  (Olszewski, Compt rend. 99, 706; 100, 350, Wroblewski and Olszewski, Ann Chim

Phys [6] 1, 112)

Carbon monoxide combines with potassium at about 80° to form an explosive compound, KCO (Brodie, Chem Soc Trans 1860, 12, 269). It is rapidly absorbed by a solution of cuprous chloride in ammonia or hydrochloric acid, by which means it may be directly estimated in a gaseous mixture (cf Thomas, Chem News, 37, 6). According to Manchot and Brandt (Annalen, 1909, 370, 286), it forms the compound CuCl CO,2H<sub>2</sub>O, with copper chloride, and the 2H<sub>2</sub>O can be replaced by 2NH<sub>3</sub> It is also absorbed by moist silver oxide. It unites directly with chlorine, forming phosgene gas (Schutzenberger, Zeitsch f Chem [2] 4, 321) It is absorbed by heated potassium hydroxide at about 200°, forming potassium formate (Berthelot, Ann. Chim. Phys [3] 61, 463) Frohlich and Geuther (Annalen, 202, 317) recommend passing carbon monoxide over soda-lime for this purpose. combines with sulphur to form carbon oxysulphide; with platinum tetrachloride to form C<sub>3</sub>O<sub>3</sub>PtCl<sub>4</sub> and C<sub>2</sub>O<sub>2</sub>PtCl<sub>2</sub> (Schützenberger, Ann. Chim. Phys. [4] 21, 430). It is rapidly absorbed

by anhydrous hydrocyanic acid cooled by a freezing mixture, two layers being formed, but the gas is evolved on removing the tube from the mixture (Bottinger, Ber. 10, 1122). It acts on metallic alcoholates with formation of acids by synthesis (Geuther, Annalen, 202, 288; Schroeder. ibid 221, 34)

Carbon monoxide has been used in electrolytic cells by Haber and Moser (Zeitsch Elektro-

chem. 1905, 11 593).

nault)

Carbon dioxide was known to Paracelsus and Van Helmont, and was carefully studied by Its true composition was first demonstrated by Lavoisier in 1775 It was liquefied by Davy and solidified by Thilorier It is formed by the combustion of carbon in oxygen or air (Dixon, Chem Soc Proc 1899, 118, Nauwaan, Zeitsch, angew Chem 1896, 200) According to Potter (Proc Roy Soc. 1908, 80, B, 239), amorphous carbon, such as charcoal, lampblack, coal, &c., when exposed to air, is slowly oxidised by the agency of bacteria, to carbon dioxide, the amount of which increases with rise in temperature The temperature at which carbon will form carbon dioxide and monoxide, when heated in oxygen, depends largely on whether the temperature has been reached by heating or cooling (Manville, Compt rend 1906, 142, 1190) The presence of moisture is necessary for the combustion of carbon in oxygen (Brereton Baker, Chem Soc. Trans 1885, 349, Rhead and Wheeler, Chem. Soc Trans. 1912, 101, 846; *ibid* 1913, 103, 1210) It is a constant product of ordinary processes of combustion. It is also formed by the respiration of animals, in various processes of fermentation, and by the decay of animal and vegetable substances It is evolved from fissures in the ground in volcanic districts, and from the craters of active volcanoes, and exists in solution in natural waters, some of which contain it in such quantities as to effervesce is found also in mines, quarries, wells, and caverns, particularly in limestone districts is a constant constituent of the atmosphere, which contains on the average about 0 034 p.c. The air in streets often contains as much as 0 05 to 009 pc In crowded rooms it may reach 03 pc. It is further produced by the decomposition of carbonates either by the action of heat or of stronger acids, and is frequently formed when organic bodies are subjected to high temperatures In the reduction of many metallic oxides by carbon by burning carbon monoxide; by heating together carbon monoxide and steam; and by the action of steam on calcium carbonate at red heat, by heating a mixture of potassium dichromate and sodium carbonate.

Best prepared by acting on chalk, marble, or magnesite with dilute hydrochloric acid solution. The gas may be collected over water or by displacement of air On the large scale it is obtained by heating chalk or limestone to redness in iron or earthen vessels (in lime burning) or by burning charcoal. It is manufactured also as a byproduct in the combustion of fuel. Also pure on large scale by heating carbonates with steam (J. Soc. Chem. Ind. 3, 568).

According to Thom and Pryor (ibid. 1909,

1087), pure carbon dioxide can be manufactured from limestone by the following process. The limestone is heated in closed retorts around a central combustion chamber, beneath which is a furnace, the whole apparatus being enclosed in a casting which excludes an from the retorts Superheated steam is admitted to the retorts at their lower ends, and this decomposes the limestone and carries the carbon dioxide through outlets at the top of each retort, leading to a collecting gas main running round the top of the The retorts have closely fitting mouthpieces, at which they are charged and discharged respectively. By a system of air and waste-gas flues, perfect combustion and the fullest use of heat from the waste gases is ensured (Eng. Pats. 20102, 24332, 1908).

Carbon dioxide is obtained commercially from natural waters from the Saratoga springs in New York, and also in South Germany North Germany the gas is obtained by the combustion of coke, which is generally considered to be the cheapest and best commercial method of producing carbon dioxide Coke is burnt in a generator, A (Fig. 14), the products pass into a combustion chamber, B, into which hot air is

it leaves, almost saturated, by the overflow siphon and accumulates in the tank L. The pump J then drives it through the tubular vessels M and o (where it is heated to 60° and 90° respectively) into the heater c, where its temperature is raised to 100°. The 'poor ley' circulates in the opposite direction back to the tank K. The carbon dioxide evolved from c passes into a cooler, then to a gasholder (Schwatolla, Zeitsch. angew Chem 1900, 1284)

Other methods of obtaining carbon dioxide from coke are described by Candia and Merlini (J Soe Chem Ind 1908, 847), Leshe (ibid. 1905, 240), Gravillon (ibid 1900, 164, Eng Pat.

8377, 1904), and many others

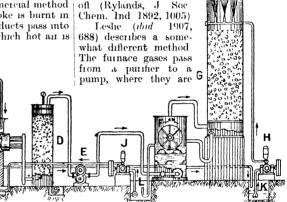

pend upon its absorption

by potassium or sodium

carbonate solution, from

which it is then boiled

Numerous patents also exist for obtaining carbon dioxide from furnace gases and from lime kilns, most of which de-

admitted to complete the combustion, thus oxidising all the carbon monoxide and hydrogen sulphide. The hot gases now pass through tubes contained in the vessel c, thus heating and decomposing the bicarbonate solution The gas now passes contained in this vessel through one or more wash towers, D, containing limestone over which water trickles, and is freed here from dust and sulphur dioxide E 18 a blower or fan, which sucks the gas through the furnace and drives it through the absorbing apparatus. F is a rectangular vessel filled with potash ley, and provided with a number of semicircular baffle plates, so airanged that the gas accumulates under each successively, thus remaining exposed for a considerable time under the pressure of the column of fluid to a large surface of liquid The absorption is further helped by an agitator, which throws the liquid into the upper portion of the vessel the gas passes into the tower c, where the absorption is practically completed, and then leaves the apparatus. The circulation of the potash lev starts from the tank K, whence it is pumped by H through the Korting's jets into the upper part of G, which is thus filled with fine spray. The siphon at the bottom of the tower delivers the partially saturated ley into F, which

compressed, after which they are cooled in a heat interchanger, from which they are led to a drying vessel, containing calcium chloride, into a refugerator, in which the carbon dioxide is condensed to snow, the other gases, still above their critical temperature, are passed back through the interchanger, whilst the carbon dioxide is liquefied and drawn off into tubes and cylinders (Eng. Pat. 11902, 1906)

A method of obtaining steribsed carbon

dioxide, with disinfecting properties, is described by Bouchaud-Praceiq (J Soc. Chem. Ind 1908, 994)

Many attempts have been made to collect the earbon dioxide given off during fermentation processes, and some of these have been successful from a commercial and industrial

point of view

Fig. 14

Mixtures of a carbonate or bicarbonate with a salt or double salt, which is readily hydrolysed in aqueous solutions, have been prepared for the generation of carbon dioxide (Menter and Sedhtzky, J. Soc Chem Ind 1908, 1151; Eng. Pat 14863, 1908).

Ageron and Remy (J. Soc. Chem. Ind. 1906, 847) have prepared a compound by heating a mixture of magnesium sulphate and sodium sulphate or bisulphate with sulphuric acid,

which they use as a substitute for acids in liberating carbon dioxide from carbonates.

Carbon dioxide is a colourless, inodorous gas. neither combustible nor a supporter of combustion. Strongly heated potassium or sodium and brightly burning magnesium burn in carbon dioxide

When quite dry it has no action upon litmus, but if moisture be present the litmus is coloured wine-red. The colour disappears on exposure to air, owing to escape of the gas. Passed into lime-water, carbon dioxide renders it turbid, owing to the formation of calcium carbonate, but if the gas be in excess, the neutral carbonate is converted into an acid carbonate, and the liquid becomes clear.

Carbon dioxide is rapidly absorbed by a solu-

tion of caustic potash

Between -85° and +54° absolutely dry carbon dioxide does not react with absolutely dry alkalı hydroxides. At or above 54°, the dry substances do react, and at 85° a trace of moisture at once starts the reaction, which is completed very rapidly (Moissan, Compt rend. 1903, 136, 723) It is also absorbed by sulphuric acid [100a = 926], where a = Bunsen's absorption coefficient (Bohr, Chem Zentr 1910, n. 1414).

Its solution in water has a sp gr. 1 0018 It has a slightly acid taste, colours litmus winered, and partially neutralises alkalis and dissolves carbonates of barium, strontium, calcium, and

magnesium, &c.

The solution corrodes iron Krohake (J. Soc Chem Ind 1900, 520) found that water containing about 40 mgrms. of CO<sub>2</sub> per litre reduced iron pipes in a short time from 26 mm to 7 mm diameter, owing to the formation of a brown crust, the pipe itself being corroded to a depth of 1-3 5 mm

Its solution in water probably contains carbonic acid  $\rm H_2CO_3$ . At ordinary temperatures, and under I atmosphere, the mass of carbon dioxide dissolved increases as the pressure. But at pressures of 2, 3, or more atmospheres, the mass of carbon dioxide dissolved is less than that calculated by Dalton and Henry's law (v Khanikoff and Louguinine, Ann Chim Phys [4] 11, 412). By the action of carbon dioxide under pressure on water at low temperatures, the crystalline hydrates CO<sub>2</sub>,6H<sub>2</sub>O (Villard, Compt. rend. 1894, 119, 368), CO<sub>2</sub>,8H<sub>2</sub>O, and CO<sub>2</sub>,9H<sub>2</sub>O (Hempel and Seidel, Ber 1898, 31, 2997) have been obtained

Water which has been saturated with carbon dioxide under pressure gives it up as soon as the pressure is removed This property is made use of in the manufacture of effervescing drinks and

aërated waters (v AERATED WATERS)

Under the same pressure the volume of gas absorbed by water diminishes as the temperature rises, the whole of the gas being expelled at boiling heat. Hence carbonic acid water, hold ing an earthy carbonate in solution, deposits it when the water is boiled This is the cause of the furring of kettles, boilers, &c, in which spring or river waters have been boiled.

Potassium burns in carbon dioxide at a red heat with a red incandescence, depositing charcoal mixed with potassium carbonate Sodium decomposes it in a similar manner, as do phosphorus and boron in presence of an alkalı.

It is decomposed by the electric spark into

carbon monoxide and oxygen, if hydrogen, or mercury, or some other metal is present to combine with the oxygen, otherwise the carbon monoxide and oxygen recombine to form carbon dioxide (Collie, Chem. Soc. Trans. 1901, 1063).

Partly decomposed by electric sparks, a condition of equilibrium is attained when change of CO, into CO+O equals that of CO+O into CO2 (Dixon and Lowe, Chem Soc Trans 47, 571).

Carbon dioxide is decomposed by the silent electric discharge, the amount of decomposition varying with the degree of dryness of the gas, the intensity of the discharge, and the form of ozoniser employed, but in all cases a diminished pressure of the gas results in a greater decomposition (Holt, Chem Soc Proc 1908, 24, 271).

Ultra-violet light decomposes dry carbon dioxide at the ordinary temperature into carbon monoride and oxygen, similar results are obtained by the action of radium emanations (Herschfinkel, Compt rend 1909, 149, 395; Ramsbottom, Chadwick, and Chapman, Chem. Soc Proc 1906, 23)

It is partly changed to carbon monoxide and oxygen by heating to 1300° in a porcelain tube (Deville, Compt rend 56, 729, also Berthelot, ibid 68, 1035)

When heated at 350° with hydrogen over reduced nickel or cobalt, it is completely reduced to methane (Sabatier and Senderens, *ibid.* 1902,

With carbon at 500°-650°, it forms carbon monoxide, equilibrium being reached when the mixture of gases contains 61 p c unreduced  $CO_2$  (Boudouard, *ibid* 1899, 128, 824, 1524; 1905, 141, 252)

Mixed with hydrogen and heated to bright redness, or submitted to induction sparks, carbon monoxide and water are formed, if the water is removed, the whole is converted to carbon monoxide (Dixon, Chem. Soc. Trans. 49, 94, Gautier, Bull. Soc. chim. 1906, 35, 929). A mixture of carbon dioxide and hydrogen passed over red-hot pumice yields carbon and water (Dubiunfaut, Compt, rend. 74, 125).

Mixed with sulphur-vapour and passed through a red-hot tube it gives carbon monoxide, sulphur dioxide, and a little carbon oxysulphide (Berthelot, Bull. Soc chim. [2] 40, 362) Passed through a red-hot tube with sulphuretted hydrogen, it forms carbon monoxide, water, and sulphur (Kohler, ibid. 11, 205) Reduced to carbon monoxide by hydrogen, iron, and zinc or copper which has occluded hydrogen (Tissandier, Compt rend 74, 531; Schrotter, Wied Ann. 34, 27); by potassium cyanide (Eiloart, Chem. News, 54, 88), by protoxides of iron and tin (Wagner, Zeitsch anal Chem. 1879, 559); and partially by ferrous sulphate, and a little water in a closed tube (Horsford, Ber 6, 1390).

Carbon dioxide is reduced to carbon by heating with potassium, sodium, magnesium, or silicon (Schmole, J. Soc. Chem. Ind. 1895, 1060). Alkaline carbonates heated strongly with phosphorus or boron give carbon dioxide, which is reduced to carbon (Tennant, Crelles Annalen, [1793] 1, 158; Dragendorff, J. 1861, 111; Leeds, Bull. Soc. Chim. 12, 1834 and 2131); decomposes moist potassium iodide at high temperatures, yielding hydriodic acid (Papasogli, Gazz. chm. ital. 1881, 227); it also decomposes alkaline aluminates (Ditte, Compt.

rend. 1893, 116, 386); and, according to Moore, liberates nitrous acid from nitrites (J. Amer. Chem. Soc. 1904, 26, 959). Solution of carbon dioxide in water yields sodium formate with metallic sodium (Kolbe and Schmidt, Annalen, 119, 251) Carbon dioxide is assimilated by the chlorophyll of plants under the influence of sunlight, carbon being abstracted and oxygen set free. Carbon dioxide diffuses through caoutchouc (Kobbe, Chem. Zot. 1890, 14, 1142)

The specific heat of carbon dioxide is greater at high than at ordinary temperatures (Berthelot and Vieille, Compt. rend. 98, 770 and 852). According to Hoppe-Seyler (Zertsch. physikal Chem. 10, 201, and 10, 401), the carbonic acid and marsh gas found in water-logged soils is due to a widespread process of fermentation of

cellulose

In any working- or living-room the carbon dioxide should not be more than 10 volumes per 10,000 of an.

To estimate the carbon droxide in air, a measured sample of the air is passed through a known quantity of barium hydroxide, coloured with phenolphthalein, and by noting the quantity of air needed to decolourise the hydroxide the carbon droxide can be calculated. The method is sometimes modified by using a limited volume of air, and titrating the hydroxide remaining unneutralised (Ballo, Ber. 1884, 1097; Wiener, Monatsh. 1894, 15, 429, Henriet, Compt. rend. 1896, 123, 125; Woodman, J. Amer. (hem. Soc. 1903, 25, 150., Jean, Compt. rend. 1902, 135, 746., J. Pharm. Chim. 1903, 27, 418., Pécoul and Levy, J. Soc. Chem. Ind. 1906, 655., Davies and McLellan, 454d. 1909, 232)

Carbon dioxide is used extensively in the arts for the manufacture of aerated waters, in sugar manufacture for separating lime from the juice of the sugar-cane, in bread making, and for raising

and clarifying beer.

It is also employed for protecting wines from moulds and acetifying organisms. It preserves their aroma and bouquet, and makes the wine fresher, sweeter, and stronger. Wines can also be revivified by the gas (Piaz, J Soc Chem Ind. 1894, 266, 1903, 644, Pini, Bull de l'Assoc. des Chim 1898, 15, 741) It also possesses antisoptic properties and retards the putrefaction of meat (Kolbe, J pr Chem [2] 28, 61) It has also been proposed to use it as a motive power where fuel is expensive (Herbert, Chem. Zentr. 1885, 543, 558, 572)

Mixed with acetylene (about 5-8 pc.), it decreases the smokiness of the flame and prevents the clogging of the burners (J. Gas Lighting,

1898, 72, 916).

Liquid carbon dioxide (Buchner, Zeitsch physikal Chem. 1906, 54, 665) can be obtained in large quantities by an apparatus described by Thilorier (Annalen, 30, 122) Natteier compressed carbon dioxide by a specially constructed air-pump (J pr Chem 35, 169), v also Goie, Phil Trans 1861, 63) It is prepared from bisulphates by the action of carbonates, the apparatus consisting essentially of a leaden vessel containing a solution of the bisulphate and having a stirring apparatus and gear fixed air-tight to it. By means of a tube and pump an equivalent quantity of calcium carbonate (obtained as a waste roduct in the manufacture of caustic soda) suspended in water in a second vessel is forced

in and the stirrer set in motion The liberated carbon dioxide is dried and passed into a gasometer from which it is afterwards condensed. An apparatus is also described which allows the evaporation and expansion of liquid carbon dioxide to take place round a tube containing a solution of calcium chloride. The latter is so cooled that it may be used for the manufacture The carbon dioxide thus used is passed over moist sodium carbonate, converting it into bicarbonate, which may be again used in the carbonic acid manufactory (Thomas, Zeitsch. angew. Chem 1900, 386) (For description and figure of apparatus for hquifying CO2 and for bottles in which it is stored and sold, see Sisson, J Soc. Chem Ind 1904, 242)

Liquid carbon dioxide may be bought in monor steel bottles containing 8 kilos. (about 4000 litres of the gas at ordinary temperature and pressure), costing about 1 shiper kilo. It furnishes the cheapest means for aerating waters, and is used for raising sunken ships, for driving torpedoes, for extinguishing fires, for cooling purposes, and, as 'Pictet's fluid,' for freezing machines, and by the firm of Krupp, in Essen, for the condensation of steel and other metals, and is further suggested as a motive power for traincars and balloons (J. Soc. Chem.

Ind 4, 610)

It is also used for making carbonates and other chemical products, for filtering and sterilising organic liquids (d'Arsonval, Compt. rend. 1891, 112, 667), and in Germany for the generation of pressure on storage casks of beer to the faucets above where the beer is drawn for consumption. In Engineering, Dec. 3, 1903, a description is given of its use in railway signalling in outlying stations, to supply the motive power for working the signals, so as to avoid the expense of compression machinery or of long lengths of connecting pipes.

Liquid carbon dioxide is colourless, very soluble in alcohol, ether, and volatile oils, but does not mix with water. When the pressure is suddenly relieved, part of the carbon dioxide immediately vaporises, producing sufficient cold to solidify the remainder. Landolt allows the liquid to evaporate freely into woollen bags, and compresses the solid carbon ploxide in coincal wooden moulds by wooden pistons (Ber 17, 309), of Purcell (J. Soc Chem Ind 1892, 936, Eng Pat 13684, 1891). A vessel for storing solid carbon dioxide is described by Heyl and Wultze (J. Soc. Chem Ind 1904, 1215, Eng Pat. 344957, 1904)

An apparatus for obtaining small and large quantities of solid carbon dioxide is described by Fechlu (J pr. Chem. 1903, 67, 423, J Soc. Chem. Ind. 1903, 626), also by Elsworthy (J. Soc. Chem. Ind. 1905, 1231). (For an apparatus for collecting solid carbon dioxide, v. Ducietet,

Compt rend 99, 235.)

Solid carbon dioxide is a white, flocculent, snow-like mass, melting at -567° at 5 atmospheres pressure, and may be left exposed to the air for some time without sensible evaporation. An air or spirit thermometer immersed in it sinks to -79°, it can, however, be placed on the hand without any acute sensation of cold. By mixing with ether its refrigerating power is greatly increased. This is denied by Villard and Jerry (l.c.) but the temperature sinks to

-85° when it is mixed with chloroform. The temperature can readily be reduced to  $-90^{\circ}$  by passing a current of air through the mixture. 5 mm pressure the temperature of solid carbon diovide soon falls to  $-125^{\circ}$ .

Magnesium powder burnt in a dish of solid CO<sub>2</sub> deposits carbon (Brunner, Ber 1905, 38,

1432).

#### COMPOUNDS OF CARBON

Carbon tetrabromide or Tetrabrommethane CBr4 White lustrous crystals of a characteristic pungent smell; m.p.  $91^{\circ}$ ; b.p.  $189.5^{\circ}$  with slight decomposition; b.p.  $101^{\circ}$  at 50 mm without decomposition Occurs in two enantiotropic forms (Rothmund, Zeitsch physikal. Chem 1899, 664). Insoluble in water, soluble Best obin alcohol, ether, and chloroform tained by action of bromine on carbon disulphide in presence of iodine (Bolas and Groves, Chem Soc Trans. 1870, 161, 1871, 773)

Carbon tribromide or Hexabromide, Tetrabrommethylene dibromide C2Br6 Small rect angular prisms obtained by action of bromine on ethylene dibromide, or by heating C2HBr5 with bromine and water at 170° Soluble in carbon disulphide; insoluble in alcohol and ether Decomposed at 200° into C<sub>2</sub>Br<sub>4</sub> and Br<sub>2</sub> (Reboul,

Annalen, 124, 271)

Carbon dibromide, Tetrabrommethylene C, Bi White crystals; mp 53°; formed by action of nascent hydrogen on C<sub>2</sub>Br<sub>6</sub> (Lowig, Annalen, 3, 292, Lennox, Chem Soc Trans 1862, 14, 209)

Carbon bromide, Dibromacetylidene C CBr2, b p 76°. Prepared from tetrabromoethane by removal of two molecules of hydrobromic acid Spontaneously inflammable in air and very explosive (Lemoult, Bull Soc chim 1905, 43, It contains a double bond (Lawrie, Amer Chem. J 1906, 36, 487)

Chlortribrommethane (CIBr, Colourless plates, mp 55°, bp 160° Prepared by heating chloroform with bromine at 250°, and retaining fraction distilling at 160° (Besson,

Compt rend 1892, 114, 223

Dichlordibrommethane CCl. Br. Fine needles, m p 22°, b p 135° Obtained from chloroform by action of bromine as above, retaining the fraction of the product boiling at about 135° (Besson, lc).

Trichlorbrommethane CCl<sub>3</sub>Br, mp b.p. 104°. From chloroform and bromine (Besson, lc) From bromine and trichloracetic acid

(J. H van't Hoff, Bet. 1877, 678)

Chlorotribromethylene CCIBr ('Br<sub>2</sub>; mp  $34^{\circ}$ , bp  $203^{\circ}$ – $205^{\circ}$  at 734 mm (Denzel,  $\psi_{ij}$ ) 1879, 2208)

aa-dichloro- $\beta\beta$ -dibromoethylene  $CCl_2 \cdot CBl_2$ , b p 194° (Bourgoin, Bull Soc chim 1875, 116, and Denzel, Annalen, 1879, 208).

 $\alpha\beta$ -dichloro- $\alpha\beta$ -dibromoethylene CCIBr CCIBr, b.p. 172° at 765 mm. (Swarts, Chem Zentr 1899,

i. 588).

Trichlorobromoethylene CCl<sub>2</sub> CClBr, mp -12° to -13°, bp 145°-148° (Besson, Compt rend. 1894, 119, 88)

Chloropentabromoethane C<sub>2</sub>ClBr<sub>5</sub>, m p. 170°

Denzel, Ber 1879, 2207)

#### aa-dichloro- $a\beta\beta\beta$ -tetrabromoethane CCl, Br CBr,

Colourless crystals; m.p 180° (Denzel, Ber 1879, 2207).

# $\alpha\beta$ -dichloro- $\alpha\alpha\beta\beta$ -tetrabromoethane CClBr. CClBr.

m p 191° (Swarts Chem. Zentr. 1899, [1] 588)  $\alpha\beta\beta$ -trichloro- $\alpha\alpha\beta$ -tribromoethane

CClBr, CCl, Br

m p. 178°-180° (Besson, Compt. rend 1894, 88).  $\alpha\beta\beta\beta$ -tetrachloro- $\alpha\alpha$ -dibromoethane

CClBr<sub>2</sub>·CCl<sub>3</sub>

Prisms from alcohol, smells like camphor. May be sublimed (Paternò, Gazz chim ital. I, 593, Bourgoin, Bull Soc. chim [2] 23, 4, Gossner, Chem Zentr 1903, n 1053)

 $aa\beta\beta$ -tetrachloro- $a\beta$ -dibromoethane

CCl<sub>2</sub>Br·CCl<sub>2</sub>Br

Tables from alcohol (Malaguti, Ann Chim Phys.

1846, 24, Gossner, Chem Zentr 1903, n. 1053).

Fluorotribromomethane CBr<sub>3</sub>F, a colourless, heavy, pleasant-smelling liquid, b p 107°/760 mm, obtained by heating carbon tetrabromide at 50°-60° with silver fluoride

Difluorodibromomethane CBr<sub>2</sub>F<sub>2</sub>, a mobile hquid, b p. 24  $5^{\circ}/760$  mm, mp below  $-80^{\circ}$ formed by the action of the preceding compound on silver fluoride (Rathsburg, Ber 1918, 51,

Carbon tetrachloride or Tetrachlormethane CCl<sub>4</sub> was first obtained by Regnault (Annalen, 1840, [33] 332), who prepared it by the action of chlorine on chlorform in sunshine

 $\mathrm{CHCl_3} + \mathrm{Cl_2} - \mathrm{HCl} + \mathrm{CCl_4}$ 

Dumas afterwards obtained it by the action of chlorine upon marsh gas (Annalen, 1840, [33] 187) It can also be prepared by passing carbon disulphide saturated with chlorine through a The mixture of carbon tetrared-hot tube chloride and sulphur chloride thus obtained is treated with potash or milk of lime and the tetrachloride distilled off (Kolbe, Annalen, 1843, 45, 41, 1845, 51, 146) The tetrachloride may contain carbon disulphide if that substance was in excess, or if the heat was insufficient may be removed by leaving the liquid for some time in contact with potash Geuther removes the carbon disulphide by converting it into potassium xanthate by dissolving the mixture in alcohol, adding alcoholic potash so long as the liquid becomes darker in colour, and heating gently, the unaltered tetrachloride is separated by water and purified by washing (Geuther, Annalen, 1858, 107, 212, and Selmitz-Dumont, Chem Zentr. 1897, n 265).

The complete chlorination of carbon disulphide and of many other carbon compounds can be more readily accomplished in the presence of a chlorine carrier Thus, in the case of carbon disulphide, bromine has been used (Crump, Chem News, 1886, 14, 154) and nodine, both alone (Morel, Compt. rend. 1877, 84, 1460) and in the presence of metallic iron (Serra, Chem. Xentr. 1899, 11. 1098) · antimony pentachloride reacts with carbon disulphide alone, without the addition of chlorine. The mixture becomes hot, and on cooling deposits crystals of antimony trichloride mixed with sulphur, whilst carbon tetrachloride remains in solution (Hofmann, Annalen, 1860, 115, 264)

A large number of other substances can be used as catalytic agents, e.g. molybdenum pentachloride (Aronheim, Ber. 1876, 1788), the chlorides of phosphorus and arsenic, and also a

series of chlorides of metals, especially those of the iron group. In the presence of these substances, sulphur chloride reacts readily with carbon and excess of chlorine, giving carbon tetrachloride A stream of chlorine is led over a red-hot mixture of charcoal and sulphur Carbon disulphide is first formed, then carbon tetrachloride and sulphur monochloride, the latter then breaks up into chlorine and sulphur, and the process begins over again The carbon tetrachloride prepared in this way is usually contaminated with sulphur chlorides and chlorethane compounds (Combes, Chem Zentr 1909, 1, 326, J Soc Chem Ind 1902, 272 and 1469) In the presence of manganese chloride the reaction can be carried out with precipitation of sulphur, which can be used to manufacture more carbon disulphide (Côte and Pierron, *ibid* 1903, 962. Febvre, *ibid* 1905, 1189) Other carbon compounds beside carbon disulphide can be completely chlorinated. Thus chloroform heated with iodine chloride at 165° gives carbon tetrachloride (Friedel and Silva, Bull Soc chim 1872, 537), the same reaction taking place, to a slight extent, in the presence of aluminium trichloride instead of iodine chloride (Monneyrat, ibid 1898, 262)

Perchlormethyl formate, when treated with aluminum chloride in the proportion of 50 parts to 1 of chloride, also yields carbon tetrachloride CClO<sub>2</sub> CCl<sub>3</sub>=CCl<sub>4</sub>+CO<sub>2</sub> (Hentschel,

J. pr Chem 1877, 306)

The technical preparation of carbon tetrachloride is generally carried out by the direct chlorination of carbon disulphide in the presence of powdered aluminium chloride, the quantity of catalyst necessary being only about 1 p c of the carbon disulphide used

$$CS_2+3CI_2 = CCI_4+S_2CI_2$$

The sulphur chloride reacts separately with more carbon disulphide in the presence of iron filings, and the crystalline sulphui which is formed is employed again in the manufacture of carbon disulphide (Urbain, Chem Zeit 1902, 1086; Breteau, J Pharm Chim 1908, 110, Urbain, J Soc Chem Ind 1902, 926, Eng Pat 13733)

Later modifications of the process consist in the further chlorination of the sulphur monochloride, in the presence of antimony chloride, before treatment with carbon disulphide (Haworth and Baker, J. Soc. Chem. Ind. 1906, 559), and the use of a solution of sulphur in sulphur monochloride, in a finely divided condition, as a chlorine carrier (Acker and Strue, ibid. 1908, 833). Instead of aluminum chloride, aluminum amalgam has been employed (Castner Co. ibid. 1905, 903). Under this patent, the resulting carbon tetrachloride is purified by treatment with a solution of alkaline sulphide containing free alkali, the carbon disulphide being removed as thiocarbonate (cf. Dow Chemical Co. U.S. Pat. 1204608; J. Soc. Chem. Ind. 1916, 35, 1271)

The Isco Chemical Co (US Pats. 1260621 and 1260622) treat carbon disulphide containing free sulphur with chlorine in presence of a catalyst to form sulphur dichloride and carbon tetrachloride, and an additional quantity of carbon disulphide is then added to convert the sulphur dichloride into sulphur monochloride,

with the formation of more carbon tetrachloride. The product is treated with sufficient tin to convert the sulphur monochloride into sulphur, with the formation of stannic chloride, and after separating the sulphur, water is added to hydrate the stannic chloride, and the carbon tetrachloride is recovered from the mixture by distillation.

A number of electric-heating processes have been suggested A mixture of sodium chloride and silica is heated in the lowest portion of a furnace lined with magnesia, and provided with three sets of electrodes, one above the other The middle electrodes heat a mass of coke, and the chlorine from the alkali chloride reacts with the incandescent carbon, forming carbon tetrachloride, which, after passing through the ares between the third set of electrodes, is distilled off The temperature does not exceed 2000° (Machalske and Lyon, J Soc Chem Ind 1903, 1298, Machalske, Chem Zentr. 1904, 1, 1069) The chlorine can also be supplied from an external source, the carbon only being heated by electricity (Maywald, J Soc Chem Ind 1907, 1253)

Another process consists in heating together hime, calcium chloride, and carbon in the absence of air in an electric furnace, in the proportions indicated by the equation

$$2\text{CaO} + 2\text{CaCl}_2 + 10\text{C} - 4\text{CaC}_2 + 2\text{COCl}_2$$

The carbonyl chloride is led over heated coke, animal charcoal, or pumice, where it is decomposed into carbon tetrachloride and carbon doxide by surface contact (Machalske and Darlington, J Soc Chem Ind 1906, 559)

A mixture of calcium chloride and coke, heated in the electric furnace in a stream of chlorine, also yields carbon tetrachloride (Matthews and Darlington, *ibid* 1906, 1232)

The halogenation of metallic or other carbides, such as acetylene, also yields carbon halides, so long as the temperature is kept below the dissociation point of the halide required (Blackmore, *ibid* 1908, 712)

Carbon tetrachloride is a transparent colourless liquid, with a pungent aromatic odour; mp — 22 7°, bp 76 74°, and spgr 1 63195, 0°/4° (Thorpe, Chem Soc Trans 1880, 201); 76 96° (corr) (Thorpe and Rodger); (Moles, Anal. Fis Quim 1912, 10, 30). Its specific heat increases regularly from 0 2010 at 0° to 0 2031 at 70° The specific heat of the vapour falls from 0 14 at 0° to 0 115 at 70° (Mills and MacRae, J Physical Chem 1911, 15, 54)

The vapour pressure of carbon tetrachloride has been measured by Schreinemakers (Zeitsch physikal Chem 1904, 48, 445). The compressibility has been measured by Richards and Stull (Amer. Chem J. 1904, 26, 408). In the solid state carbon tetrachloride is trimorphous, the three modifications melting at  $-28~6^{\circ}$ ,  $-23.77^{\circ}$ , and  $-21~2^{\circ}$  respectively, the second being the form usually obtained (Tammann, W. Ann. 1898, 480) The refractive index for the line F is 14726, and for the line D is 14658 (Gladstone, Chem Soc Trans 1886, 623).

Its dielectric constant has been measured by Turner (Zeitsch. physikal. Chem. 1900, 385), Drude (Zeitsch. physikal. Chem. 23, 267), and Veley (Phil. Mag. [6] 11, 73). Its solubility in water, which is extremely small,

has been measured by Rex (Zeitsch. physikal. Chem. 55, 355).

It is soluble in alcohol and ether, and dissolves a large number of organic substances, especially those of a fatty nature, whence its wide application in the arts. It is preferable to carbon disulphide on account of its non-inflammability. With sulphonated oils and resins it yields a gelatinous soap, which is miscible with water (Stockhausen, Chem. Zentr. 1906, ii. 731). It yields chlorine and lower chlorides of carbon on passing through a red-hot tube (Regnault, lc). When mixed with hydrogen and passed through a red-hot tube with pumice, it yields marsh gas and ethylene (Berthelot, Ann. Chim. Phys. 1858, 53, 69).

Phys 1858, 53, 69).

The same mixture passed over reduced nickel yields hexachlorethane (carbon truchloride) at 270°. With excess of hydrogen at the same temperature, tetrachlorethylene (carbon dichloride) is obtained (Sabatier and Mailhe, Compt.

rend 1904, 138, 407)

Mixed with sulphuretted hydrogen and passed through a red-hot tube, the vapour of carbon tetrachloride yields hydrochloric acid and carbon sulphochloride CSCl<sub>2</sub> (Kolbe, Annalen, 1843, 45, 41, and 1845, 54, 146)

Heated under pressure with oxygen and water at 250°, it forms carbonyl chloride and carbon dioxide (Goldschmidt, Ber 1881, [14] 928). In alcoholic solution, and treated with potassium amalgam, it yields chloroform, marsh gas, and methylene chloride (Regnault, *l.c.*) Phosphorus pentoxide at 200° acts in two ways in the first, carbonyl chloride and carbon dioxide are produced, in the second, in the presence of more phosphorus pentoxide, carbon dioxide alone is obtained.

$$\begin{array}{c} 2\text{CCl}_4 + \text{P}_2\text{O}_5 = \text{COCl}_2 + \text{CO}_2 + 2\text{POCl}_3 \\ 3\text{CCl}_4 + 2\text{P}_2\text{O}_5 = 3\text{CO}_2 + 4\text{POCl}_3 \end{array}$$

(Gustavson, Zeitsch, f. Chem. 1871, 615).

A similar reaction takes place at 100° with sulphur trioxide, carbonyl chloride being formed

$$CCl_4 + 2SQ_3 = S_2Cl_2Q_5 + COCl_2$$

(Erdmann, Ber. 1893, 26, 1993).

With the oxides of many metals, a similar production of carbonyl chloride, together with carbon droxide and the chloride of the metal, takes place (Demarcay, Compt. rend. 1887, 104, 111; Quantin, *ibid.* 1887, 104, 223, 1888, 106, 1074; Delafontaine and Linebarger, Amer Chem. J. 1896, 532).

With zine and dilute acid, carbon tetrachloride is converted into hydrochloric acid and chloroform (Geuther, \$lc\$). Alcoholic potash slowly converts it into potassium chloride and carbonate (Regnault, \$lc\$). By long-continued action at 100° in sealed tubes, alcoholic potash converts it partially into ethylene (Berthelot, Ann. Chim Phys 1859, 109, 118) With alcoholic potash and aniline it yields phenylsocyanide (cf. Chloroform). With phenylamine it yields diphenylaminobenzamide (Hofmann, Proc. Roy. Soc. 9, 284, and 10, 184, Wieth, Ber. 1877, 10, 358; Michler and Walder, Ber. 1881, 14. 2174), a reaction facilitated in presence of a coppermercury couple (Hartung, Chem. Soc. Trans. 1918, 113, 163). By the action of sulphur at 220°, a number of sulphochlorides of carbon disulphide (Klason, Ber. 1887, 20, 2376). It is

decomposed at 200° by molecular silver, being converted into hexachlorethane  $C_2Cl_6$  (Goldschmidt, Ber. 1881, 14, 927). By heating with aluminium bromide it is readily converted into carbon tetrabromide (Gustavson, Bull. Soc. chim. 1881, 556).

Heated in a sealed tube for 10 hours at 130° with hydrodic acid, carbon tetrachloride yields iodoform and hydrochloric acid (Walfisz, *ibid* 1893, 7, 256) Acetylene reacts with carbon tetrachloride, yielding free carbon in a very finely divided form, hydrochloric acid being formed at the same time (Sandman, Chem Soc Abstr. 1902, 82, 1–581) Carbon tetrachloride reacts with benzene in the presence of aluminium trichloride, giving, as chief product, diphenyldichloromethane, CCl<sub>2</sub>(C<sub>6</sub>H<sub>b</sub>)<sub>2</sub> (Boeseken, Chem Soc Abstr 94, 1, 189) Carbon tetrachloride absorbs ozone, giving a blue solution

In its physiological action, carbon tetrachloride strongly resembles chloroform.

Its popularity as a solvent in the arts has been somewhat diminished by the increasing manufacture of tetrachlorethane C<sub>2</sub>Cl<sub>4</sub>H<sub>2</sub>, as the latter is more indifferent toward metals, and is readily produced by the action of chlorine on a double compound of antimony pentachloride and acetylene (D. R. P. 154657, 1906).

Carbon trichloride, Carbon hexachloride, Tetrachlorethylene dichloride, Hexachlorethane, Perchlorethane C.Cl<sub>8</sub>, discovered by Faraday (Phil. Trans 1821, 47), also investigated by Regnault (Ann Chim Phys 1838, [2] 69, 166, and 1839, [2] 71, 371) Is obtained by the action of chlorine in sunshine upon various derivatives of ethyl and ethylene, on carbon dichloride, on ethylene chloride (Faraday, lc), and also (Liebig, Annalen, 1, 219) on ethyl chloride, first in the shade, afterwards in sunshine (Laurent, Ann. Chim Phys 1837, [2] 64, 328), on mono-, di-, or tri-chlorinated ethyl chloride (Regnault, lc), on ethyl sulphite (Ebelmen and Bouquet, ibid. 1846, [3] 17, 66), on ethyl oxide (Regnault); on hydrochloride of ethylamine (Geuther and Hofacker, Annalen, 1858, 108, 51) (in this process some chloride of nitrogen is produced), by passing the tetrachloride through a red-hot tube (Kolbe, Annalen, 1845, 54, 147), by distilling perchlorethylic oxide, and repeatedly treating the distillate with water (Malaguti, Ann Chim. Phys 1846, [3] 16, 14), by heating carbon tetrachloride with copper powder at 120° (Radziszewski, Ber. 1887, 17, 834) or with molecular silver at 200° (Goldschmidt, ibid. 1881, 14, 928), by heating acetyl chloride with excess of phosphorus pentachloride at 180° (Hubner and Muller, Zeitsch f Chem. 1870, 328); by heating propyl chloride or isobutyl chloride with iodine trichloride at 200° (Krafft and Merz, Ber. 1875, 8, 1298), by treating pentachlorethylchloroformic ester with aluminium chloride (Muller, Annalen, 1890, 258, 63).

Carbon trichloride crystallises from a mixture of alcohol and ether in right rhombic prisms (Gossner, Chem Zentr 1903, ii. 1052). Colour-less, transparent, and nearly tasteless, but having an aromatic odour resembling that of camphor, sp. gr. 20; mp. 184°-186° (Bolton, Zeitsch. Elektrochem. 1902, 8, 165; 1903, 9, 209), volatilising even at ordinary temperatures; b.p. 185° (Hahn, Ber 1878, II, 1735). Insoluble in water; soluble in alcohol and ether,

and in all oils. Converted, by repeated distillation, into the dichloride and free chlorine. Burns with a red light in the flame of a spirit lamp. Mixed with hydrogen and passed through a red-hot tube, it yields dichloride and hydrochloric acid (Geuther, l.c.) Metals heated in its vapour form metallic chlorides, chaicoal being deposited. Heated in sealed tubes with potassium hydroxide, it yields potassium oxalate and chloride

$$C_2Cl_6 + 8KHO = K_2C_2O_4 + 6KCl + 4H_2O$$

(Geuther, J. 1859, 277) The same products together with hydrogen and ethylene are formed when it is heated with alcoholic potash in sealed tubes (Berthelot, Annalen, 1859, 109, 118).

Reducing agents such as zinc and dilute sulphuric acid, or alcoholic potassium hydrogen sulphide (Regnault, lc), reduce it to tetrachlorethylene (carbon dichloride). The same reaction takes place when it is heated with silver at 280°. Sulphur trioxide acts upon it at 150° according to the equation

 $CCl_3 CCl_3 + 2SO_3 = CCl_3 COCl + S_2O_5Cl_2$ (Prudhomme, Annalen, 1870, 156, 342)

Carbon dichloride, Tetrachlorethylene C2(14 (Faraday, Phil Trans 1821, 47, Regnault, Ann Chim Phys 1839, [2] 70, [2] 71, 372), is formed as a liquid coloured with chlorine when the vapour of carbon trichloride is passed through a red-hot tube filled with fragments of glass. It is purified by passing it repeatedly through a red-hot tube, then shaking up with mercury and rectifying at a low temperature (Faraday) More easily obtained by adding carbon trichloride in small portions to an alcoholic solution of hydrogen potassium sulphide, as long as sulphuretted hydrogen is given off. The liquid is distilled and carbon dichloride separates from the distillate on dilution with water (Regnault, l.c); or by reduction of carbon trichloride with zinc and sulphuric acid Mobile liquid of sp gr 1 619 at 20° (Regnault), 1 612 at 10° (Geuther). b p 122° (Regnault), 116° (Geuther), 120 74° (corr.); sp gi 1 6551 0°/4° (Thorpe and Rodger), remains liquid at -18°, and does not conduct electricity Insoluble in water, acids, and alkalis, but dissolves in alcohol and other, and Decomposed at a red heat into the oils hexaclorobenzene C<sub>6</sub>Cl<sub>6</sub> and free chlorine When its vapour is passed over baryta at a red heat, it is decomposed with vivid ignition into barium chloride, carbon dioxide, and charcoal It absorbs bromine in the sunshine, forming carbon chlorol romide C<sub>2</sub>Cl<sub>4</sub>Br<sub>2</sub> It is converted by continued heating to 200° with potassium hydroxide into potassium oxalate and chloride, hydrogen being given off (Geuther, Annalen, 247) It absorbs dry chlorine in sunshine, forming the trichloride, but is converted into trichloracetic acid when exposed to an atmosphere of chlorine under water

$$\mathrm{C_2Cl_4} + 2\mathrm{H_2O} + \mathrm{Cl_2} = 3\mathrm{HCl} + \mathrm{C_2HCl_3O_2}$$

(Kolbe, Annalen, 1845, 54, 181)

as-Heptachloropropane  $C_5Cl_{10}$ , a crystalline substance, mp 32°, formed by the action of phosphorus pentachloride on pentachloroacetone; also obtained by the direct addition of chloroform to tetrachloroethylene under the influence of aluminium chloride (Boeseken and Prins).

Hexchlorobenzene C<sub>6</sub>Cl<sub>6</sub>, m p. 225°; discovered in 1821 by Julin and investigated by Phillips and Faraday (Phil. Trans 1821), and by Regnault (Ann. Chim. Phys. [2] 70, 144), who prepared it by passing the vapour of chloroform or tetrachlorethylene through a porcelam tube filled with fragments of porcelam and heated to redness Obtained from methylene chloride by ICl or ICl<sub>3</sub> (Holand, Annalen, 240, 234), the crystalline product is dissolved in ether, filtered, evaporated to dryness, and sublimed. Obtained by Hugo Muller as a final product of the action of antimony pentachloride or chlorine in presence of rodine on It is also obtained by sending a benzene. current of 5 5 amperes and 42 volts for ½ hour between carbon electrodes in an atmosphere of If a higher current and voltage are used, and it is continued for much longer, the trichloride C2Cl8 is formed Bromine yields similar compounds (Bolton,  $l \epsilon$ .). Forms white delicate needles with a silky lustre, tasteless, but with an odour resembling spermaceti. sublimes without fusion at 120°.

Insoluble in water, acids, and alkalis, but soluble in alcohol, ether, and hot oil of turpentine. Decomposed into chlorine and charcoal on passing through a red-hot porcelain tube filled with glass or rock crystal. Burns with a bluish colour in the flame Potassium burns on being strongly heated in its vapour Formerly regarded as carbon monochloride: molecular formula established by Bassett (Chem Soc. Trans. [2] 5, 443)

Carbon tetraiodide, Tetraiodomethane Cl<sub>4</sub>
Dark-red octahedra, sp gr 4 32, obtained by action of aluminium rodide on a mixture of carbon tetrachloride and disulphide (Gustavson, Ber 14, 1705) For other methods, see Spindler, Annalen, 231, 257, Moissan, Compt. rend 113, 19, Robineau and Rollin, Chem. Centr. 1894, 1 1140, Lantenois, Compt rend. 1913, 156, 1385.

Carbon nitride (v. Cyanogen, art. Cyanides) Carbon subnitride C<sub>4</sub>N<sub>2</sub> has been obtained by Moureu and Bongrand (Compt rend 1910, 150, 225) by removing two molecules of water from the diamide of acetylene dicarboxylic acid CONH<sub>2</sub>C CCONH<sub>2</sub>=N: CC:CC:N+2H<sub>4</sub>O. It forms fine white needles. mp 20 5°-21°, bp 76° at 753 mm, and its vapour has an odour and an irritating action resembling that of cyanogen. It is readily combustible, and takes fire spontaneously at 130°, burning with a puiple flame, also resembling that of cyanogen. It has an abnormally high molecular refraction and dispersion, and a density of 0 9703 at 25°/4° For its behaviour towards ammonia and amines, see Moureu and Bongrand, Compt. rend. 1914, 158, 1092.

Carbon oxychloride COCl<sub>2</sub>, Carbonyl dichloride, Chlorocarbonic acid, Phosgene gas. First obtained by J Davy by action of sunlight on mixture of carbon monoxide and chlorine. (For details of this mode of preparing it, r. Emmeling and Lengyel, Annalen Suppl 7, 101, and Wilm and Wischin, ibid. 147, 450.) By passing the gases over heated animal charcoal combination occurs in the dark. Also obtained by passing carbon monoxide into boiling antimony pentachloride (Hofmann, ibid. 70, 129; Butle row, Zeitsch. f. Chem. 1863, 484; Kraut,

Gm.-K. I 2, 380); by heating carbon tetrachloride with zinc oxide in closed tubes at 200° or by mutual action of carbon tetrachloride and carbon monoxide at 400°, or by heating a mixture of chloroform, potassium dichromate, and sulphuric acid (cf Plotnikow, J. Russ. Phys. Chem Soc 1916, 48, 457)

Carbon oxychloride is a colourless liquid, boiling at 82°, and of sp gr. 14320/4°. Soluble in acetic acid and benzene, decomposed by water  $COCl_2 + H_2O = CO_2 + 2HCl$  With alcohol forms chlorocarbonic ester Cl COOC 2H 5 bines with ammonia to form urea and ammonium chloride With aniline it forms diphenyl-Its presence in air may be detected by this reaction (Kling and Schmutz, Compt. rend.

1919, 168, 773)

Carbonyl cyanide CO(CN)2 is a yellow amorphous non-volatile solid, formed by subjecting a mixture of carbon monoxide and cyanogen to the ultra-violet rays from a mercury-quartz lamp It dissolves in alkalis, forming a yellow solution, and slowly hydrolyses on the addition of acid, giving carbon dioxide and hydrogen cyanide (D. Berthelot and Gaudechon, Compt. rend 1913, 156, 1766)

Carbon disulphide, Throcarbonic anhydride, Sulphocarbonic and CS, This compound was discovered by Lampadius, in 1796, by heating pyrites with charcoal Clement and Desormes, in 1802, in examining the action of sulphur on red-hot charcoal, obtained the same product

Its nature was established by Vauquelin.

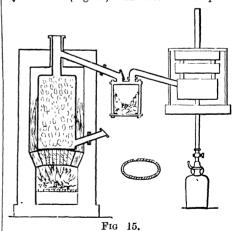

Manufacture—Schrotter in Germany, and Peroncel in France, first prepared carbon disulphide on a manufacturing scale Schrotter employed a cylinder of Hessian clay in which the charcoal was heated, the sulphur was introduced through a hole near the bottom, to the upper end was fixed an exit tube for the vapour of the carbon disulphide formed The apparatus produced about 20 kilos of the disulphide in 12 hours

Deiss and Fisher employed cast-iron cylinders in which the vapour of sulphur passed over charcoal heated to redness Fireclay retorts glazed internally to prevent the escape of vapour through the pores were also used, each cylinder was about 5 feet high and nearly 20 inches diameter Four retorts were arranged in a single furnace in such a way that the flame of the fire could play entirely round Each retort was divided internally into two parts by means of a perforated shelf, the upper compartment, which was the larger of the two, served to contain the charcoal, which could be thrown in through a special opening in the lid without interrupting the working. A second opening in the top of the retort was provided with a tube about 2 mehes in diameter, which led directly into the lower compartment, and was used to throw in sulphur as required The vapour of carbon disulphide which was formed during the process was conducted through a delivery pipe connected with a third opening in the retort into the condensers four retorts, having been filled with charcoal and the lids closed, were heated to redness by a coal Pieces of sulphur wrapped in cylindrical paper packets were then dropped in the pipes leading to the lower partitions of the retorts Two such packets, each containing about 51 oz. of sulphur, were thrown in at intervals of

about 3 minutes, the opening at the end of each tube being closed at each successive addi-The charcoal was renewed every 7 hours, and was heated about an hour and three-quarters each time before the necessary temperature was attained for its combination The vapour of carbon disulphide with sulphui mixed with that of sulphur escaped through the delivery tubes, passing into the first row of condensers, where it was partially condensed, together with some sulphur, the undissolved sulphur was recovered and used over again. Thence the uncondensed vapours passed on into the second row of condensers, and so on till the The condensers, amounting to 18 or 20 m all, were connected together by pipes, the last of which was connected with the chimney of the works, or better, with vessels or tubes containing layers of pulverised lime to absorb the sulphuretted hydrogen which would otherwise create a nuisance in the neighbourhood of the factory

The condensers were made of sheet zinc, were cylindrical in shape and about 26 inches in diameter, bottomless, with slotted sides, and stood in a kind of shallow cistern containing water a little deeper than the openings, so as to form a water lute, permitting the passage of the condensed liquid while closing the exit against vapours. The lids of these condensers were furnished with rims forming a kind of saucer, containing water to assist in the condensation of Each hid had two openings in the the vapour form of tubulures, into which the pipes were fixed for the transmission of the vapours from condenser to condenser

Gérard employed a vessel of cast iron 63 feet in height, about 4 feet 8 inches in diameter, and sides 13 inch thick (Fig. 15). The retort was elliptical

in section, stood upon a brickwork arch, and was heated from below by a fire. Near the bottom was a pipe fitted with a valve, through which sulphur could be introduced into the cylinder. At the upper extremity was a wide pipe which could be closed with a lid, and served for the introduction of charcoal into the apparatus. Another pipe, cast in one piece with the upper one, sloped forward and passed into a receiver in which the sulphur which passed over during the

operation was condensed, and could be easily removed by opening a valve in a tubulus placed at a bend in the pipe; the more volatile carbon disulphide passed forward into the condensers. The condenser consisted of three vessels, cylindrical in form, arranged one above the other, and communicating by vertical pipes. The topmost condenser had an exit pipe for sulphuretted hydrogen, &c, and the condensed carbon disulphide could be drawn off into a receiving vessel beneath by opening a cock in a pipe proceeding from the lower condenser.

The three condensess were contained in a tank 5 feet high and 5 feet wide, filled with water,

which could be renewed at pleasure

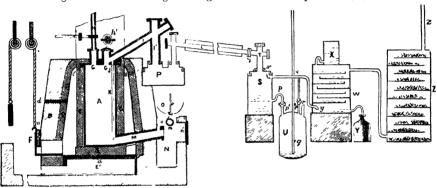

The sulphur was added in portions of about 3 lbs at intervals of 3 minutes. The oven was heated during the night to volatilise the sulphur, and the residual charcoal was added to the new charge. This apparatus yielded in 24 hours about 570 lbs of carbon disulphide, consisting theoretically of 480 lbs of sulphur and 90 lbs of carbon, in practice 530 lbs of sulphur and 242 lbs of wood charcoal were used. Gerard found it advantageous to surround the generating

vessels with brickwork, which rendered them more durable.

Only retorts of a certain size could be employed, as, when they were too large, the heating was megular, causing waste of sulphur. When using unrefined sulphur, the retorts needed cleaning every fortnight, but with purified sulphur they could be kept working for two months

The present mode of manufacture is thus described by Ignatius Singer (J. Soc. Chem. Ind. 8, 1889, 83) (see Fig. 16).

A is a vertical east-non retoit, or, better still, made of earthenware, glazed inside, of elliptical shape, about 66 inches high, and 20 by 12 inches internal diameter. It rests on a support, B, made of firebricks, and is protected by a mantle of best firebricks, C, about 4 inches thick, leaving a space of from ½ to ¼ inch between it and the retoit. The metal of the retoit should not be less than 2 inches in thickness. D is the outer brickwork of the furnace lined on the miside with firebricks, D', E, E, fire-grates, E', ash pits, F, furnace doors, made of frames, a, into which a lire-proof slab, b, is inserted. The

F10 16.

furnace doors are suspended by cables running over pulleys, and are counterpoised, so that they can be raised or lowered At d is shown a small peep-hole, through which the temperature in the furnace may be watched. In the lid of the retort are cast two tubes, a and a', of about 5 inches internal diameter and not less than 1 inch in thickness, but it is advisable to have them made somewhat stronger, as the lid will then outlast several retorts Over the openings, G, a vent-pipe or flue, H, is suspended by a lever, so that it can be raised or lowered at will, one end of which passes through the roof fresh charges of charcoal are to be introduced into the generator A, which is done through the tubulure a', the lid closing the tube a is first removed, and the vent-pipe H quickly lowered, which serves the purpose of carrying off the noxious gases that would otherwise be injurious to the workmen G' may now be opened, and the carbon fed in without the slightest inconvenience

From the tubulure g' issues a pipe, I, inclined upwards, through which the disulphide of carbon vapours escape. Most of the free sulphur passing over will condense here and run back into the retort. But the partially cooled sulphur

falling on to the surface of the incandescent carbon would be immediately vapourised again, at the same time cooling down the top layer of the charcoal. To obviate this, Singer suggests that an opening should be made in the lower part of the pipe I, to which a hopper can be fitted, as shown at J, terminating in an earthernware pipe K, reaching nearly to the bottom of the retort. By this means the sulphur distilling over uncombined would be conducted back to the bottom of the generator, the pipes would be loss liable to be choked up, while the resulting product would be purer

From the lower end of the retort, close to the bottom, a pipe M branches off, a little upwards inclined, passing through the brickwork and terminating in a chamber N, with door n During work this pipe is carefully closed by a lid. It serves the purpose of raking the ashes out of the retort, which is done once a week. At m a flue is shown, carrying the noxious gases into the chimney. The ashes are allowed to cool here before their removal Adjoining this chamber is a hearth into which an iron vessel, O, is fitted, for melting the sulphur. It is heated by a flue from the furnace passing underneath it, provided with a damper

to regulate the heat. (In Fig. 16 this sulphur vessel is raised so as to make it visible in the drawing) A pipe, o', closed by a conical valve to which an iron rod, o, is attached, connects the sulphur pot with the arm M of the retort, by which means the sulphur can conveniently be

introduced into the latter

The sulphur flowing down the incline of the arm M arrives at the bottom of the retort, where it is volatilised: the vapours, passing upwards, combine with the carbon. The generated disulphide vapours escape through pipe I, and then pass down the vertical tube I' into a vessel P, where any excess of sulphur is deposited. The lid of this vessel rests in hydraulic seals, and is connected with the inlet and outlet pipes by a kind of telescopic tube made air-tight by water. When the vessel P is to be removed, the lid is raised, the vessel taken away, another similar one put in its place, and the hid lowered again. This should be done once a week only, and never while distillation is going on.

The carbon disulphide vapours, now freed from the greater part of uncombined sulphui, pass through a Liebig's condenser, L, about 30 feet long, into a receiver, s, partially filled The crosspiece T, connecting the with water Liebig's condenser with the receiver, is made so that it can be detached—being secured at v by flanges bolted together, and at n1 by water seal-for purposes of cleaning, &c. From here the disulphide is allowed to run through a siphon, p, direct to the storage tanks A better plan, however, is to keep the storage tanks for the crude product on a high level, which greatly facilitates the after-process of purification. this case the disulphide of carbon is allowed to flow into a montejus, v, as shown in drawing, A pipe q, reaching nearly to the bottom, is passed through the cover of the montejus to the high-level tank. A second pipe, r, connects the vessel u with a force-pump On air being pumped into v through r, the stop-cocks  $p^1$  and p<sup>2</sup> having been shut off, the disulphide is pressed up through pipe q into the tank. This is a far better method than using pumps, as in the latter it is difficult to prevent leakage, the ciude disulphide having a very corrosive action on most metals. For the same reason, the receivers, tanks, &c., for the crude substance should all be lined with sheet-lead, as wrought-iron vessels soon perish, while copper is even more energetically acted upon. Cast iron withstands corrosion much better, but is objectionable on account of its porosity This might be remedied, however, by giving the vessels repeated coatings of dilute silicate of soda, both inside and outside, the vessels being first slightly heated with

steam and the silicate applied while warm

Near to the top of the receiver s is a pipe, s, for carrying off the uncondensable vapours—chiefly sulphuretted hydrogen. The gases are conducted into a rectangular vessel, w, where they are made to circulate in zigzag over a series of shallow trays filled with a vegetable oil, to absorb any disulphide vapours which have escaped condensation. The oil can be made to trickle from a reservoir, x, as shown, through a goosenecked pipe, which, passing from tray to tray in an opposite course to that of the gases, finally trickles through x into a receiver Y. When a sufficient quantity has accumulated here, the

disulphide is distilled off and the oil returned to x. Before the gases enter this absorber they are 'washed' by making the end of the pipe s dip into the oil as shown at y whereby the apparatus is disconnected from contact with air. The gases are now passed through a second vessel, z, similar in construction to the one just described, only substituting lime or oxide of iron for the oil, to absorb the  $H_2S$ , and are then allowed to escape

into the open air through the pipe z.

Above the retort A, and between it and the chimney, set at right angles to each other, is a smaller retort, similar in construction to A, but only about one-third the capacity of the latter, and is heated by causing the products of combustion coming from the furnace to circulate round it before finally passing into the chimney (Only the discharge hole h', corresponding to the arm m of the retort A, is visible in the drawing.) As the generator a requires fresh charges of carbon every 8 hours, it is very economical to keep this small retort always filled with charcoal, which by the time it is required will be red hot, and no more time need be lost than is required for transferring it from the one into the other By this arrangement, part of what would otherwise be waste heat is utilised, and a great saving in time and fuel effected. A still better plan is to make the charcoal on the spot, E hours being more than sufficient to char the wood and to heat it up to bright redness. Spent dyewoods, tanner's refuse, or sawdust, are excellent for the purpose, and as these would not require crushing as when charcoal is bought in lumps—a saving in labour, possibly also in money, might be made, besides being more cleanly. By a small outlay, the vapours might be condensed, and pyroligneous acid obtained as

a by-product
The apparatus is worked as follows. After having allowed the brickwork to set and partially dry for a few days, the fires are started, at first gently, to prevent the brickwork from cracking, then gradually increasing the heat until the retort becomes a dull-red colour. The latter is now filled with small charcoal, and the smaller retort with chips, sawdust, &c., and the fires are now urged until the retort and the charcoal in it have become a 'cherry red'. This heat should never be exceeded, nor should it be allowed to fall below this, as in either case it would result

in a lesser yield of carbon disulphide When the proper temperature is attained, the two openings in the lid of the retort are closed, the hds being screwed down tightly, with some clay made into a thick paste as a lute. A better way would be to cast in the top of these tubulures grooves, and the lids with a rim loosely fitting into these grooves, forming what is called an hydraulic seal, only using lead in the place of water. The heat there is sufficient to melt lead, but not so great as to prevent its use. would form a much better lute, and could be opened and closed in much less time, which, in the case of disulphide of carbon manufacture, is a great desideratum. Having previously secured all the joints throughout the apparatus, sulphur is now run in by raising the rod o' in the sulphur pot. A bubbling will immediately be heard in the gas washer at y, caused by the escape of sulphuretted hydrogen, &c. In a few minutes, this bubbling ceases, and carbon disulphide

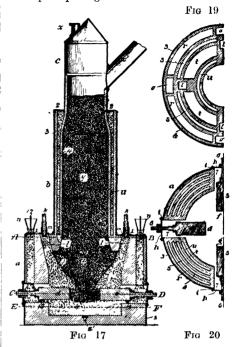

begins to distil over Distillation is now pro- which can be replenished through the hoppers n, ceeding, sulphur being charged in every 5 minutes, about  $1\frac{1}{2}$  to  $1\frac{3}{4}$  lbs. each time, for 7 hours, when the supply of sulphur is stopped, and one hour allowed to elapse before fresh charcoal is filled in. The lid is then removed from c, and the flue-pipe H lowered. c' may now be opened, and last of all the  $lid\ h'$  is removed from h of the carboniser, and the red-hot charcoal raked from the carboniser, by means of a funnel or hopper, into the retort A The retort is now closed, taking care that the opening communicating with the flue H is the last to be shut off, and work started again At the end of each week, neither coal nor sulphur is charged in for 8 hours, after which the whole apparatus is cleaned out in the following manner flue H having been lowered on to G as described above, the cover at the end of the delivery pipe 1 is removed, and wet bags or pieces of canvas are tightly rammed down the pipe I, and past its junction with the vertical pipe I', so as to isolate the condensers, &c, from the furnace ashes are now raked out through M, as described above, the retort refilled with fresh charcoal, and while this is getting heated up, the other portions of the apparatus are examined, and where sulphur is present it is removed.

With one such retort, from 4 to 5 cwts. of carbon disulphide can be made in a day, but it is much more economical, both in labour and fuel, to have several retorts-say four-in the same furnace

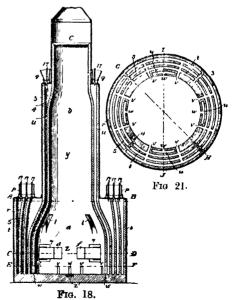

# MANUFACTURE OF CARBON DISULPHIDE BY THE ELECTRIC FURNACE.

Carbon disulphide is now made on the large scale, near Penn Yan, NY., America, by the Taylor Chemical Company, by means of an electric furnace, devised and patented by Mr. Edward R Taylor (US Pat 688364, Dec 10, 1901, 871971, Nov 26, 1907), who has kindly supplied the information upon which the following description of the process is based construction of the furnace is shown in Figs 17, 18, 19, 20, 21. Fig. 17 shows a section in elevation through the electrodes, and Fig. 18, shows a cross section in elevation at right angles, the figures being taken from the patent specifications In Fig 17 is shown the position of the electrodes d, D, near the bottom of the furnace shaft, which is represented as filled with charcoal; in Fig. 18, they are seen at d. At k (Fig. 17) are pipes through which are passed broken carbons, i erefuse from the factories of carbons for are lights, for the purpose of reinforcing the main carbons; these pass down, upon, and over the ends of the main carbons, and convey the current from the electrodes to the charcoal. The intermediate conductive material protects the electrodes proper from the intense heat and eroding action and thereby prolongs their life It also tends to steady the current, fluctuations being mainly due to variations in power and not to changes of resistance in the furnace itself. The charcoal for the reaction is fed into the furnace through the opening x (Fig. 17). Preferably four electrodes are used in this construction, supplied with two-phase alternating current. Provision is made for keeping the metallic portions of them comparatively cool by feeding cold sulphur on to them through the inlets shown as o (Fig. 17), and is needed. The furnace is 16 feet in diameter

the sulphur passing into the annular chambers

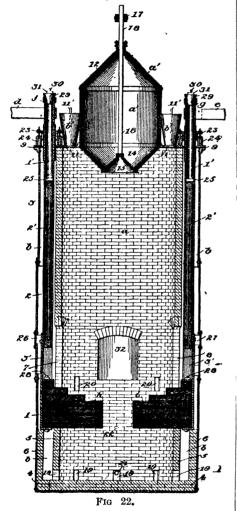

shown below the hoppers, seen in detail in Figs 19, 20, and 21. The interior of the furnace thus filled with sulphur, which is gradually melted and finds its way to the reaction zone. By this construction, the heat that would otherwise be radiated from the external walls of

the furnace is absorbed, and no outside lagging

and 41 feet high. It needs much less care and is easier to manage than one of the small non or clay retorts generally used

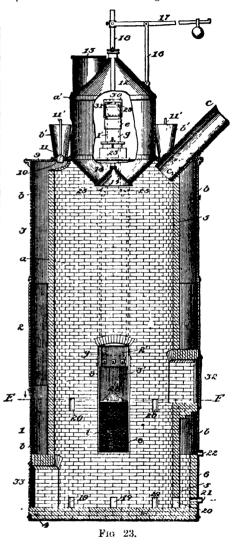

In working, charcoal is put into the charger above the bell and the opening scaled. The charcoal falls into the shaft of the furnace as often as there is room for it, the charger being replenished from time to time. The shaft should be kept filled with charcoal and the internal spaces filled with sulphur—thus there is no loss of heat by radiation and the heat

absorbed in melting the sulphur is returned to the furnace.

Electricity is supplied in such quantity that the electrodes are not submerged in the melted sulphur to such an extent as to restrict the passage of the current. The electricity is ordinarily passed from the one electrode to the other immediately opposite, but the direction can be changed at any time so as to pass to the adjacent electrode, thus burning out any piers or 'scaffolds' that may form in the corners and which would prevent the regular descent of the

charge. The sulphur within the working chamber z soon becomes melted, and its level rises more or less nearly to the top of the electrodes. As it approaches the heat zone, the sulphur is vapourised and rises through the charcoal which, when sufficiently heated, combines with it, forming the disulphide, the vapour of which ascends through the charcoal

in the shaft, and passes out through the pipe x to a condenser. The furnaces are run for about a year before renewing the electrodes or cleaning out. Aluminium bars, 6 inches wide and  $\S$  inch thick, connect the insulaced electrodes with two Stanley inductive type dynamos, each of 330 kilowatts capacity, run, as a rule, by water power. The average voltage is about 50. The yield is usually about 14,000 lbs. of the disulphide in 24 hours, but it is capable of being increased to 25,000 lbs.

An improved type of electric furnace, more

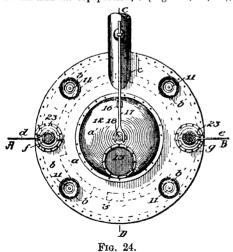

particularly adapted for a smaller installation, is seen in Figs. 22 and 23, reproduced from the

patent specifications.

Fig. 22 shows the furnace in sectional eleva-Fig 23 shows a sectional elevation with the plane of the section at right angles to that of Fig. 22, and with portions broken away at top to expose parts behind the plane of the section. Fig 24 is a top view on which the planes of Figs. 22 and 23 respectively are indicated by broken lines, A-B and C-D, and Fig 25 represents a horizontal section on the line m-F (Fig. 23). Like reference characters refer to like parts in all the figures There is an outer shell of iron or steel within which, at the bottom, is a flat hearth of floor 4 (Figs. 22, 23, and 25) of firebrick, which supports a circular wall of like material, within which is the working chamber a of the turnace, and an outer wall, 6, concentric with the wall 5, extending upward a short distance and terminating substantially on a level with the bolster, forming lower ends of a pair of diametrically opposite embrasures, 7 and 8.

The wall 5 of the working chamber a is continued upward to the top of the outer shell 1, 2, 3; a feed chamber b for sulphur being formed between the walls 5 and 6 at bottom and between the wall 5 of the working chamber and the outer shell above the top of the outer wall 6.

The shell 1, 2, 3 terminates at top in a horizontal annular top portion, 9 (Figs. 22, 23, 24),

which is provided at suitable intervals with hoppers b' and with openings 10 (Fig. 23) at their bottoms, communicating with said feed space b, each of the hoppers being provided with a suitable plug 11, having a handle, 11', extending above the top of the hopper, so that the hoppers may be filled above the plugs, and the plugs then lifted to drop the contents of the hoppers into the feed space b, and quickly replaced to prevent the escape of fumes and the admission of air. Within the central opening of the top portion 9, of the shell, a charcoal hopper, a' (Figs. 22, 23, 24) is supported: this is constructed with a conical top, 12, provided with a capped charging neck,

13, through which the charcoal is introduced into the hopper, and a conical bottom, 14, depending within the upper end of the working chamber and provided with a central opening closed by a bell, 15, the top of the hopper being further provided with the supporting link 16 of a weighted lever, 17, connected with the said bell 15, by a rod, 18, and rendering the hopper a' normally closed at bottom A discharge pipe, c (Figs. 23 and 24), extends from the working chamber a through the top portion 9 of the shell, in an oblique direction, as shown in Fig. 23.

Openings 19 and 20 (Figs 22, 23, and 25) for the sulphur, are formed in the working chamber

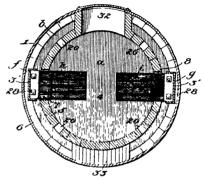

Fig. 25.

wall 5, immediately above the floor 4, and at one or more higher points, connecting the feed space b with the working chamber a, and pipe openings 21 and 22 extend through the outer wall 6 and the lower shell section 1 at different heights to allow the sulphur to enter the furnace proper. Metallic conductors, d and e (Figs. 22 and 24), connected with the source of electricity, are attached respectively to the protruding upper ends of metallic electrode stems f and g, which extend to the top of the outer wall 6, and rest upon the top of this wall, as in Fig 22 Each of the electrode stems d and e is made in three sections, numbered respectively, 1', 2', and 3' in Fig 22, the upper section 1' of each of the stems being hollow and cylindrical, and extending through a stuffing box, 23, mounted on the top of the shell, and preferably constructed with a water chamber, 21, for keeping the gland sufficiently cool The lower end of the upper section has flanges 25, on opposite sides, adapting it to be coupled to the partly closed upper end of a flat middle section 2', which is tubular, excepting its lower end, and this end is trough-shaped in common with the lowermost section 3', which is detachably bolted to the trough-shaped lower end of the middle section 2'.

A pair of manholes, 26 and 27 (Fig. 22), in the middle section 2' of the outer shell, afford access to the bolts connecting the middle and lowermost sections 2' and 3' of the electrode stems, and facilitate disconnecting the lowermost sections 3' when the latter need to be renewed

The electrodes proper, h and t, are of carbon, made m sections of different lengths, but all of one and the same size, and all rectangular m cross section (compare Figs 22 and 25). Such carbon sections project at right angles from the

lower ends of the stems f and g, and may be clamped within the trough-shaped stem sections 3'. A sufficient number of the longer carbon sections are united at bottom to form the main body of each electrode and above these the shorter sections are arranged in steps, as shown in Fig 22. The electrodes h and i project inwardly, as shown in Figs 22 and 25, and are supported beneath by the bolster-forming lower ends of the embrasures 7 and 8, through which the respective electrodes extend toward each other, into the working chamber a, as shown in Fig 22
The tubular or hollow-stem sections 1' and

2' provide for feeding the material downwards upon the electrodes. The upper end of each stem is provided with a conical plug, 29, and with a gallows or yoke, 30, between which and the top of the plug 29 a wooden wedge, 31, 1s

driven to render the closure air-tight

In charging the furnace, the lower part of the working chamber a is filled with broken sulphur to the plane of the electrodes h, and a sufficient quantity of charcoal is superimposed The lower part of the furnace is then tightly closed and sealed, and the working chamber a is thereafter filled with charcoal to any desired extent by way of the charcoal hopper a' by depressing the bell 15 by means of the lever 17 The hopper a' is then automatically closed at bottom by the re-elevation of the bell 15 Crushed sulphur is fed into the annular feed space b surrounding the working chamber wall from time to time as required by way of the hoppers b', which are filled with the sulphur, and may serve to measure the quantity introduced, and are emptied into the feed space b by partly withdrawing their plugs 11 and replacing them immediately to prevent the entrance of air The disulphide and the escape of fumes vapour, as it is formed, passes off through the pipe c into a suitable condenser

An upper manhole, 32, extending outward from the working chamber a through the shell sections 1 and 2, as shown in Figs. 22, 23, and 25, facilitates access to the interior of the furnace when it is cold for adjusting or renewing the electrodes h and  $\iota$ , and for arranging the charge at the beginning of an operation; and a subjacent manhole, 33 (Fig. 23), facilitates removing the ash from time to time as may be necessary. The electrode stems f and q, and their stuffing boxes 23, are insulated with mica and asbestos

paper

This furnace is designed to be 8 or 10 feet in diameter and 18 or 20 feet high, and will produce 5000 lbs. of carbon disulphide in 24 hours. Two

electrodes only are employed

Purification of Carbon Disulphide —Tho crude product, which contains considerable quantities of sulphur, may be purified by distillation. The distilling vessel is made of sheet zinc, and is fitted in a water-bath. The vapours of carbon disulphide are passed through a wide tube into a worm surrounded by cold water, and ending in a lap at the bottom; the liquid as it condenses is allowed to trickle into a vessel placed to receive it.

Deiss employed large boilers with flat bottoms, which were 10 feet in length,  $6\frac{1}{2}$  feet in diameter, and 31 feet high. They had domed covers, externally coated by badly conducting

material, so as to reduce to a minimum the amount of carbon disulphide returned to the boiler by condensation. The boiler was capable of receiving 5 tons of crude disulphide at a single charge, and had six delivery tubes which terminated in six vertically placed condensers. At the bottom of the boiler, there were two serpentme pipes, through one of which steam was passed until the crude carbon disulphide boils. For the purpose of distilling off the last portions steam was passed through the second serpentine pipe direct into the boiler, by which means carbon disulphide vapour and steam pass over together into the condensers, when the former accumulated in a layer below the surface of the water. The distillation of 5 tons lasted 3 or 4 days, and the products of the distillation at different stages were separately collected, and served for different purposes In the first portions, foul-smelling constituents predominate, such as sulphuretted hydrogen; the intermediate portions are the purest, while the last portions are contaminated with sulphur. Much of the sulphuretted hydrogen was removed by placing a small quantity of caustic soda in the boiler.

Bonière purified the crude material by running it into a still containing a strong solution of caustic soda and heated externally by steam; the vapour was then passed through several other vessels of a similar kind containing alkaline liquids, solutions of salts of iron, lead, or copper, from which it was distilled and condensed. Millon patented a process which consisted in mixing the disulphide with half its weight of milk of lime, and then carefully distilling.

Sidot first distils the crude product, and then agitates it with mercury till the shining surface of the metal is no longer blackened by Carbon disulphide, when pure, is not affected by contact with mercury for any length of time. Or it may be shaken with 0.5 p.c. of mercuric chloride, which removes a feetid compound of The clear liquid is then decanted, 0 02 of its weight of an inodorous fat is added, and the mixture distilled in a water-bath at a low

temperature (Cloez).

Another method of purification is to add to 100 parts of commercial product from 2 to 3 parts of dried copper sulphate, and to shake the The copper salt blackens and settles mixture down, with removal of the smell of sulphuretted hydrogen Absolute purity is obtained by again rectifying over dry copper sulphate. The latter can be rendered fit for further use by ignition, treating with sulphuric acid, and again igniting. The sulphide may be retained in a state of purity by allowing it to stand constantly over dry copper sulphate (J. Soc. Chem. Ind. 2, 246).

Singer has employed the following simple

method with very satisfactory results:—
A cylindrical vessel, about 30 inches in diameter and 6 feet high, is provided with a perforated coil of lead pipe at the bottom. Into this vessel the impure carbon disulphide is run to about one-third its height. Lime-water is then pumped into it by means of a force-pump through the perforated coil. The lime-water, being specifically lighter than the carbon disulphide, rises to the surface, and, while traversing the body of the disulphide in a finely divided spray, the lime combines with the sulphuretted

81

hydrogen, &c. This washing is continued until the lime-water, which leaves this vessel through an overflow pipe near to the top, is perfectly clear. The carbon disulphide is now run into a still, about 1 p.c. its weight of a cheap colourless oil added, and covered with a layer of about 1 inch of water, to which some sugar of lead may be added. The carbon disulphide is now distilled in a water-bath and condensed in the usual way

Carbon disulphide comes into the market in sheet-iron drums, the plates forming the top and bottom being bent inwards for their better protection from blows in moving about, and in the upper end there is an opening which can be closed by a screw stopper. Great care should be taken in the storing of carbon disulphide on account of its extreme volatility, the explosive nature of a mixture of the vapour with air, and the fact that its products of combustion are three irrespirable gases, viz. carbon dioxide, sulphurous oxide, and nitrogen. The store room ought to be isolated from other buildings, and should be well ventilated. The vessels in which the substance is kept ought to be tolerably large and placed where they are not likely to receive a blow or get thrown over When required for use, the carbon disulphide can be drawn off by means of a siphon.

Properties .- Carbon disulphide is a colourloss and extremely volatile liquid, the commercial product has a repugnant and feetid smell, but when purified it has a sweetish ethereal odour, and an acrid pungent taste is highly refractive, its power in this respect being 1 645; its sp.gr. is 1 29215, 0°/4° (Thorpe) Water dissolves about 1000 of its volume of the disulphide, and yields it up again unchanged on distilling, the solution in water possesses the odour of the disulphide, and has a slight burning The aqueous solution acts as an anti-Carbon disulphide dissolves sulphur, phosphorus, iodine, bromine, chlorine, camphor, caoutchouc, oils, and fats, and may be mixed in almost any proportions with alcohol, ether benzene, and the fixed and volatile oils Sulphur and phosphorus may be obtained in crystals by the spontaneous evaporation of their solutions When a rapid stream of in carbon disulphide air is passed through it, the vapour, as it rises, is condensed to cauliflower-like masses, which make their appearance on the surface of the liquid (Waitha, Bei 3, 80) When the whole of the liquid has disappeared, the resulting solid has a constant temperature of  $-12^{\circ}$ , so long as it remains unvolatilised. According to Wroblewski and Olzewski, it solidifies at -116°, and remains solid for a considerable time, emitting a peculiar aromatic odour

Carbon disulphide boils at 460° (Thorpe), 46 42° (corr) (Thorpe and Rodger), and the vapour ignites in air at 149°. When mixed vapour ignites in air at 149°. with three times its volume of oxygen, or an amount of air containing that volume of oxygen, it is very explosive. The flame of burning carbon disulplade is blue, and gives rise to sulphurous and carbonic acid gases: CS+302 =CO<sub>2</sub>+2SO<sub>2</sub>. When carbon disulphide is burnt in a lamp on the principle of the Bunsen burner, and special precautions taken to prevent explosions, it produces a flame with an actinic power superior to that of magnesium (Compt. rend. 79, M78).

Vol. II.—T.

A mixture of the vapour of carbon disulphide with nitric oxide burns with a blue flame, which is very rich in rays of high refrangibility, and on this account has been employed in photography.

Carbon disulphide is highly poisonous, inhalation of the vapour producing giddiness, vomiting, congestion, and finally coma. Even in small quantity only, it produces in time very serious effects on the nervous system. In the workmen employed in its manufacture, it causes weakness, depression, and loss of memory. Solution of ferrous carbonate in carbonic acid water has been found in some cases effectual Carbon disulphide vapour, when as a remedy passed through a tube heated to bright redness, is partly resolved into its elements, carbon depositing and sulphur passing off with the undecomposed compound

The following table represents its vapour tension at varying temperatures (Seyferth) .-

$45.5^{\circ}$			1 atn	osphere
57 7			1 1/2	,,
66.9			2 atn	ospheres
74.3			$2\frac{1}{2}$	,,
80.6			3	,,
86 1			$3\frac{1}{2}$	,,
90 9			4	,,
$95\ 5$			$4\frac{1}{2}$	,,
$99\ 0$			5	,,

(For table of vapour pressures between  $0^{\circ}$  and 50°, v. Ramsay and Young, Chem. Soc. Trans 47, 653, also Herwig, Pogg. Ann. 137, 69, 141, 83 , 147, 161 )

The vapour of carbon disulphide, when passed over metallic oxides at a red heat, yields sulphur dioxide and carbon, together with metallic sulphides, which are generally found crystallised and resemble those found in nature Carbon disulphide is one of the most powerful sulphurising agents known, and by means of it many sulphides may be produced which are not otherwise obtainable (Fiémy) It converts oxides into sulphides when heated with them in sealed tubes The vapour is strongly attacked by nitric acid, yielding sulphuric acid and nitrous vapours

A mixture of the vapour of carbon disulphide and sulphuretted hydrogen, when passed over red-hot copper, yields copper sulphide and maish as  $CS_2 + 2SH_2 + 4Cu = 4CuS + CH_4$ 

The vapour of carbon disulphide when passed over wood undergoing destructive distillation alters the character of the carbonaceous residue, producing a material having high conducting powers for heat and electricity, and extremely sonorous when struck

Carbon disulphide is a powerful disinfectant. Meat and other putrescible bodies have been kept in an atmosphere containing its vapour for

months without change.

Heated potassium burns in the vapour of carbon disulphide with formation of potassium sulphide and liberation of carbon

When brought in contact with a solution of an alkaline hydroxide, carbon disulphide is decomposed, a carbonate and a sulphocarbonate being formed:

 $6KHO + 3CS_2 = 2K_2CS_3 + 3H_2O + K_2CO_3$ When the vapour of carbon disulphide is

passed over heated calcium hydroxide, it is decomposed, carbon dioxide and sulphuretted hydrogen being evolved.

This reaction has been utilised in the removal

of carbon disulphide from coal gas.

Chlorme has but little action on carbon disulphide at the ordinary temperatures, but in the presence of iodine, the chlorides of antimony and molybdenum, &c., chlorine replaces the sulphur with conversion of the carbon disulphide into carbon tetrachloride, and, if the action is interrupted before it is complete, intermediate compounds or sulphochlorides are formed (J. Soc Chem. Ind 6, 729)

Carbon disulphide combines with triethylphosphine  $P(C_2H_5)_3$  to form a solid compound, crystallising in red crystals of the composition

P(C2H5)3CS2

Owing to its volatility it may be made to produce great cold by its own evaporation, and if this takes place very quickly under the airpump, a temperature of  $-60^{\circ}$  may be obtained

An aqueous or alcoholic solution of caustic potash, boiled with carbon disulphide, yields with lead salts a black precipitate of lead sulphide. This is a delicate test for the substance

Carbon disulphide may be detected in coal gas by passing the gas when completely freed from sulphuretted hydrogen over red-hot copper foil, when the copper acquires an indescent lustre, and its nitric acid solution diluted with water yields after some time a precipitate with barium chloride (A Vogel, Zeitsch anal Chem [2] 6, 253).

Carbon disulphide combines with metallic sulphides, forming sulphocarbonates

$$CS_2+Na_2S=Na_2CS_3$$

Sulphocarbonic acid is a yellow oily liquid, obtained by decomposing its potassium salt with hydrochloric acid

$$K_2CS_3+2HCl=H_2CS_3+2KCl$$

Potassium sulphocarbonate has been used for the destruction of phylloxera

Uses.—Carbon disulphide is applied to a large number of useful purposes, the chief of which is in the preparation of vulcanised caoutchouc, and as a solvent for the latter in the manufacture of waterproof goods, by the deposition of a thin layer of the dissolved caoutchouc on the fabric; for the extraction of fat from crude wool; fatty oils from oil seeds and pressed residues; and for the purification of paraffin It is used in the extraction of uncombined sulphur, and of bitumen from minerals A solution of guttapercha in carbon disulphide is employed in making seamless joints and for the preparation of caoutchouc cement, various colours, ammonium thiocyanate, &c. It is also used for filling prisms on account of its high dispersive power

Advantage is taken of its poisonous properties to expel weevils and other insects from stored grain without injuring the cereal. For this purpose, a small quantity of the carbon disulphide is sprinkled over the grain; both the larvæ and eggs are killed without injury to the grain (Doyère). It is also employed to destroy chicken lice and fleas, moths in furs, and in America to kill burrowing animals, such as gophers, ground squirrels, woodchucks, prairie dogs, rats, mice, moles, &c., and as a plant

insecticide. It is used in Brazil to expel the Sauba ant from the foundations of houses. It may also be used in the analyses of oil seeds as a solvent for the purpose of ascertaining the proportion of oil which the ground seeds contain.

As carbon disulphide dissolves iodine in large quantity, but does not appreciably dissolve in water, it is employed for determining the amount

of moisture in commercial iodine.

It may be used for dissolving quinine and other alkaloids; for extracting the aromatic principles from seeds and spices, and for the extraction of the scent of flowers. For these purposes, however, the purest quality of the

disulphide can alone be employed.

A solution of phosphorus in carbon disulphide has been employed in the electrotyping of very deheate objects, such as grasses, flowers, feathers, &c. These are dipped into the solution, when, by exposure to the air, the carbon disulphide evaporates and leaves a thin film of phosphorus on the surfaces; they are then dipped into a solution of silver nitrate, by which silver is precipitated in a thin film, upon which, by the electrotype process, any thickness of silver, gold, copper, &c, can be deposited Ιf a few drops of carbon disulphide are put into a solution of silver cyanide, from which the metal is being electro-deposited, the silver is deposited bright, whereas without the disulphide it would be dull

Deiss, who first employed carbon disulphide in the extraction of fatty oils from seeds, oilcakes, and other pressed residues, used the fol-

lowing airangement —

Carbon disulphide was introduced into a large cemented blickwork reservoir, with a manhole, which is generally kept closed, 22 feet long, 6 feet in diameter, and nearly 6 feet deep, and limed with lead up to the point to which it was filled with the disulphide and water, the latter being added as a thin layer to prevent the too rapid evaporation of the carbon disulphide. Immediately above this reservoir is a worm condenser, whose tail pipe dips into the liquid in the reservoir below; on one side of the condenser there is an extractor having a capacity of 4400 gallons, and capable of receiving a charge of 12 tons of oilcake This extractor is supplied by means of a pump with carbon disulphide from the reservoir below through a pipe leading up from the reservoir to the extractor apparatus has two perforated shelves, one nearly at the top and the other nearly at the bottom, between which the substance to be operated upon is placed. In the space between the lower perforated shelf and the bottom of the extractor is a coil of pipe through which steam can be passed. Just above the upper perforated shelf there are nine pipes on the same level for the purpose of carrying the vapours produced in the operation to the condenser. There are also operation to the condenser pipes just above this shelf which are in direct communication with a still on the opposite side of the condenser, to which disulphide saturated with oil is carried, the saturated disulphide rising to the surface in the operation owing to the difference in the sp gr of the carbon disulphide (1.29) and oil (about 0.900). The still in which this liquid is distilled is about 11 feet long, 5 feet wide, and 15 inches deep, holding when half filled about 400 gallons. The liquid

is heated by steam supplied through two pipes coiled several times round the bottom of the still, and the vapour of the volatilised carbon disulphide is led through nine pipes into the condenser, and thence into the reservoir below the condenser, and is ready to be used again in the extractor for macerating a fresh quantity of material.

The time taken to fill the extractor with carbon disulphide is 8 hours, the maceration of the material 4 hours, the emptying of the contents of the extractor into the reservon at the close of the operation 2 hours, and the steaming of the oil in the still in order to free it from carbon disulphide from 8 to 12 hours Working with an apparatus such as described, about  $2\frac{1}{2}$  tons of oil can be obtained in 30 hours from 25 tons of oilcake

Extraction of fat from wool -Morson and Jerome employ for this purpose a large cylindircal vessel with a close-fitting cover and double walls, between which hot water circulates The wool is placed on a perforated shelt near the bottom of the cylinder, whilst a perforated plate, a kind of piston, could be pressed upon the wool by an arrangement of sciews Carbon disulphide is pumped from a reservoir into the extractor, and as the liquid becomes saturated with fat it is led through a pipe into a still, heated by a coil of steam pipe at the bottom, the vapour being passed to a worm condenser and the liquid disulphide passed into the reservoir which is immediately beneath. By a second arrangement of steam pipes, steam can be passed directly into the still so as to remove the last portions of disulphide. A current of air, heated to 70°, is then forced through the wool by means of an an-pump As all the parts of the apparatus are in direct communication with each other, it is necessary to supply the diminished pressure on the reservoir When air is pumped out of it and sent through a tube several times bent and the last portion fitted with a hot-water jacket, the equilibrium of pressure should be maintained, and this is done by a supply of air from a gasholder in connection with the apparatus The last portions of carbon disulphide are thus swept out of the extractor and are carried through a pipe into a second worm condenser, and thence to the reservoir. At convenient points between the macerating vessel and the still, as well as at the ends of the condensing worms, there are windows in the pipes, which serve to form an idea of the state of the operation, and close to each of these windows is a cock from which a little of the liquid can be drawn and evaporated, in order to see if a residue of fat remains

The macerating vessel or extractor is charged with about 10 tons of wool, which is then reduced to about half its bulk by screwing down the perforated plate The carbon disulphide is pumped into the extractor, and, after filtering through the wool, ascends through the perforations and passes into a pipe leading to the condenser. This is continued until the liquid comes over colourless, and leaves no residue on evapo-When the extracting process is finished, the cock admitting carbon disulphide into the extractor is closed, and a partial vacuum is formed by drawing air out of the extractor by the air-pump, the greater part of the disulphide

the first few strokes. The water-jacket is then heated by water at 70°, and the cocks are so arranged as to allow the heated air to pass through the wool, and thence into the open air By this method a considerable quantity of fatty substance is obtained from sheep's wool which was formerly lost

The following materials are treated with carbon disulphide in order to obtain fatty

matters from them .-

1 The dark-coloured residues of stearm manufactories, which are products of the treatment with sulphuric acid. They yield from 18 to 20 p.c. of fatty acid, which was formerly almost entirely lost. The residues are mixed with sawdust to facilitate the filtration of the dissolved portion.

2 The dark-brown cart-grease from the axles of carts, carriages, &c This is first treated with

sulphuric acid, washed, and dried.

3. Tow and rags used in cleaning machinery. This treatment of rags, &c, has a threefold advantage, recovery of fat or fatty acids, purification of the rags so that they can be used again, and the prevention of spontaneous combustion, which these materials are hable to on exposure

4 The refuse of the preparation of beeswax, which on treatment with carbon disulphide yields a yellow wax useful for many purposes.

5 Sawdust that has been used for filtering

oils after purification with sulphuric acid.

6. The sediment produced by the treatment of various oils with sulphuric acid contains about 50 p c. of oil, which may be extracted by carbon disulphide after washing with boiling water, drying, and mixing it with sawdust

7 Bones from slaughter-houses and kitchens to be used in the preparation of bone-black yield to carbon disulphide from 10 to 12 p c

8. The expressed residues of oil seeds, such as rape, sesamé, flax, &c, when they cannot be properly employed as fodder In all cases it is necessary to break up the orleake into small pieces before treating it with carbon disulphide, so as to ensure thorough penetration of this substance. The residue left after extracting the fat is hardly suitable for fodder, but is valuable as a manure

9. The 'cracklings' or greaves obtained by

the melting of tallow.

10. The pressed cacao beans from which no further cacao butter can be obtained by pressing 11 The pressed residues obtained in the

preparation of olive oil.

Extraction of bitumen, &c , from minerals — Carbon disulphide can be employed in the extraction of bitumen from mineral bodies which contain so small a percentage as not to pay when obtained by the ordinary process of distillation. The apparatus used consists of a close reservoir for the carbon disulphide, over which is a cooling apparatus which serves as condenser. Below the reservoir are two filters provided near the bottom with perforated shelves. are introduced into the filters upon the shelf through doors near the bottom, which are then closed and made air-tight. Carbon disulphide is now admitted through a pipe at the bottom of each filter, and as the liquid rises it percolates adhering to the wool being carried with it at through the minerals, dissolving out the bitumen,

and when full flows out at the top through a pipe leading to a still, where the saturated liquid is distilled, the vapour of carbon disulphide ascending into the condenser, and the liquid carbon disulphide as it condenses trickles into the reservoir beneath. The bituminous matters, which remain in the still, are drawn off by a cock at the bottom, and the disulphide which remains absorbed by the minerals in the filters is expelled by a current of steam. This apparatus is practically continuous, very little loss of the disulphide taking place at each operation, and as much as 12 p c of bitumen can be obtained, whereas only 7 or 8 p c. could be had by distillation

Extraction of spices, &c.—Bonière has devised an apparatus for extracting the aromatic principles of various spices and other substances used for seasoning food, by means of carbon disulphide It is on the same principle as the apparatus already described, and consists of a series of wire-gauze sieves arranged one over the other in an air-tight case The carbon disulphide is made to pass through the sieves, which contain the substance to be operated upon, e.g. pepper, thus dissolving out the active principles, and as it reaches the top it flows through a pipe into a boiler The boiler contains salt, sugar, lactose, dextrin, saltpetre, or other material The liquid is distilled in the boiler, by admitting steam into a kind of jacket, when the disulphide distils over and is condensed in a worm condenser, while the salt or sugar remains behind, retaining all the aromatic or active principles of the spice.

Beigot has constructed an apparatus for rapidly determining the quantity of oil in seeds, &c, by means of carbon disulphide It consists of a glass vessel in the neck of which a cylindrical glass vessel is accurately fitted, and at the side in a tubulure is inserted a small air-pump 50 grams of the finely ground seed to be examined are placed in the cylindrical glass vessel, and are covered with a diaphragm upon which 50 more grams are placed and covered with a second diaphragm Carbon disulphide is now poured on until the seed is fully moistened, and after a few minutes a partial vacuum is made in the apparatus by means of the air-pump, when the pressure of the air drives out the disulphide and oil in solution into the vessel beneath. This is repeated until the carbon disulphide comes off colourless and leaves no oily stain on contact with filter About 400 or 500 grams of carbon dipaper sulphide are sufficient to exhaust the above amount of seed

The oily solution thus obtained is heated ver a water-bath, and as soon as the disulphide is expelled, the residue is allowed to cool and is weighed.

H. L. Greville has extracted with advantage the carbon disulphide absorbed in the purifiers of the gasworks The lime used for this purpose, after being discharged from the purifiers, is introduced into a boiler capable of receiving a charge of several hundredweights, fitted with a perforated false bottom, pressure gauge, and an arrangement for admitting steam. The yield of carbon disulphide from 100 tons of spent lime is about 11 tons In addition to the value of the crude product thus obtained, the lime in 1867; occurs in certain hepatic waters or

remaining is, with a small addition of fresh lime, fit for further use in the purification of coal gas. As is well known, oxide of iron, after continued use in the absorption of sulphuretted hydrogen from coal gas, contains about 50 pc of free sulphur. The crude carbon disulphide, obtained as described, can be used for the extraction of this sulphur, and the oxide which remains is revivified, and is again fit for purifying purposes The sulphur is recovered by distillation, and the carbon disulphide can be used over again (J. Soc. Chem. Ind. 2, 488).

The principal seats of manufacture of carbon disulphide in England are London, Manchester, certain towns in Yorkshire, and Ironbiidge, in France, Paris, Boideaux, and Marseilles. Germany, Austria, and Sicily have several manufac-

Carbon monosulphide (rCS) A reddish-brown powder obtained by exposing carbon disulphide to sunlight Insoluble in water, alcohol, turpentine, and benzene (Sidot, Compt rend. 69, 1303; 74, 180, 81, 32).

It is also formed when thiocarbonyl chloride reacts at ordinary temperature with nickel carbonyl  $x \text{CSCl}_2 + x \text{Ni}(\text{CO})_4 = x \text{NiCl}_2 + 4x \text{CO} + (\text{CS})_{x}$ The reaction also takes place at -20°, although more slowly The nickel chloride produced is extracted with water, and the brown residue is dried by heating at 100°, then at 150°-200° under reduced pressure.

Carbon monosulphide has sp gr. 1.6, but after compression into a solid block the sp gr is 183. It is a non-conductor of electricity. In concentrated sulphuric acid it forms a purplish-brown solution, the colour of which is destroyed on boiling, when carbon dioxide and sulphur di-oxide are evolved. When poured into water the purplish-brown solution yields the unchanged It also forms brown solutions monosulphide in aqueous or alcoholic ammonia, in ammonium sulphide, in potassium-hydroxide sulphide and hydrosulphide With nitric acid it gives a red solution. When heated in a vacuum at 360° or below, no change takes place, only a small quantity of hydrogen sulphide is evolved, but at a dull red heat it decomposes thus

$$2(CS)_x = xC + \tau CS$$

When carbon disulphide vapour at low pressure is subjected to the action of the silent electric discharge, sulphur is deposited, and gaseous carbon monosulphide is The gas can be collected in a tube evolved cooled with liquid air, when it condenses together with carbon disulphide If the temperature of the condensing tube is allowed to rise, the monosulphide polymerises with explosive violence to the brown solid carbon monosulphide  $(CS)_x$ . In presence of excess of carbon disulphide, the gaseous monosulphide is fairly stable under certain conditions even at high temperatures, but it is completely decomposed when passed through 10 cm of a red-hot tube packed with Roy. Soc. 1911, 85, 574.)

Carbon oxysulphide or Carboxyl sulphide or Carbonyl sulphide COS. Discovered by Than,

mineral springs Prepared (1) by passing a mixture of carbonic oxide and vapour of sulphur through a hot tube. CO+S=COS.—(2) By the action of sulphuric acid upon potassium or ammonium thiocyanate.

$$\begin{array}{l} \text{CNKS} + 2\text{SO}_4\text{H}_2 + \text{OH}_2 \\ = \text{COS} + \text{SO}_4\text{HK} + \text{SO}_4(\text{NH}_4) \end{array}$$

The gas is purified by passing it successively through strong caustic alkali, concentrated sulphuric acid, and finally through a mixture of triethylphosphine (1 part), pyridene (9 parts), and nitrobenzene (10 parts) It is then cooled to 10°-20°, and the last traces of impurities are removed by liquefying it, when the impurities remain uncondensed (Hempel, Zeitsch. angew Chem 1901, 14, 865).—(3) By heating together trioxide and carbon disulphide.  $CS_3 + 3SO_3 = COS + 4SO_3$  (Armstrong) —(4) By heating urea with carbon disulphide in a sealed tube to  $110^{\circ}$ :  $COH_4N_2 + CS_2 = COS + CNS NH_4$ . The oxysulphide is given off together with hydrogen sulphide on opening the tube, and the latter is absorbed by passing through lead accetate (Ladenburg)—It is also formed in the combustion of carbon disulphide with oxygen (Dixon and Russel, Chem. Soc Trans 1899, 610), and by the passage of the dark electric discharge through a mixture of carbon disulphide and carbon monoxide (Losanitsch and Jovitschitsch, Ber. 1897, 30, 135)

Properties.—It is a colourless gas, odourless when quite pure (Stock and Kuss) It acts strongly on the nervous system, a rapid overpowering action following the inhalation of small quantities It is readily inflammable, and forms with oxygen an explosive mixture (Russell, Chem Soc Tians 1900, 356) The gas is soluble in water, 1 cc dissolving 0.8 cc of the gas at 13 5° and 756 mm pressure The solution gradually decomposes, forming hydrogen sulphide and carbon dioxide A platinum wire heated to whiteness in the gas decomposes it into sulphur and carbonic oxide, the latter occupying the original volume of the gas It has a specific gravity of 2 1046, and may be easily poured from one vessel to another burnt in air, it produces carbon dioxide and sulphur dioxide With caustic alkalis, it yields a mixture of carbonate and sulphide

$$COS + 4KHO = CO_3K_2 + K_2S + 2H_2O$$

Carbon oxysulphide reacts with solutions of metallic salts, forming the metallic sulphide and carbon dioxide, and is readily oxidised to carbon dioxide and sulphure acid by bromine water or acid permanganate.

It is slowly decomposed by acid cuprous chloride, thus

$$COS + 2CuCl + H_0O = CO_0 + 2HCl + Cu_0S$$

(Berthelot, Ann. Chim. Phys. 1898, [7] 14, 205). With magnesium organic compounds, it can be employed in the synthesis of thio-acids and of s-trisubstituted carbinols (Wiegert, Ber. 1903,

36, 1007)

Its critical temperature is 105°, and its critical pressure is 60 atmospheres. It is liquefied at a pressure of 125 atmospheres and temperature 0° to a colourless, mobile, and highly refractive liquid, 1D—87° 124; m.p.—1382°, boiling at —50°2°, at 76° mm., which dissolves sulphur and mixes with alcohol and

ether, but not with water [Ilosvay, Bull Soc. chim. [2] 37, 294; Stock and Kuss, Ber 1917, 50, 159).

Carbonyl ketene; Malonic anhydride) C<sub>3</sub>O<sub>2</sub>. CARBON SUBOXIDE (Carbon carbonyl; pared by distilling ethyl malonate under reduced pressure into a vessel containing a large excess of phosphorus pentoxide and some glass wool, the vessel being kept at a temperature of 300° The resulting products are passed through a dry tube, and then into a vessel immersed in liquid air to condense the ethylene and carbon suboxide The ethylene volatilises from the mixture at the ordinary temperature, leaving a small quantity of colourless liquid. This is volatilised and collected in a tube kept at between 60° and 70° (Diels and Wolf, Ber 1906, 689). Diels and Meyerheim (191d. 1907, 355) showed that carbon suboxide may be obtained by similar methods from methyl, benzyl, and phenyl malonates and also from ethyl methanetucarboxylate; and that by heating malonic acid at 140°-150° there is formed acetic acid, carbon dioxide, and about 10-12 p c of carbon suboxide Staudinger and Bereza obtained carbon suboxide by treating malonyl chloride with silver, lead, or zinc oxides, the yield is only 10 pc (Ber. 1908, 4461) By treating an ethereal solution of dibrommalonyl chloride with zinc shavings, a method similar to that for preparing the ketenes. Staudinger and Klever obtained a 50-80 pc yield of carbon suboxide (Ber. 1908, 906) Stock and Stoltzenberg (Ber 1917, 50, 498) find that the poor yields of carbon suboxide usually obtained by the action of phosphoric oxide on malonic acid are largely due to the polymerisation of the suboxide under the catalytic influence of the dehydrating agent, and they describe an apparatus in which the suboxide is rapidly removed by carrying out the reaction in a vacuum and condensing the product by liquid air.

The pure oxide is a colourless, very mobile, refractive liquid with a pungent smell resembling acetaldehyde and mustard oil It is poisonous the bols at 7° under 761 mm, and its vapour density corresponds to the formula ( ${}_{3}O_{2}$ ; mp -107° (-111.3° Stock and Stoltzenberg), density of liquid 1.11. On passing the vapour through a constricted tube, a metallic mirror resembling arsenic is obtained. At low temperatures, carbon suboxide is quite stable, but between 0° and 15° a trace of impurity rapidly polymerises it to a red solid. This polymeride is very hygroscopic, and on addition of water, heat is developed, carbon dioxide evolved, and an eosin-red solution formed · by heating the red compound carbon dioxide, carbon monoxide and carbon suboxide are formed, and at higher temperatures, carbon monoxide and dioxide are produced, the residue being a mixture containing more carbon than is required for carbon suboxide. By keeping carbon suboxide for 2 days in a sealed tube at 15°, it completely changes into the polymeride, forming a dark-red solid mass, soluble in water to a dark-red solution; this change is instantaneous at 100°. Carbon suboxide burns with a bright-blue but smoky flame, forming carbon dioxide. Carbon suboxide does not combine with aldehydes, Schiff's bases or hydrogen cyanide (Diels and Lalin,

Ber. 1908, 3426), but in liquid sulphur dioxide at  $-40^{\circ}$  to  $-50^{\circ}$  forms a white crystalline compound with formic acid, and a colourless syrup with acetic acid; the constitution of these compounds is doubtful Water quickly reconverts it into malonic acid

Two formulæ have been proposed for carbon suboxide; Diels and Wolf represent it as the anhydride of malonic acid () C:C.C (), Michael (Ber. 1906, 1915, 1908, 425), as the lactone of  $\beta$ -hydroxypropiolic acid  $C \subset C \subset C$ .

The first formula seems to be correct, for the following reasons (v. Diels and Blumberg, Bei.

1908, 82, 1233) .-

(1) Bp 7° Propiolic acid boils at 144°, and if  $\beta$ -hydroxypropiolic acid had a boiling-point, it would boil higher still, and its lactone would certainly not boil at so low a temperature as 7°.

(2) The values for the molecular refraction and molecular dispersion are high:  $M_{\rm p}=16.6$ ,

 $\gamma - \alpha = 0.736$ , 0.739, 0.862 (three determinations). (3) Similarity of carbon suboxide to the

metallic carbonyls.

- (4) Similarity to the isocyanates and ketenes (5) Addition of four atoms of bromine to form dibrommalonyl bromide and the regeneration of carbon suboxide from this compound
  - (6) The following chemical reactions.
- O C C C O+2H2O=HOOC CH2 COOH(malonic acrt) O C C C O+2HCl=CloC CH2 COCl(malonylchloride) O C C C O+2NH3
- $\begin{array}{c} = H_{3} \text{N OC CH}_{2} \text{ CONH}_{2} \text{ (malonamide)} \\ \text{O C C O} + 2C_{6}H_{5}^{2}\text{NH}_{2} \\ = C_{6}H_{5}^{2}\text{HN OC CH}_{2} \text{ CONH } C_{6}H_{5} \text{ (malonanilide)} \end{array}$
- (7) The improbability of the existence of a  $\beta$ -lactone containing two carbon atoms triply linked together (v Ketones).

CARBONADO v DIAMOND.

CARBONITE, or natural coke A coke-like material formed by the baking action of intrusive igneous lock-masses on seams of bituminous coal Found in Ayrshire and in Chesterfield co, Virginia L. J S.

CARBONITE. An explosive consisting of nitroglycerine, 25-27 parts, barium nitrate and potassium nitrate, 30-36 parts, wood meal, 40-43 parts, sodium carbonate, 0.5 parts (vwood meal,

EXPLOSIVES)

CARBONYLS Metallic compounds of car-The existence of this class of bon monoxide compounds was first made known in 1890, when Mond, Langer, and Quincke discovered that carbon monoxide, passed over heated, finely divided nickel, yielded a colourless volatile liquid

Iron, cobalt, molybdenum, and ruthenium have since been found to yield carbonyls by

similar treatment.

The production of the carbonyl is facilitated by conducting the operation under pressure and, in most cases, at a fairly high temperature.

For the production of the iron and nickel compounds, the carbon monoxide is simply passed over the heated metal, but for the other compounds a special apparatus is used This consists of a nickel-steel tube, in the form of a test-tube, capable of withstanding a pressure of 500 atmospheres and a temperature of 450°. It is copper lined to prevent the action of carbon monoxide upon the iron. The carbon monoxide under pressure is led in through a pressure valve

and down a copper tube reaching almost to the bottom of the nickel-steel tube, where it comes in contact with the metal to be experimented upon, contained in a glass tube loosely fitted to the top of the apparatus The excess of the to the top of the apparatus carbon monoxide, and other vapours, escape through a pressure valve and pass through a tube immersed in a freezing mixture, in which any compound that is formed is collected (Chem. Soc. Trans. 1910, 97, 798).

The carbonyls have very similar chemical Upon heating, in some cases an properties intermediate compound is formed, but they all decompose ultimately, yielding the metal, which is deposited as a bright mirror, and carbon Dilute acids are practically without monoxide action upon them, but strong acids decompose them readily, giving the corresponding salt, with the evolution of carbon monoxide and hydro-The halogens also decompose them are decomposed by moist air, giving precipitates of the metallic hydroxides and, in some cases, what is probably a hydrated basic carbonate. They are more or less soluble in the common organic solvents, but all are insoluble in water

In physical properties, they vary considerably, thus, in volatility, they range from the non-volatile Fe<sub>2</sub>(CO)<sub>4</sub> of sp gr. 2 08 to the very volatile Ni(CO)<sub>4</sub> of sp gr. 1 32 They are highly coloured, except in the cases of molybdenum and nickel carbonyls, which are white and colourless respectively Some can exist in the three states of solid, liquid, and vapour, and others in only one or two of these phases

Owing to their diversity in composition, a general chemical formula cannot be assigned to them, but it is probable that they are similarly

constituted. A ring formula, e g Nic `CO:ĊO

does not explain all their properties, and the compound Fe<sub>2</sub>(CO)<sub>2</sub> cannot be brought into line with the other compounds which only contain one atom of the metal Presumably they have a molecular rather than an atomic constitution (Mond, Hertz and Cowap, Ic.). The various known carbonyls are described under the several metals.

CARBORUNDUM (Crystalline silicon car bide) SiC. This compound was discovered accidentally by Acheson, in 1891, and is now manufactured under his patent (Eng Pat 17911, 1892) by the Carborundum Co at Niagara Falls, USA, and to a smaller extent in Canada.

Preparation —Amorphous silicon carbide is formed by heating carbon and silica together at about 1200°, as a greenish powder (Schutzenberger, Compt rend 114, 1089), but carborundum is only formed at a temperature of 1950° (Tucker and Lampen, J Amer Chem Soc 1906, 28, 853) (1820° according to Gillett), which is attained by means of the electric arc thus prepared pure silicon carbide from the vapours of carbon and silicon (Compt. rend. 1893, 114, 1089)

The method of manufacture used at Niagara is as follows .—The furnaces are built of firebrick and are about 16 feet  $long \times 5$  feet  $high \times 5$  feet wide. The ends are solid, about 2 feet thick, and carry the terminals. Each terminal consists of 60 carbon rods, 30 minches long and

3 inches diameter, into the ends of which fit copper plugs which in turn fit into sockets in a square copper plate bolted to the outside of the wall, and connected with the leads Only the end walls and the bed are permanent, the sides are built up with the charge and taken down to remove the product.

In charging, the furnace is half filled with the materials, which must not touch the electrodes, and a cylindrical core 21 inches diameter, composed of pieces of coke 1-1 inch diameter, is built up between the electrodes Over this the charge is built up to a height of 8 feet. current passes through the coke and forms numerous arcs which heat the charge to a very high temperature The charge is composed of:

Coke .		34 2 parts
Sand .		54 2 ,,
$\mathbf{Sawdust}$		9.9 ,,
Salt .		17

The salt is added as a flux, the sawdust to increase the porosity of the charge and allow the escape of the carbon monoxide formed in the reaction ·

$$S_1O_2 + 2C = S_1 + 2CO$$
  
 $S_1 + C = S_1C$ 

During the run, about 6 tons of this gas are given off; it is allowed to burn at the top of the furnace.

The alternating current supplied by the Niagara Power Co at 2200 volts is transformed down to 165 volts, and a large water rheostat is used to regulate or interrupt the current, the usual means being too dangerous with the heavy currents used At the beginning of a run, the EMF. is 165 volts, but within 13 hours the resistance decreases and the EMF. is reduced to 125 volts, during this period, the current increases from 1700 amperes to 6000 amperes The conditions then remain steady during the whole run of 36 hours

A modification of the process consists in preheating the charge by combustion of gaseous or solid fuel (Tone and the Carborundum Co US Pat 908357, 1908) By moving the position of the arc relatively to the charge, the process may be made continuous (ibid US Pat 937119, 1909).

The charge per furnace is about 30,000 lbs. of which the core forms about 3 p c, the energy used is about 26,400 kilowatt-hours, and the product contains about 6700 lbs of carboiundum and 5000 lbs. of amorphous silicon carbide.

The carborundum is dug out in large masses and pounded with water in a mechanical crusher, and then digested with sulphuric acid (1:2) for 3 days at 100°, and finally washed with The finer portions, which are washed away, are collected separately and known as flours. The residue is dried in a kiln and graded through a system of screens Hand-washed powders are of various grades of fineness, according to the length of time they remain suspended in water (Kohn, J. Soc. Chem. Ind. 1897, 863).

Some analyses of these product are tabulated above :--

	I.	II.	III.	IV.	v.

MgO			0.11		0 21
mgo					

I. is the calculated composition for SiC; II is Moissan's pure product (Compt. rend. 1893, 114, 1089), III is commercial carborundum, IV is the same after purification by Muhlhauser's method-heating in oxygen for I hour and treating with hot sulphuric and hydrofluoric acids (Dingl poly J. 1893, 289, 164); V is amorphous silicon carbide

Weber has patented a method of production from kaolin and coke in the electric furnace. The product is treated with water, which decomposes the aluminium carbide, leaving the carborun-

dum (U.S. Pat 728528, 1903).

The production of a dense, compact variety, by the action of the vapours of carbon and silicon upon silicon carbide has been patented by the Carborundum Co. (US Pat. 913324) and by Bouvier (Fr. Pat 350369, 1904) It is very hard, resists acid, and is a good insu-

Its preparation from silicon monoxide and carbon has been described by Potter and Westing house (U.S. Pat 875673, 1907)

Articles may be formed in pure carbon and afterwards converted into carborundum by heating to a very high temperature in a bed of finely powdered carborundum or of sand and carbon (Bolling, Eng. Pat. 6693, 1905, D. R. P. 195533, Fr Pat 353017)

Properties —Carborundum crystallises in flattened hexagonal rhombohedia, having an adamantine lustre and a hardness of 9 5 (Muhlhauser, Zeitsch anal Chem 1893, 637). The colour of the commercial product is greenishgrey to yellow or blue; obtained pure from pure materials, the compound is colourless. Its sp gr is 3 23 at 15° (Fitzgerald, J Soc. Chem. Ind 1897, 246).

It is infusible and quite unaffected up to a temperature of 2220°, when it decomposes into silicon and graphitic carbon (Tucker and Lampen, J Amer. Chem Soc 1906, 28, 853). Acids have no action upon it, but it is attacked by fused alkalis with formation of a silicate and carbon.

The determination of silicon in carborundum is made by converting it to silicate as above, and precipitating as silica; carbon is estimated by oxidising the finely powdered substance with lead chromate (Matthews, J. Soc. Chem. Ind. 1895, 755, Muhlhauser, Zeitsch. anal. Chem. 1893, 637)

Uses —Carborundum is used chiefly instead of emery as an abrasive. Though it is more costly, it does the same work more effectively in one-third to one-fourth the time (Muhlhauser, lc.) The powder is used in glass cutting and grinding, and for polishing

It is made up into wheels, hones, &c., by mixing with moistened kaolin and felspar, moulding under hydraulic pressure, and firing the articles in a kiln for 7 days. Other binding materials, such as shellac, are used for special purposes, and papers, similar to emery paper, are made. The binding material may be dispensed with by moulding the carborundum with water and then heating the articles to 2500°F. In an oxidising flame (Imray, Eng. Pat. 9963, 1904, Tone, U.S. Pat. 772262)

Carborundum can be used instead of diamond for drill heads, if incorporated in a suitable metallic or ceramic matrix (Bouvier, Fr. Pat.

375338, 1907).

Silicon carbide is used instead of ferro-silicon as a source of silicon in steel making. About 0·1-0·4 p.c. is placed in the ladle and dissolves readily in the molten steel, ensuring solid castings (Kaufmann and Bouvier, Fr. Pat. 344906, 1904; Eng. Min J. 75, 481)

The amorphous silicon carbide, formerly a waste product, is used for making highly refractory firebricks and the retorts for zinc distilling (Chesneau, Ann Chim. anal appl. 1908, 13, 85). A refractory cement is made from carborundum 90-60 parts, fireclay 10-40 parts, lime 0-4 parts, and water-glass solution 47°Bć 20-50 parts, mixed, dried, and repowdered (Muller, Fr. Pat. 338914, 1903)

Neumann has shown that silicon carbide reduces silver, copper, nickel, and lead from the chlorides (Chem. Zeit 1900, 24, 1013)

By the action of silicon carbide on metallic oxides, many metallic silicides may be obtained. This reaction may be used for the preparation of special ternary or quaternary steels at a single operation (Baradac-Muller, Soc. Mg. Cie. de France, Proc. verb. 1998, 245)

o-CARBOXYPHENYLTHIO-G L Y C O L L I C ACID. o - CARBOXYPHENYLTHIOLACETIC ACID v. PHENYLTHIOGLYCOL-O-CARBOXYLIC ACID.

CARCLAZITE or CARCLAZYTE. A name suggested by J. H Collins (The Hensbarrow Grante District, Truro, 1878) for the china-clayrock from which china-clay is prepared Sonamed from the Carclaze mine, near St. Austell, in Cornwall L. J. S.

CARDAMOM OIL v OILS, ESSENTIAL

CARDAMOM SEEDS. Cardamomi Semina, B.P. The dried ripe seeds of Eletteria Cardamomum (Maton)

CARDINAL-RED, Syn Acid magenta (v. Triphenylmethane colouring matters)

**CARDOL.** A non-volatile oil found in the pericarp of the cashew nut, *Anacardium occidentale* (Linn).

CARICIN. An oil found in the seeds of the papaw tree, Carica papaya (Linn.) (Peckolt, Pharm J. [3] 10, 343)

CARMINAPH v Azo- colouring matters CARMINAPH GARNET v Azo- colouring MATTERS.

CARMINAZARIN v Cochineal.

CARMINE. The red colouring matter extracted from the cochineal insect. It is of somewhat variable composition, containing besides the colouring matter some organic matter from the insects and a little of the salt used to precipitate it from solution.

Preparation — The powdered cochineal is boiled with water, the solution filtered or al-

lowed to settle, and the colouring matter precipitated by addition of some salt, such as alum, stannous chloride, cream of tartar, Roman alum, &c. The precipitate is allowed to settle, and collected. Sometimes fish glue or white of egg is added before precipitation. Carmine is somewhat soluble in water and very freely soluble in alkalme solutions. The whole of the colouring matter is immediately precipitated by alum in the form of a lake.

In dyeing with carmine, a mordant of alum or stannous chloride is used. Kielmeyer recommends the following mixture for printing on woollen goods 14 kilos, gum, 17 5 kilos, cochineal lake, and 2 25 kilos, fustic lake, are mixed and warmed with 15 lit water till the gum is dissolved, then I kilo of oxalic acid and 1 75 kilos, acid sodium oxalate added, and the mixture allowed to cool, after which 2 25 kilos, sodium acetate are added. After printing, the fabric must be dried for a day or two, steamed under a slight pressure, and washed in a stream of water.

Detection of carmine in cloth—Alcohol takes no colour from the cloth, but when it is boiled in solution of aluminium sulphate the solution turns red and the colour is unchanged by the addition of acid sodium sulphate.

The absorption spectrum of carmine in alkaline solution is remarkable, showing two dark bands between the lines D and E very similar to those of blood. Murexide and madder show no such bands. When wine is coloured with carmine, the characteristic absorption bands cannot be seen unless more than 12 p.c. of the total colour is due to carmine (Gautier), but the adulteration can be detected by adding alum, when the colour changes to a rose tint.

It is said that the finest shades of carmine can only be obtained by working in direct sunlight (v. COCHINEAL)

CARMINIC ACID v COCHINEAL.

CARMOISINE. Syn for Azorubin (v. Azocolouring matters)

**CARMUFELLIC ACID**  $C_{12}H_{20}O_{16}$  An acid crystallising in thin plates, said to be formed by the action of nitric acid on oil of cloves (Muspratt and Dawson, Phil Mag [4] 2, 293).

CARNALLITE. Hydrated double chloride of potassium (KCl 268 pe) and magnesium, KCl MgCl<sub>2</sub> 6H<sub>2</sub>O. It occurs abundantly in the uppermost layers ('carnallite zone') of the beds of abraum-salts in the Prussian salt deposits, and is the chief commercial source of potassium chloride It is also found at Wittelsheim in Upper Alsace. The mother-liquor, remaining after the potassium chloride has crystallised out, contains traces of bromine and rubidium, the former of which is a valuable by-product. Thallium has also been detected in traces. When pure, the mineral is colourless and water-clear, but it is often coloured yellowish or reddish by intermixed impurities. Red carnallite owes its colour and metallic sheen (resembling that of sunstone) to the presence of minute scales of hæmatite. Crystals are rare; they are orthorhombic, and have the form of six-sided pyramids with numerous well-developed faces. Owing to the extreme deliquescence of the salt, crystals must be preserved in scaled vessels.

Carnallite and bromcarnallite, in which bromine takes the place of chlorine in the above formula, have been prepared artificially from solutions containing a large excess of magnesium chloride and at a temperature of over 25°. L. J. S

CARNAÙBA WAX or CARNAHUBA WAX v. WAXES.

CARNAÜBIC ACID C23H47COOH 18 obtained from Carnauba wax; m.p. 72 5° (Sturcke, Annalen, 1884, 223, 283, Darmstaedter and Lifschutz, Ber. 1896, 619, 2899).

CARNELIAN v. CHALCEDONY.

CARNINE is the name given to a base isolated from meat extract by Voit (Weidel, Annalen, 1871, 158, 353), it occurs also in beer yeast extract (Schutzenberger, Chem. Zentr 1877, 73), in the muscle of some freshwater fish and frog's flesh (Kruckenberg and Wagner, ibid 1884, 107), and in beet juice (v. Lippmann, Ber. 1896, 29, 2645). Carnine crystallises in chalk-white druses, is spaningly soluble in cold, readily so in hot, water, insoluble in alcohol or ether, it forms a crystalline hydrochloride and platinichloride, and a spaningly soluble compound with silver nitrate (Weidel,

Haiser and Wentzel (Monatsh 1908, 29, 157) have shown that carnine is an approximately equal molecular mixture of hypoxanthine and inosine C10H12O5N4, and the two are separated by the action of acetic anhydride which converts the mosme into the acetate ('10H9O2N4(OAc), m p. 236° (decomp) Inosine crystallises in silky needles, m p. 215° (decomp ),  $[a]_{D}^{18°}$  –49 2°, and 100 c c of aqueous solution saturated at  $20^{\circ}$ contains 1 615 grams When mosine is hydrolysed by sulphuric acid it yields hypoxanthine and a pentose, originally termed carnose by Levene and Jacobs (Ber 1909, 42, 2102, 2474) and afterwards identified with a-ribose Inosine is closely related to inosic acid (hypoxanthine phosphoriboside) (Levene and Jacobs, wid 1910, 43, 3147, Proc. Amer. Soc Biol Chem 1910, 25, Haiser and Wentzel, Monatsh 1909, 30, 147), for by heating a dilute aqueous solution of barium mosate at 125°-130° for 6 hours, mosine and barium phosphate are formed relation between the two compounds is probably represented by the following formulæ:

CO-NH

M. A. W. CARNITINE C<sub>7</sub>H<sub>15</sub>O<sub>3</sub>N, a base isolated from Liebig's beef extract and present also in fresh beef, is readily soluble in water yielding an alkaline solution, the nitrate crystallises in needles and has  $[a]_{D}$  about  $-22^{\circ}$ ; the platinchloride C14H32O6N2, PtCl6 forms minute orangered needles, m.p. 214°-218° (decomp) (Gulewitsch and Krimberg, Zeitsch physiol. Chem 1905, 45, 326), the hydrochloride is hygroscopic and lævo-rotatory. The aurichloride

forms pale yellow needles and orange needles or prisms, m p.  $150^{\circ}$ , the mercurichloride

is an oil that slowly crystallises , the compound  $\rm C_7H_{16}O_3N.2HgCl_2$  has m p  $\rm 196^\circ-197^\circ$  (Krimberg, ibid 1907, 50, 361) The monoacetyl derivative of the hydrochloride OAc C7H, O2N, HCl forms a yellow crystalline platinichloride

m p 199° (Engeland, Ber 1909, 42, 2457) The ethyl ester is identical with Kutscher's oblitine (Zeitsch Nahr. Genussm 1905, 10, 534), (Krimberg, Zeitsch physiol Chem 1908, 58, 417; Ber 1909, 42, 3878, Engeland, lc)

Carnitine is identical with Kutscher's novaine (Krimberg, Zeitsch physiol Chem 1908, 55, 466; Engeland, Ber 1909, 42, 2457), and is probably a hydroxy derivative of a betaine, since on reduction with hydrogen rodide and red phosphorus at 130°, it yields a product identical with Willstatter's γ-trimethylbutyrobetaine

$$NMe_{3} < \begin{matrix} CH_{2} & CH_{2} \\ O & -OC \end{matrix} > CH_{2}$$

(Ber 1902, 35, 584, see also Fischer and Goddertz, Ber 1910, 43, 3272–3280) Krimberg (Zeitsch physiol Chem 1907, 53, 514) According to Engeland (Ber 1909, 42, 2457, 43, 2705) and Rollett (Zeitsch physiol Chem. 1910, 69, 60), cainitine hydrochloride is the chloride of ahydroxy-\gamma-trumethylamino-n-butyric acid

the isomeride,  $\beta$ -hydroxy-trimethylamino butyiic acid chloride crystallises in needles, gives a chloroaurate, m.p. 145°, which decomposes 225° (Engeland, ibid. 1910, 43, 2705-2707) V. BETAINES M. A. W.

CARNOSINE C<sub>9</sub>H<sub>14</sub>O<sub>3</sub>N<sub>4</sub>, a base isolated from Liebig's extract of beef (see Smorodinzew, Zeitsch physiol Chem. 1913, 87, 20, ibid 92 19 and 227, for the percentage of carnosine found in muscle extracts) is soluble in water, crystallises in rosettes of large colourless needles, mp  $246^{\circ}$ – $250^{\circ}$  (decomp). It has  $[\alpha]_{D}+21$  independently of the concentration (Gulewitsch (Zeitsch physiol Chem 1913, 87, 6-11), and has a strongly alkaline reaction The vapours of carnosine give the pyrrole reaction with a pine splinter, Gulewitsch (ibid. 87, 8) Carnosine may be precipitated from an aqueous extract of muscle by a saturated solution of mercuric sulphate in 5 p c sulphuric acid, the precipitation is accelerated by the addition of two volumes of alcohol and a little ether (Dietrich, Zeitsch physiol Chem 1914, 92, 212-213). Smorodinzew (101d. 214-220) recommends a 10 pc. solution of mercuric sulphate in 5 pc sulphuric acid solution Carnosine can be isolated by precipitation with a copper salt, Mauthner (Monatsh. 34, 883-900). The nitrate  $C_9H_{15}O_9N_8$  crystallises in large stellate clusters of needles, m.p. 219° (decomp.),  $[\alpha]_D^{19}^{55}+222$ , p=7.603 p.c., c=7.820 p.c. The rotatory power increases slightly on dilution; it falls to about

half its value in presence of nitric acid (Gulewitsch, ibid. 1-6), the copper derivative

C9H14O4N4Cu

is crystalline and decomposes at 220°. The silver derivative and acid double salt with silver nitrate closely resemble the corresponding derivatives of arginine (Gulewitsch and Amiradžibi, Ber. 1900, 33, 1902). Carnosine is probably identical with Kutscher's ignotine (Zeitsch Nahr Genussin 1905, 10, 528, Gulewitsch, Zeitsch physiol Chem 1906, 50, 201, 51, 258; 52, 527). Compare, however, Kutscher (ibid. 1907, 50, 445, 51, 545)

When carnosine is hydrolysed by boiling with barium hydroxide it yields histidine, the other product of hydrolysis being probably

alanıne

$$C_9H_{14}O_3N_4 + H_2O = C_6H_9O_2N_8 + C_3H_7O_2N$$

According to Gulewitsch (Zeitsch physiol Chem. 1911, 73, 434–446) three-quarters of the carnosine nitrogen belongs to instiduce and the rest to  $\beta$ -alanine.

That carnosine is  $\beta$ -alanylhistidine is shown by its synthesia from histidine and  $\beta$ -iodopiopionyl chloride (Baumann and Ingvaldsen, J Biol Chem 1918, 35, 263). This is further proved by its behaviour towards 2 4 5-timitrotoluene. It has been synthesised by condensing  $\beta$ -nitropropionyl chloride with histidine methyl ester and reducing the resulting products with stannous chloride and hydrochloric acid (Barger and Tutin, Bio-Chem J 1918, 12, 402)

The carnosine content of flesh extracts may be estimated by two colormetric methods which control one another, the one depends on the colour yielded by the histidine complex in the carnosine molecule with diazobenzenesulphonic acid (Werss and Sobolev, Biochem Zeitsch 1913, 58, 119–129), the other on the violet colour yielded by carnosine when boiled with cupric hydroxide, Furth and Hryntschak (Biochem Zeitsch 1914, 64, 172–194)

M. A W

CARNOTITE, A hydrated vanadate uranium and potassium, occurring abundantly as a bright canary-yellow powder disseminated in sandstone in western Colorado C Friedel and E Cumenge (Compt rend 1899, 128, 532), by whom it was first described and named (after A Carnot), expressed the composition by the formula  $2U_2O_3V_2O_5K_2O3H_2O$  Detailed analyses were made by W.F. Hillebrand (Amer. J. Sci 1900, 10, 120), and he concluded that the This view mineral is not simple, but a mixture is, however, not borne out by T Crook and G S Blake (Mm. Mag 1910, 15, 271), who find that the material, both from Colorado and from South Australia, is definitely crystallised in minute plates possessing orthorhombic symmetry and with characters analogous to those of autunite [Ca(UO<sub>2</sub>)<sub>2</sub>P<sub>2</sub>O<sub>8</sub>,8H<sub>2</sub>O] The original material was found by M and Mme Curie to contain radium and polonium.

The carnotite-bearing sandstones occur over an extensive tract of country on both sides of the Colorado-Utah boundary, the nichest deposits being in the neighbourhood of La Sal Creek, Roc Creek, and Paradox Valley, in Montrose Co., and in San Miguel and Dolores Cos., in southwest Colorado, other deposits are met with near Coal Creek in Rio Blanco Co. and Skull Creek in

Routt Co in north-west Colorado, and at Mauch Chunk, Pennsylvania. Most of these deposits are in Jurassic (La Plata) sandstone, but some of those in the N.W. are in sandstones of Cretaccous age. They have been mined at several spots, and a plant for the extraction of uranium, radium, and vanadium salts has been erected near Cedar in San Miguel Co., Colorado; but the sandstone ofe is of a low grade, and the difficulties of transport are considerable. An average sample of marketed ore assayed  $U_{\rm s}O_{\rm s}$  11-49 p.c. and  $V_{\rm s}O_{\rm s}$  6-40 p.c. (R. B. Moore and K. L. Kithil, U.S. Bureau of Mines, Bull 70, 1913. C. L. Parsons and others, while Bull 104, 1915)

In South Australia, at Radium Hill, near Olary, carnotite occurs in films on the jointplanes of a large deposit of ilmenite rutile, and

magnetite.

A closely allied mineral, named ferganite (I A Antipov, 1908, Abstr in Jahrb. Min 1909, ii, 38), is a hydrated vanadate of uranium and lithium. It occurs, together with other uranium minerals, in prov. Fergana in Russian Turkestan.

L. J. S.

CARO'S ACID. Monopersulphuric acid (v. Sulphur).

carobs are found to possess the following percentage composition water, 9-13; introgenous compounds, 5-7, cellulose, 8-12, fat, less than 1; ash, 2, sugars (dextrose and sucrose in variable proportions), 30-43; phosphoric oxide, 0·16-0 24 (Balland, J. Pharm Chim. 1904, [6] 19, 569).

CARONE v KETONES.

CARONY BARK v CUSPARIA BARK

CAROTIN. The colouring matter of Daucus carota (Linn) Found also in the leaves of plants to the extent of 0 1 to 0 2 pc (Arnaud, Compt rend 1890, 109, 911) in full vegetation, and to a slight extent in etiolated leaves (Immendorf, Chem Zentr 1890, 1 163), and in the tomato; is present in maize, squash, orange-peel, flax seed, mustaid seed, black sesamé seed, palm oil, but not in rape seed, white sunflower seed, turnip, safflower, cotton seed or turmeric. It forms the colouring matter of yellow and orange pollen, the oily drops on the surface of the pollen of Verbascum thapsiforma contain not less than 66 pc of carotin, and in the animal kingdom it occurs as the colouring matter of milk-fat, hence in butter and the body-fat, corpus luteum and skin secretions of the cow, it constitutes the yellow lipochrome of bloodserum and is found in Diaptomus bacillifer (Blanchard, Compt rend 1890, 110, 292) It can also be extracted from stinging-nettle leaves with light petroleum (Willstatter and Mieg, Annalen, 1907, 355, 1). Carotin crystallises in copper-coloured leaflets which appear red by transmitted light, and have mp 167.8°. It is insoluble in water, readily soluble in carbon disulphide or benzene, sparingly so in alcohol, ether, petroleum, or chloroform Carotin is able to decompose carbon dioxide with formation of oxygen, and this probably explains why etiolated leaves can, under certain conditions, generate

oxygen (Kohl, Chem Zentr 1906, 11 442) Carotin is an unsaturated hydrocarbon having the formula  $C_{40}H_{56}$  (Willstatter and Mieg. lc); it combines with iodine to form the iodide  $C_{40}H_{56}I_2$ , which crystallises in rosettes

of dark-violet prisms, and decomposes at  $140^{\circ}-170^{\circ}$ ; and the  $\mathit{rodide}$   $\mathrm{C_{40}H_{56}I_{3}}$ , which forms dark-violet plates and decomposes at 136°-137°. The bromo-compound C<sub>40</sub>H<sub>36</sub>Br<sub>23</sub> decomposes at 171°-174° (Willstatter and Escher, Zeitsch. physiol Chem 1910, 63, 47) Carotin dissolves slowly in concentrated sulphuric acid, forming an indigo-blue solution from which the hydrocarbon is precipitated in green flakes on the addition of water; it absorbs oxygen to the extent of 34 3 p c of its weight, yielding a colourless substance. When carotin is oxidised with a small amount of acetic acid solution of chromic anhydride, and the temperature kept below  $30^{\circ}$ – $40^{\circ}$ , an oil  $C_{40}H_{66}O_8$ , or  $C_{40}H_{60}O_5$  is obtained, and this does not solidify at  $-104^{\circ}$ (Euler and Nordenson, Zeitsch. physiol. Chem. 1908, 56, 223)

Carotin has no appreciable toxic acid, quantities of 0.2 gram injected into guinea-pigs had no effect on the health of the animals.

CAROUBIN and CAROUBINOSE. According to Effront (Compt rend. 1897, 125, 38), the seeds of Ceratonia siliqua, used as a cattle food in Portugal, contain a carbohydrate, caroubin, which, when purified, forms a white spongy friable mass, giving with water a thick syrup or jelly By hydrolysis, it yields Caroubinose  $(C_6H_{12}O_6)$ , which has about the same reducing power as dextrose Is probably identical with mannose (Van Ekenstein, Compt rend 125, 197) (v Carbohydrates)

**CARPAINE**  $C_{14}H_{25}O_2N$  occurs in papaw leaves (*Carica Papaya* (Linn)) It forms glancing prisms, in p. 121°,  $[\alpha]_p + 21^\circ$  55′, and has a bitter taste (Greshoff, 1890, Med. s'Lands Plantentum, Java, No. 7, 5; van Rijn, Arch Pharm. 1893, 231, 184, 1897, 235, 332). According to Baiger (Chem. Soc. Trans 1910, 97, 466) it is a lactone of carpainic acid C<sub>14</sub>H<sub>27</sub>O<sub>2</sub>N, and may be written

CARRAGEEN. Carageen, Carragheen, or Carragaheen (Fr Gaëmen) Irish or Pearl moss. An alga (Chondrus crispus) found on all the western coasts of Furope and on the east coast In Ireland it is collected, of North America dried, and bleached in the sun Found in commerce as flat, dry, yellow-white pieces 2 to 3 inches long, usually branching, of a very faint odour and mucilaginous taste, swelling in water like gelatine Almost completely soluble in boiling water; the solution sets to a jelly on cooling Contains a high percentage of nitiogen, and is of value as a food in diseases of lungs and general weakness, usually taken dissolved in hot milk. It has also been applied as a size and for stiffening silk, also occasionally in making jellies.

Sometimes found largely adulterated with Gigartina mamillosa, which is less valuable and recognised by its stalked fruits and channelled stem (v. Algæ and Irish Moss Gum, Art Gums.

CARRAWAY OIL v. OILS, ESSENTIAL.

## CARRIAGE VARNISH v. VARNISH.

CARROT, the tap root of Daucus carota (Linn). Several varieties exist, and the roots are employed as cattle food and as a table vegetable Kellner gives as the average composition

According to American analyses, the average composition of the edible portion, as a table vegetable, is

The Belgian white carrot is often used for the field crop, whilst the red carrot is preferred for table purposes The reddish colouring matter of the carrot, carotin, is sometimes used in colouring butter and cheese. It has the composition  $C_{40}H_{56}$ , and can be obtained by rasping the roots, precipitating the juice with lead acetate, with which the carotin forms a lake This is dried and extracted with carbon disulphide The solution is evaporated to dryness and repeatedly extracted with cold petroleum spirit in order to remove the phyto-The residue is then dissolved in carbon disulphide, from which the carotin is precipitated by the addition of alcohol—It can then be recrystallised from benzene in the form of rhombic plates with a metallic lustre, blue by reflected, orange-red by transmitted light The substance which Husemann discovered in the carrot and called hydrocarotin is a mixture of sitosterol and stigmasterol, and consists of the same phytosterols as are found in other plants

(Beschke, Bei 1914, 47, 1853) (v Carotin)
As a farm crop, carrots are particularly valued for horses and dairy stock. They are best grown on light land, free from stones and н 1. weeds and well tilled.

CARVONE " KETONES

CASCARA SAGRADA, BP, US.P. The dued bark of the Rhamnus Purshiana (DC), a small species of thorn tree inhabiting the Pacific slopes of the Rocky Mountains (For botanical characters, see Hooker (Flora Bor Amer 43), Prescott (Amer J Pharm 1879, 165), Moller (Pharm J [3] 14, 467), Moss (ibid. [3] 649, 19).) Cascara sagrada had been long known as a cathartic to the Indians and trappers of Califorma, when it was later introduced into American and European medicine Its physiological action is similar to the other and better-known Rhamnus frangula (Linn.), but the Purshiana is the more esteemed (Cf. Kennedy, Amer J Pharm 1885, 496)

Cascara bark has been examined by Prescott (*ibid* 1879, 165), Limousin (J Pharm. Chim. [5] 6, 80); Wenzell (Pharm Rundsch. 1886, 79); Meier and Webber (Pharm J. [3] 18, 804), Schwabe (Arch Pharm. 226, 569); Zeig (Pharm. J. [3] 20, 173); Le Prince (Compt. rend. 115, 286), Dohme and Engelhardt (Amer. Chem. J. 20, 534); but the statements made regarding it

are very conflicting, for a summary of which see Jowett (Rep. Amer. Pharm. Assoc. 1904, 1), who has also made an exhaustive examination of the bark. He has confirmed the presence of emodin together with a small proportion of an isomeric substance which may be identical with the iso-emodin obtained from Rhamnus frangula by Thorpe and Miller (Chem Soc. Trans. 61, 6) Glucose is also present, and a substance which, on treatment with acid, yields syringic acid. No evidence was obtained of the existence of chrysophanic acid or chrysarobin or of glucosider yielding on hydrolysis emodin, chrysophanic acid, or rhamnetin. The cascarine of Le Prince and the purshianin of Dohme and Engelhardt are probably impure products Emodin is not the active principle of the drug, and no clue could be obtained as to the nature of this principle (Compare Nouveaux Remèdes. 1909, 471, where the active principle is stated to be precipitated by lead acetate and ammonia, after treatment with lead acetate alone ) It is a light yellow powder of bitter taste, probably a glucoside According to Tschirch and Monikowski (Arch Pharm. 1912, 250, 92) the patent cascara preparation 'peristaltin' consists of a mixture of glucosides, hydrolysed by steam to rhamnose, chrysophanic acid, emodin methylether and cascarol C15H10O5, yellow needles, m p 218°. Cascara bark contains about 2 p c of fat and a small proportion of a volatile oil The constituents of  $\tilde{R}$ . Californica appear to differ very little from those of R Purshiana For methods for the estimation of the active constituents of Cascara sagrada, see Warin (J Pharm chim. [6] 22, 12), whose coloring method is approved by Tschirch and Pool (Arch Pharm 1908, 246, 315) For differential tests of Cascara and Rhamnus frangula, see Kroeber (Schweiz. Woch Chem Pharm 1910, 48, 377); Beal and Okey (J. Amer Chem Soc. 1917, 39, 716) For standards for the evaluation of liquid extracts of Casacara and Rh frangula, see Apot Zeit 1913, 39, 579).

CASCARILLA BARK, Cascarilla (BP)
The bark of Croton Eluteria (Benn), or 'seaside
balsam,' a cuphorbiaccous tree growing in the

West Indies

Duval obtained from it a substance, cascarilline C<sub>12</sub>H<sub>18</sub>O<sub>4</sub>, in p 205°, which Alessandri (Arch Pharm 220, 690) also isolated by extracting the bark with ovalic acid and precipitating the extract with ammonia. This substance dissolves in hydrochloric acid, producing a rose-coloured solution, which changes through purplish-red, violet, and green to a sky-blue without the addition of water. The drug also contains betaine (Naylor, Pharm. J. 59, 279), and 15 p c. of an essential oil (q.v)

CASCARILLA OIL v OILS, FSSENTIAL.

casein. Casein occurs in the milk of mammals, and is the principal protein of cow's milk, which, up to the present, is its only commercial source. Cow's milk contains, on an average, about 3 pc of casein, which exists in a suspended or colloidal condition, probably as a lime compound in combination with calcium phosphate, giving the milk its opaque appearance. This can easily be proved by allowing the milk to pass through a filter of unglazed porcelain, when a white mass of casein and fat will be found on the surface of the filter, and the

filtrate will contain the lactose, soluble albumen, and soluble salts of milk,

Preparation of pure casein. Separated milk is diluted to about five times its volume with water and sufficient acetic acid added to give 0.1 p.c. of acid in the solution. The casein is precipitated, carrying down with it the fat. The curd is washed about ten times by decantation, collected on a cloth filter, washed, and pressed as dry as possible. It is then dissolved in the least quantity of ammonia, and filtered. The filtrate is precipitated with acetic acid, washed, and redissolved in ammonia. This process is repeated three or four times. The curd is then rubbed up in a mortar several times with 80 p.c. alcohol, and finally with absolute alcohol. It is next similarly treated with ether, and extracted with ether in a Soxhlet apparatus, and the casein finally dired at 100°C.

Properties — Thus prepared, casein is a white, amorphous body without taste or smell. It is very sparingly soluble in water, and quite insoluble in alcohol and ether. Its most probable percentage composition is: C, 53·13; H, 706; N, 15·78, P, 0.86, O, 22·40; S, 0.77.

Casem is a phospho-protein. Its molecular weight is stated to be about 1135. It is a weak dibasic acid, forming acid and neutral salts with alkalis. In dilute alkaline solutions, it has a lawo-rotatory action on polarised light. At the ordinary temperature, I gram of casem combines with 9 c c. of N/10 hydrates or carbonates of alkalis, and with nearly 7 c c. decinormal solutions of common acids. It is soluble in caustic alkalis, and in the carbonates, bicarbonates, phosphates, &c, of the alkali metals, and is precipitated unchanged by addition of sufficient acid to neutralise the alkali

Casein is soluble in strong hydrochloric acid, giving a fine violet colour, and is also soluble in dilute hydrochloric acid containing 0.2 p.c. of the fuming acid, but is insoluble in 2 or 3 p.c. acid

Preparation of industrial casein. There are many methods of preparing casein, but on the large scale these are generally limited to three:

(1) Precipitation by means of acid—usually sulphuric, though acetic, phosphoric, lactic, hydrochloric, &c., are also employed.

(2) Curdling by means of rennet(3) Curdling by 'self-souring.'

A very interesting method of preparation is by means of electricity, but so far this does not seem to have progressed beyond the laboratory stage. The method, however, will be described later. Whichever method be employed, the first essential is a machine-separated milk, containing the smallest possible quantity of fat Milk taken from cows shortly after calving, and containing colostrum, is unsuited for casem manufacture. It gives a soft curd which squeezes through the filter cloths, and holds a great deal of water. It has sometimes been found necessary to throw away a whole batch as the curd has been quite unworkable.

Also, if the milk has been pasteurised at such a high temperature that some of the lact-albumin becomes insoluble, the curd will give a great

deal of trouble.

The milk from the separators is run into a tank of suitable dimensions, and brought to the required temperature by means of steam.

CASEIN 93

Precipitation by sulphuric acid.—The requisite quantity of sulphuric acid, previously diluted with water in a wooden or enamelled iron bucket, is then introduced, and the whole well agitated, when the milk will gradually lose its opaque appearance and become clear with separation of the curd. As soon as the whey is yellow and transparent, the agitation is stopped, and the curd falls to the bottom of the tank. The whey is run off, the curd allowed to drain and washed with cold water until all the whey has been separated. The bulk of the water is then removed by means of a suitable press or by a centrifugal machine.

Curdling with rennet —The amount of rennet required depends upon the acidity of the milk and the temperature. The more acid the milk and the nearer the temperature approaches 106°F., the less is the rennet required. At 118 5°F, and at 86°F, the curdling power of rennet is only about 70 pc of that at 106°F

If the acidity of the milk be 15°, about 2½ oz. rennet should curdle 100 gallons of milk in about I hour. When the acidity reaches 30°, half this quantity will suffice The requisite quantity of rennet is diluted with water and thoroughly stirred into the milk at a temperature of about 106°F The milk is then allowed to rest until it has 'set' like a junket The mass is cut up into small cubes by special knives, and then agitated gently at first, and afterwards vigorously while being very slowly heated up to about 120°F by means of free steam or a steamjacket The curd will then be in hard grains or nodules at the bottom of the tank. The whey is rapidly run off, the cuid washed well with cold water, and pressed

Curdling by 'self-souring.'-When milk is exposed to the air, it becomes acid. This change is effected by the Bacillus acidi lactici, which converts the lactose into lactic acid sufficient acid has been formed, the curd separates from the whev On the large scale, the separated milk is run into a tank, the temperature brought to and maintained at about 98°F, at which point the growth of the bacilli is most After some hours, according to the freshness of the milk, a sour smell will be noticed and the milk will begin to curdle When the right point has been reached, steam is turned on and the mass agitated in order to make the curd firm, and in a suitable condition for washing The whey is then run off and the and pressing curd finished in the usual manner

Drying of the curd —When as much moisture as possible has been removed from the curd, it is broken up and dried. This may be effected either by spreading on trays in heated drying-rooms fitted with ventilating appliances to facilitate the removal of the moisture, or in a drying cylinder heated from inside or outside or both, and rotated to keep the contents in constant motion. Another method of drying the curd is by means of a Passburg vacuum drier, consisting of a cast or wrought-iron case, which can be hermetically closed by doors. A vacuum is produced by an air pump, and the moisture is vapourised at a low temperature so that drying is soon effected.

Whatever process be adopted, the temperature must be carefully watched, as a few degrees too much heat will 'burn' the casem to a rich brown colour, and if the temperature be too low the curd will take a long time to dry, and may become sour and mouldy.

The dry casein is then ground to a fine

powder, when it is ready for the market

Curdling by electricity.—Although this process is so far not a commercial one, it is sufficiently interesting to warrant a short description milk is heated to 120°F, and a porous cell, containing dilute milk, is placed in the centre. A current of electricity of sufficient tension is passed, and the soluble elements, the phosphates in particular, are decomposed anode is placed in the milk and the cathode in the porous cell Phosphorie acid is then liberated in the milk, and causes the precipitation of the casein, while the liquid in the porous cell becomes strongly alkaline. The chief difficulty lies in the choice of electrodes—the cathode in the porous cell can be carbon, but the anode must be of platinum, which makes the original cost very heavy Any of the common metals are attacked in a very short time, and carbon throws off small particles which cause the precipitated cuid to become black. It is, of course, possible to have both electrodes of carbon in porous cells, but it is found that the curd soon fills up the pores and the action becomes very slow

Properties.—Industrial casein, prepared with sulphuric acid, will dissolve in the following quantities of alkalis or alkaline salts, though larger quantities are always used in the various industries—

 Sodium bicarbonate
 3½

 Sodium carbonate
 2¼

 Sodium hydroxide
 1¼

 Sodium silicate 140°Tw.
 10

 Sodium arsenate
 20

 Sodium sulphite
 9

 Strontium hydrate
 20

 Trisodium phosphate
 8

 Ammonia, 880
 2½

Sodium tungstate

Borax

Per cent.

Solutions of the hydroxides of potassium, sodium, lithium, and ammonium of equal concentration, dissolve casein at approximately the same rate. Solutions of the hydroxides of the alkaline earths dissolve casein much more slowly, strontium hydroxide dissolves it most rapidly, calcium hydroxide more slowly, and barium hydroxide more slowly still.

Rennet casein is insoluble in carbonate and bicarbonate of soda, partly soluble in borax and ammonia, and soluble in trisodium phosphate and lime

Its solution in alkalis does not coagulate on heating, but is precipitated by acids and many metallic salts. When acted on by formaldehyde and certain other bodies, casein is rendered insoluble. Advantage is taken of this fact in various industries to give a waterproof coating of casein.

Pure casein contains only a very small amount of ash, but industrial casein may contain up to about 7 p.c. or 8 p.c.—rennet-prepared

 $<sup>^1</sup>$  The 'degree of acidity' of milk is the number of c c, of N/10-NaOH sol, required to neutralise the acid in 100 c.c.

CASEIN.

casein containing the most, and 'self-soured' casein the least.

For the analysis of commercial casein v. Hopfner and Burmeister, Chem. Zeit. 1912, 36, 1053; Analyst, 1912, 493.

Casem is employed in a Uses of casein. large number of industries, and its use is increasing every year, in fact, there are but few industries in which casein, in some shape or form, is not or cannot be employed with advantage

The greater quantity of imported casein comes from the Argentine Large quantities also are received from France and Germany, and smaller quantities from Holland, Belgium, and tne United States

Casein is used in paste and dry distempers, in cardboard manufacture, paper glazing, leather dressing, soap manufacture, cotton sizing, diessing for textiles, finishing, waterproofing, calico printing, cask glazing; imitation bone, ivory, tortoiseshell, amber, ebony, &c picture mouldings, sealing for bottles, cabinet and planoforte making, emulsions, fining wines, boot polishes, waterproot cements, polishes, films, diabetic and protein toods

Alimentary casein. Some of the best-

known food preparations of casein are Plasmon —This is a cream-coloured powder, somewhat coarse in texture It is a soda compound of casein, and is partially soluble in water. It contains nearly 2 pc of lactose (milk-sugar)

and about 70 p c of proteins

Sanagen —A fine white powder, completely soluble in water. It is a compound of casein with about 5 pc of sodium glycerophosphate made by a special process. It contains about 76-78 p.c. proteins, and is practically free from lactose, and so is specially recommended for diabetic patients.

Sanatogen -A white powder soluble in It consists of casein with about 5 pc. of sodium glycerophosphate, and is free from fat and lactose

Dr. Reigel's milk protein —A soda compound of casein, soluble in water. According to the patent specification, the curd is precipitated from the milk by means of ethyl-sulphuric acid

Eucasein - A casein-ammonia compound, soluble in water

Nutrose.—A soda compound of casein.

Casein solids. Galalith —Insoluble treated with formaldehyde and subjected to heavy pressure, gives plates of great hardness, and by blending pigments with the casein, imitations of bone, ivory, ebonite, &c., are obtained. The products are known as Galalith (from the Greek gala, milk, and lithos, stone) It is prepared from a specially pure casein, precipitated by rennet, from sweet milk freed from fat by centrifuging. The curd is drained and dried, forming lumps 8-12 mm. thick These are ground to a gritty meal, which is moistened with water, coloured as required, worked up by steel helices to a plastic mass, which is then hot-pressed in hydraulic presses. The pressed cake is hardened in a solution of formaldehyde, the length of treatment varying from 2 to 30 weeks, according to the thickness of the articles, whereby the casein acquires the qualities of horn (Bonwitt, Zeitsch. angew. Chem. 1914, 27, 2). The following articles are

made from galalith brush-backs, combs, eigar and cigarette holders, penholders, electrical fittings, umbrella and stick handles, buttons, dominoes, &c Being uninflammable, casein possesses great advantages over celluloid. It is a bad conductor of electricity, and is therefore suitable for electrical fittings A plate of galalith 1 inch thick, is impervious to a current of 16,000 volts. The sp gr. is 1317-135 (celluloid 134-140) The hardness is 25 (celluloid 2). It resists only liquids and acids, but is swelled by alkaline liquids — Its chief drawback is its hygroscopic nature, it absorbs 30 pc of its weight in 12 days. It is not elastic like celluloid, and breaks when slightly bent. On account of its tendency to flake it cannot be worked so well as celluloid, and sheets cannot be prepared less than 2 mm. in thickness (Bonwitt, lc).

Lactoform — This is a patented preparation of casein resembling horn, giving, according to the specification, a hard and tough article which does not swell or materially soften when immersed in water. It is prepared by adding various salts to solutions of casein, thus, by adding a solution of lead acctate to a solution of casem, a coagulum is produced from which lactoform, resembling horn, may be obtained, while to manufacture a substitute for ivory, carbonate of soda is added to the casein solution and precipitated by sugar of lead, thus forming carbonate of lead in the mass obtained By the use of chromium compounds, bluish-green, also yellow and orange lactoform, is obtainable; by the action of iron, just-coloured, and in combination with tannic acid, slate and blackcoloured, lactoform may be produced. These are merely intermediate products, and are not claimed as a new invention, but are converted into lactoform by treatment with formaldehyde

For glues and sizes, casem is dissolved in borax, soda, or ammonia, and the resulting coating may afterwards be rendered insoluble by formaldehyde, or the casein may be dissolved in lime, which will give a waterproof coating when dry.

Films.—Schmidt has patented a process for making casein films as follows: 100 grams of casein are dissolved by heating in 1 litre of water containing 8 grams of 25 p c. hydrochloric acid: 10 grams of 40 pc. formaldehyde and a small quantity of glycerol are added, and the solution poured on glass plates to dry. He states that films made from alkaline solutions of casein are not impermeable to moisture.

Schmidt patents the following process: 100 grams of casein and 1.5 grams caustic soda are dissolved in I litre of water, to which are added about 15 grams of a 40 p c. solution of formaldehyde, or 100 grams of casein and 10 c c. of a 10 p c solution of ammonia are dissolved in 2 litres of water, to which are added about 30 grams of a 40 p.c solution of formaldehyde. Either of these he states, gives insoluble films on drying, which may be used for photography, surgical bandages, paper-coating, &c.

Buss, in his patent for photographic films, proceeds as follows 500 to 700 grams dry casein are heated with 9 litres of water to 35° or 50°, mixed with 250 grams of citric acid dissolved in 1 litre of water, and the heating con tinued until the vhole has dissolved. Then 100

CASSIA. 95

or 200 grams of glycerol are added, and the liquid filtered. It is applied by machine to plain or baryta paper, and allowed to dry. It is next rendered insoluble by being drawn through a 5 or 7 p.c. solution of ammonium or sodium chloride, and finally sensitised in a silver nitrate bath, ranging between 4 and 12 p c. in strength

Scaling for bottles.—For this purpose, Joirgnot has patented the following preparation: Casein is treated with a hot aqueous solution of sodium phosphate, ammonium fluoride and glycerol, the whole being then heated in the water bath until it is homogeneous and viscous. This product is employed for sealing bottles of metal, glass, porcelain, &c, by applying it in a warm state to the edge of the vessel or cover, and then treating it with formaldehyde

Fining of wines.—For this purpose, a readily soluble sodium compound of casein is used is dissolved in 10 or 20 parts of water, the 5 p c. solution effecting a somewhat slower though more complete clarification. The casein compound has the advantage that it is very much cheaper than albumen, and is free from all flavour such as is found in even the purest Moreover, if in fining wines with white of egg, albumin or gelatin, too large an excess in proportion to the tannin be used, this excess remains in solution, and may lead to turbidity and alteration in the wine; whereas the casein, even when added in considerable excess, is completely eliminated, being coagulated by the acid in the wine

Casem water-paints —Casem in fine powder is intimately mixed with sifted slaked lime and incorporated with the pigments The proportion of lime to easein is very important if too little lime be used, the mixture will, after a short time, especially if exposed to air, become insoluble in water, and if too much lime be used, adverse results will follow The brushes will be rotted and the paint will be hable to flake off The next matter of importance is the proportion of lime and case to be incorporated with the pigment. If too little be used, the paint will dust off and will not stand washing, and if too much be used, the coating will be brittle and flake off

In selecting the pigments, it is necessary to employ only those which are unaffected by lime. The most suitable are

For White.
,, Yellow.
Whiting, China clay, zinc oxide.
Ochre, Hansa yellow, naphthol
yellow, chrome yellow.

,, Brown. Umber, sienna ,, Black. Carbon blacks. ... Red. Oxides, lithol red.

,, Red. Oxides, lithol red .. Blue. Ultramarine.

Green earth, ultramarine green, lime green.

The ingredients must be thoroughly incorporated and kept in air-tight packages. The paint is prepared by mixing the powder with cold water, and is ready for use in a few minutes. When thoroughly dry, the surface is washable.

L. M. N.

CASHEW GUM v Gums. CASIMIROINE  $C_{22}H_{14}O_6N_2(OMe)_2$ , m.p.  $196^\circ-197^\circ$ , and casimiroedine  $C_{17}H_{24}O_6N_2$ , m.p.  $222^\circ-223^\circ$ , occur in minute amount in the seeds of Casimiroa edulis (La Llave et Lejarza) a reputed

Mexican drug. The alkaloids are physiologically mert (Power and Callan, Chem Soc. Trans. 1911, 99, 1993, who give other references)

CASSAVA. The root of Manshot palmata (Muell), 'sweet cassava;' or of Manshot utilissima (Pohl), 'bitter cassava' These plants are widely cultivated in the tropics for the sake of their starchy edible roots. From them the substance tapicca is prepared. The starch is also known as mandice starch, Brazilian, Bahia, Rio or Para arrowroot, and by other

The giains of starch are grouped in twos, threes, or fours, the separate grains have usually one or two flat surfaces, but, on the whole, are rounded and show delicate concentric strictions and a distinct follows:

Cassava root contains a volatile poisonous substance (Fermin, 1764), which proved to be hydrocyanic acid (Boutron-Chailaid, 1836, and Francis, Analyst, 1878, 2, 4). The latter observer found 0 0168 p.c. of prussic acid in sweet cassava root and 0 0275 p.c. in the bitter root. He found 594 p.c. and 614 p.c. water in the roots, and about 30 p.c. of starch

Collens (Bull. Dept. of Agric. Trimidad and Tobago, 1915, 14, 54) found that the freshly-dug roots of the sweet and bitter varieties contain 0.0048 p.c. and 0.053 p.c. of hydrocyanic acid respectively, the leaves 0.0162 p.c. and 0.041 p.c., and the peelings of the stems 0.043 p.c. and 0.041 p.c. respectively

Leuscher (Zeitsch offentl Chem 1902, 8, 10), as the mean of six analyses of the fiesh root, found:

Water Protein Fat Starch Sugar Crude fibre Ash 70 25 1 12 0 41 21 44 5 13 1 11 0 54 He states that the yield, on well-irrigated land, may amount to 15 or 16 tons per acre

Tapioca is made from the starch of cassava by stiring the damp product on a hot iron plate until it agglomerates into the irregular, spherical masses familiar as tapioca. By this treatment, many of the starch grains become changed, being converted into shapeless, translucent

According to American analyses (Wiley, Bull 13, U.S. Dept. of Agric. Div. of Chem. 1898), tapioca contains—

Water Protein Fat Carbohydrates Fibre Ash 11 23 0 37 0 03 88 16 0 12 0 09

Owing to the exceptionally low demands of cassava for mineral matter, it has been recommended as a crop particularly well adapted for cultivation on poor sandy soils, as it feeds very largely upon air and water (Ewell and Wiley, Amer Chem J 1893, 15, 285)

H. I.

CASSEL EARTH OF VANDYKE BROWN v. PIGMENTS.

CASSEL YELLOW. Lead oxychloride. A pigment also known as Turner's Yellow, Montpelier Yellow, Mineral Yellow, and Patent Yellow.

CASSELMAN'S GREEN. A pigment made by mixing boiling solutions of copper sulphate and an alkaline acetate

CASSIA. The bark of Cinnamomum cassia (Blume), a tree belonging to the order Lauraceæ or true laurels. It is grown in China, Java, &c. C. cassia furnishes a bark which is much like cinnamon [C. zeylanıcum (Nees)], but thicker, coarser, stronger, less deheate in flavour, and

96 CASSIA.

cheaper; hence it is frequently used to adulterate cinnamon. The bark is stripped off the branches, when it rolls up in the form of quills It is said to be preferred to cinnamon itself by some chocolate makers on account of its stronger flavour. The unopened flower-buds are also sold under the name of 'cassia-buds,' and possess similar properties to the bark. Other species of the genus afford aromatic barks, eq C culilawan (Blume), native of Malaya and China, the bark of which has a flavour of cloves, tamala (Nees), which occurs in sub-Himalayan India as far as Burma, and provides a bark that is used as a substitute for or adulterant of true cinnamon: C Burmanni (Blume) is the source of the bark exported from Sumatra The bark known as clove-cassia is obtained from Dicypellium caryophyllatum (Nees), which is also a

tree of the laurel family growing in Brazil

The employment of cassia as a sophisticant of the more esteemed and more costly bark of cinnamon when in the ground state may usually be detected by adding tincture of rodine to a decoction of the powder; when, since cassia contains more staich than cinnamon, the substance will turn blue, but, where inferior qualities of the true cinnamon have been examined, their constitution has approached that of the coarser bark of cassia, and this test has proved uncertain (cf O. Hehner, Analyst,

1879, 225-228)

Cassia bark is thicker, redder, stronger to the taste than cinnamon. The powder under the microscope exhibits a general resemblance to cinnamon, but it will be seen that cassia differs from cinnamon in its coarser structure, and especially in the greater size and number of its starch corpuscles

Cassia yields by distillation an essential oil largely used in perfumery, especially for producing the scent in brown Windsor soap (v Oils, ESSENTIAL)

CASSIA OIL v OILS, ESSENTIAL

CASSIA TORA (Linn ) or TAGEREY-VEREY. This plant produces grains known in the East Indies, Arabia, and Japan as Tora, but which are known in Pondicherry and other parts of Hindostan as Tagerey-verey It is regularly used as a component of the indigo vat in dyeing, apparently serving the same purpose as the bran-madder or molasses used in Europe

The native dyers use the Tagerey-verey in the following manner. To dye about 200 yards of cloth, 111 lbs of the grain are steeped in from 5 to 6 gallons of cold water, and then boiled for four hours The grains are swellen and softened by this treatment, and the water becomes thick and gummy The whole of this is added to the indigo vat, and after standing for fifteen hours, the vat is ready to dye.

CASSITERITE or TIN-STONE. Native tin oxide, SnO2, containing 78.6 pc. of tin, and practically the only ore of the metal It varies much in appearance—the colour ranges from white to black, being usually dark brown-and its most characteristic feature is its high sp.gr. of 6.8-7.1; hardness, 6-7, easily scratching Crystals are tetragonal, with very characteristic knee-shaped twins; their faces are often very brilliant with an adamantine lustre There is an absence of cleavage; and this readily helps to distinguish the mineral from blende.

Crystals are, however, not very common, the mmeral being more frequently found as disseminated grains and water-worn pebbles. Grains of cassiterite in a concentrate panned from a river sand may be readily detected by a very simple characteristic test. When placed on a zinc plate, or in a basin with fragments of zinc, and dilute hydrochloric acid poured over, any grains of tin-stone soon show a shining white coating of metallic tin. Veins of tin ore usually occur at the junction of granitic masses and slates, and the ore also impregnates the rocks bordering the veins. Such ores are known as vein-tin, to distinguish them from the stream-tin of alluvial deposits. A compact variety with a radially fibrous and concentric structure and sometimes a botryoidal surface is known as wood-tin. The ore as prepared for market is known as black-tin, and in South America as barilla. The principal tin-producing countries are the Federated Malay States, the islands of Banka and Billiton in the Dutch East Indies, Siam, China, Australia (Queensland, New South Wales, Western Australia), Tasmania, Bolivia, Cornwall, and more recently South Africa (Transvaal and Swaziland), and Northern Nigeria. The production of tin ore amounts to about 100,000 tons per annum CASSIUS, PURPLE OF, v. GOLD J. L. S.

CASTILE SOAP v SOAP

CASTOR or CASTOREUM. (Bibergeil, Ger) A name given to a secretion of the beaver (Castor fiber), contained in pear-shaped cellular sacs (found near the genital organs of the male and female animal), which are cut off and dried, to prevent the skin being affected by water It is a substance analogous to civet and musk, and is of the consistency of thick honey and unctuous to the touch. The interior substance is solid, of a dark-brown or black colour. It has a faint smell, softens when heated, but becomes brittle When chewed, it sticks to the teeth when cold It has a bitter acrid taste, and a like wax fætid, penetrating smell. Its fracture is shining, and when the substance is genuine it shows fragments of membrane indicating organic structure

Three varieties are said to exist, the Russian, Bavarian, and American or Canadian, the firstnamed variety containing about 2 pc of the volatile oil, while the last contains only 1 p.c.

Wohler obtained phenic and benzoic acids and salicine from it Lehmann found bile in a fresh sample together with alkaline urates, sebates, and an albuminoid substance. Laugier, Brandes, Batka, Bouillon Lagrange, and Hildebrant have also examined it By extracting it with six times its weight of alcohol a colourless substance, castorin, has been isolated Used in medicine and perfumery.

CASTOR OIL is obtained from the seeds of Ricinus communis (Linn ) and R. sanguineus

The former plant appears to be indigenous to Africa (Egypt), but has been transplanted to India at a very early stage of history, so that some writers consider the plant indigenous to India itself The plant grows in enormous quantities in all tropical and sub-tropical countries, and is even found wild to day in South America, notably in Paraguay and the

The most important sources of castor seed

are East India, Java, the Mediterranean counties, Mexico, and the United States of America, whilst the cultivation of the plant has of recent years been developed in the Egyptian Sudan, Fiji, and the East African Protectorate

In 1913 the imports of castor seeds into Marseilles amounted to 25,157 tons, as compared with 16,588 tons in 1912, and 11,509 tons in 1911 (Diplom and Consular Reports, No. 5377 of 1914) By far the largest producer is East India

The total imports of castor oil into this country in 1916 were 1,322,000 gallons, in 1917 they were about 2,000,000 gallons. The imports of castor seed in 1917 were 45,000 tons, the bulk of which went to Hull, and yielded 4,176,000 gallons of oil, the greater part of which was used for aircraft engine lubrication (J Soc Chem Ind 1919, 20 R)

The seeds consist of 20 p c of husks, which are rich in mineral matter, but contain no oil, and 80 p c of kernels, forming a white, softish mass. The whole seeds contain a toxic principle—'ricine' or incinne. The kernels contain a powerful fat-hydrolysing enzyme, which can be made use of on a manufacturing scale for hydrolysing oils and fats for soap-making purposes.

poses

The enzymes lipase and esterase can be extracted from castor beans by means of ether (Falk and Suguira, J. Amer. Chem. Soc. 1915, 37, 217). The lipase is capable of hydrolysing oils at temperatures as low as  $-5^{\circ}$ , a fact which has an important bearing on the question of the enzymic hydrolysis of fats in food preserved in cold storage (Blanchet, Compt. rend. 1914, 158, 895). It is reversible in its action, and is capable of forming mono-di- and tirolein from an emulsion of oleic acid and glycerol (Krausz, Zeitsch angew. Chem. 1911, 24, 829).

The seeds contain 46 to 53 pe of oil oil is produced on a large scale either by expression or extraction For the production of best quality oil -for medicinal purposes—the seeds are decorticated before being expressed press-cake is subjected to a second and third expression, but the oils so obtained are unfit for medicinal use, and are employed for technical purposes (soap-making, Turkey-red oil, and lubricating oils). The cakes retain the poisonous alkaloid, and are therefore unfit for feeding purposes Although it is stated that by washing the cakes with 6 or 7 times their amount of a 10 pc sodium chloride solution, they can be freed from the alkaloid, no castor cake is actually used for feeding cattle, but applied exclusively to manuring the land The extracted oil is only used for technical purposes.

Another method of removing the toxic principle is to grind the seeds with water into a thin paste, which is then poured into boiling water. This coagulates the proteins, and the solid matter when strained off and expressed leaves a meal with the following composition Water, 9·2; asn, 7·3, oil, 2·6; proteins, 7·1·7, crude fibre, 5·0; and carbohydrates, 4·2 p.c (Indian Trade J. 1908, 9, 309; 1909, 11, 273)

A simple physiological method of detecting castor seed in other seeds is described by Lander and Geake (Analyst, 1914, 39, 292)

Crude costor oil is refined by steaming the oil, whereby the albuminous substances are Vol. II.—T.

coagulated, so that they can be removed by filtering.

Castor oil is a colourless or pale-greenish oil, having a taste at first mild, then harsh, this harsh taste is more pronounced in American than in Italian or French oils. The oil differs from all other fatty oils by its high specific gravity, viz up to 0.968. Contrary to older statements, the oil does not div, even when exposed to the atmosphere in thin layers. It has the following analytical characters. Sp.gr. 0.959, 0.968, solidification point, -17° to -18°; nodine value, 84-86°, Reichert-Meissl value, 2-2.5°, saponification value, 175-183°, acetyl value, 150°, and m.p. of fatty acids, 13°.

Castor oil is strongly destro-rotatory; the optical activity is due to the presence of nein-

oleic acid

The chief constituent of castor oil is the triglyceride of ricinoleic acid, both isomerides ricinoleic and isoriemoleic acid being comprised under this term, in addition thereto, castor oil contains a small proportion of glycerides of a natural dihydroxystearic acid and of stearic acid. Palinitin and olem are absent.

Owing to the presence of tririemolein, castor oil is distinguished from all other fatty oils by its high 'acetyl value' (see above and Oils and Fats) Castor oil further differs from all other fatty oils by its ready miscibility with absolute alcohol and glacial acetic acid, as also by its insolubility in large quantities of light petroleum, kerosene, and high-boiling paraffin oils. The oil gives a homogeneous solution with an equal measure of light petroleum, or one volume and a half of kerosene or paraffin oil; if more of the solvents is used, the excess will float on the top of the mixture. If castor oil be mixed with a small quantity of another fatty oil, this characteristic insolubility in petroleum distillates is

On subjecting castor oil to destructive distillation (as in the preparation of 'cognac oil'), undecylenic acid and conanthaldehyde distillation, whilst the residue solidifies to a very bulky, spongy, indiarubber-like mass, for which a solvent has not yet been found. This residue appears to consist of the anhydride of triundecenoic acid. By heating castor oil for 10 hours at a temperature of 260°-300° under a pressure of 4-6 atmospheres, the oil becomes miscible with mineral oils

When heated at 150°-250°, and then neutralised with alkali, castor oil yields soaps which are soluble in hydrocarbons, &c If, after heating, the oil is sulphonated before neutralisation, a substitute for Turkey-red oil is obtained, whilst evaporation of the product leaves a soap which does not readily form insoluble soaps with calcium and magnesium salts (Blumer, D. R. P. 227993, 1907, see also Eng Pat 24868, 1897).

Owing to its viscous character easter oil is particularly suitable for lubricating internal combustion engines, and is now largely used for aviation motors. Oil for this purpose should be colourless, have sp.gr. of 0 964–0 968, and an acid value of less than 0·3, and when heated in a flat dish for an hour at 215° should not darken to only material extent. The chief adulterants of oil supplied for lubrication are sugar and arachis oil (q.v.).

Castor oil is a good solvent for resins in

H

rubber, and may be used in the purification of ; raw rubber The solution of extracted resins may be made into soap (Schopper, Gum. Zeit. 1916, 30, 601).

A process of preparing acidyl derivatives of castor oil, which are free from the objectionable odour and taste of the oil, has been patented (D R P 226111, 1908) J L CASTOR OIL SEEDS or CASTOR BEANS.

The seed of Ricinus communis, a plant which grows as a tree in warm countries, attaining a height of 30 or 40 feet, but which in cooler climates is only an annual shrub

The following is an analysis of Indian seeds (Halenke and Kling, Landw. Versuch St 1906, 64, 51) .-

In many varieties the proportion of husk is much lower, sometimes down to 20 p c

Of the total 'protein,' 22 62 pc, 4 18 pc., and 17:13 p.c respectively, are true albuminoids, whilst of the carbohydrates, 089 pc 15.63 p.c, and 5.29 pc respectively, are pentosans

The ash of castor seeds was analysed by

Thoms (1890)-

Sand, Water etc. Fe<sub>2</sub>O<sub>3</sub> CaO. MgO. K<sub>2</sub>O. Na<sub>2</sub>O. P<sub>2</sub>O<sub>5</sub> SO<sub>3</sub>. Cl. 0 **30** 19 59 5 65 17 08 10 53 **14** 30 1 88 23 67 6 01 0 29

Castor see'ls are very poisonous Cornevin found the following were the toxic doses in grammes per kilogram of body-weight Horses. oxen, sheep and dogs, 3, pigs about 5-6, hens about 40.

The poisonous constituent was believed to be ricinine by Soane (Chem Zentr. 1895, 1 853), but is now known to be ricin, an albumin, with two non-toxic substances—a proteose and a globulin-constitute the proteids of the seeds (Osborne and Mendel, Proc Amer Physiol Soc. 1903, 36).

Ricinine, according to Macquenne and Philippe (Compt rend 1904, 138, 506 and 139, 840), has the composition  $C_8H_8O_2N_2$ ; it melts at 201.5° and yields ricinic acid  $C_7H_6O_2N_2$  by saponification. They represent its constitution as

$$N(CH)_3$$
 $C(COOCH_3): C$ 
 $CH = CH \cdot C$ 

Ricin, the poisonous principle, has been examined by Stillmark (Chem. Soc Abstr 1890, 535), Osborne, and other (lc. and Amer Jour Physiol. 1905, 14, 259), and Brieger (Chem. Zentr. 1904, 1. 1286) It can be extracted from the pressed seeds by a 10 pc. solution of common salt, from which it is precipitated by magnesium and sodium sulphates.

Ricin agglutinates the red corpuscles of the Osborne found 0.002 milligram per kilogram of body weight sufficient to kill a rabbit when subcutaneously injected. It can be kept for months without deterioration, but loses its poisonous qualities when coagulated by heat Toxic symptoms do not appear until after a latent period, of about 15 hours Castor seeds also contain an enzyme capable of decomposing fats into glycerol and fatty acids, or, according to Falk and Sugiura (J. Amer Chem. Soc 1915, 37, 217), two enzymes—esterase and lipase, the former active towards ethyl butyrate, the latter towards triacetin. They also contain an enzyme ureasc, capable of hydrolysing urea (Falk, J. Amer Chem. Soc. 1913, 1914, 36, 2166), similar to, but weaker than, the urease of soja

Castor seeds are largely used as source of castor oil (q r) The cake left is rich in protein, and if it were not poisonous, would prove of value as a cattle food It contains-

By subjecting the cake to high-pressure steam, the poisonous qualities are said to be destroyed, and cake so prepared may safely be used as a part of the ration of fattening animals According to Ehrlich, animals may be immunised against the poison by feeding them with very small quantities of the crude cake until they become accustomed to it The serum from such animals may then be used to immunise others

Neither of these methods of utilising castor cake appears to have been successful, and, in England at least, it is rarely or never used for

feeding purposes. The leaves of the castor plant are rich in lime and potash an analysis by Wayne (Pharm. J Trans 1874, 3, 749) gave as the composition of the ash of the leaves

Cl CO<sub>2</sub> SiO<sub>2</sub> H I

CASUMEN. Trade name for a soluble form of casein

CATALASE v. Enzymes, art FERMENTATION. CATALYSIS v CHEMICAL AFFINITY.

CATAPLEIITE. Hydrated silicate and zirconate of sodium and calcium, containing ZiO2 30-40 p c The crystals are yellow and have the form of thin hexagonal plates, sp gr. 28, H. 6. It occurs with other rare minerals in nephelinesyenite on the islands in the Langesund-fjord in south Norway, and at Naisarsuk in Greenland L. J S.

CATECHIN v. CATECHU.

CATECHOL (Pyrocatechol or Pyrocatechin, o-Dihydroxybenzene, 1.2-Phendiol CoH4(OH), occurs in the leaves of the Virginia creeper (Ampelopsis hederacea) (Gorup Besanez, Ber 1871, 4, 905), in the sap of various kinds of the kino plants (Eisfeldt, ibid. 906; Flückiger, Ber 1872, 5, 1, 47), in crude beet sugar (Lippmann, Ber. 20, 3298; 1893, 26, 3061; J. Soc. Chem. Ind. 1893, 535); in the dry external scales of the onion; in Paglia olive oil (Canzoneri, Gazz. chim. ital 27, 3); in the colouring matter of red grapes (Sostegni, Gazz. chim. ital. 32, 17); in Silesian and Westphalian coal (Bornstein, Ber. 1902, 35, 4324); and in the tar water of bituminous shale (D. R. P. 68944, 1892; Ber. 1902, 35, 4325). The catechol complex also exists in certain glucosides (Nedra, J Soc. Chem. Ind. 1900, 686; Schmidt and Waljaschko, Chem. Zentr. 1901, u. 121), in a large number of products of vegetable origin, as the sulphate, catechol occurs in the urine of man and herbivorous animals (Muller, Ber. 1874, 7, 1526; Schmiedeberg, Zeitreh. physiol. Chem. 6, 189); it is probably also contained in the cerebro-spinal fluid (Halliburton, J Phys Chem. 10, 247)

It is formed in the dry distillation of moritannic acid (Wagner, Annalen, 1850, 75, 351, 80, 316); of catechin (Zwenger, Annalen, 1841, 37, 327); of protocatechine acid (Strecker, Annalen, 1860, 118, 285), and of all tannins which give a green colouration with iron chloride (Uloth, Annalen, 1859, 111, 215). It is also formed when filter paper is heated to 200° or when starch or sugar is heated to 280° with water (Hoppe Seyler, Ber. 1871, 4, 15) and in many other reactions.

Catechol is prepared by fusing sodium o-benzene disulphonate (10 parts) with sodium hydroxide (10-15 parts) in an autoclave for 8-10 hours at 280°-300° and pressure of 2-3 atmospheres. The mass is then dissolved in dilute sulphuric acid, neutralised with chalk, evaporated, cooled and filtered. The mother hquor is now heated in an autoclave with 50 p c sulphuric acid (10 parts) to 180°-220° phenol is removed from the solution so obtained by blowing steam through it; it is then decolourised with animal charcoal, after which the catechol is extracted with other (Baum, Eng. Pat. 21853; D. R. P. 80817; J. Soc. Chem. Ind. 1894, 879; Ellis, *ibid*. 1897, 674; Fidl. 1894-7, Catechol is also prepared by heating catechol disulphonic acid or the sodium salt with water or mineral acid to 200°-215° for 10-15 hours under pressure (Tobias, D. R. P. 81209, 1894, Frdl. 1894-7, 117), or by treating commercial catechu with water (Gutknecht, Chem. Zeit 1891, 15, 959), or by diazotising o-aminophenol, treating the product with boiling aqueous copper sulphate, and then extracting the catechol with ether (Fidl 1905-7, 128); or by the distillation of orthobromo- or chlorophenol in vacuo or in steam (D. R. P. 76597; Frdl 1890-4, 845), or by heating with sodium hydroxide (Frdl. 1894-7, 114, D. R. P. 84828) An almost theoretical yield of catechol can be obtained by treating guaracol with fuming hydrodic acid (Perkin, Chem. Soc. Proc. 1890, 90); or by the interaction of o-hydroxybenzaldehyde with aqueous sodium hydroxide in equimolecular proportions; to the sodium sait thus formed, an equimolecular proportion of 2-3 p c hydrogen peroxide is then added and the catechol is extracted with a suitable solvent (Dakin, Amer. Chem J. 1909, 42, 477) Also formed, together with phenol, by acting on benzene with hydrogen peroxide in presence of a terrous salt Other methods of preparing catechol are described by Cross, Bevan, and Heiberg (Ber. 1900, 33, 2018), Kunzkrause (Ber 1897, 30, 1620); Meyer (ibid 2569), Hartmann and Gattermann (Ber 1892, 25, 3532; D. R. P. 70718; Frdl 1890-4, 52); Gillard, Martend Catter (D. R. P. 70700), (Chem. Monnet and Cartier (D. R. P 97099; Chem Zentr. 1898, n. 521); Messel (D. R. PP. 68944, 60637; Frdl 1890-4, 844, 846)

Catechol is readily soluble in water, alcohol. ether, benzene, and crystallises from these solutions in prismatic needles or tablets, m.p. 104°; bp. 245° (Grabe, Annalen, 1889, 254, 296). Its aqueous solution precipitates metallic silver from silver nitrate solution at ordinary temperature, and with ferric chloride it gives a green colouration, which turns violet on addition of ammonia or sodium acetate (Wishcenus,

Annalen, 1896, 291, 174), whilst in the presence of aromatic amino-sulphonic acids the colour changes to red-brown and the test is more delicate than with ferric chloride alone (Bayer, Biochem. Zeitsch. 1909, 20, 178). Unlike its isomeride, resorcinol (metadihydroxybenzene), it is converted into an unstable quinone by the action of silvei oxide, and its calcium salt  $\operatorname{Ca(C_6H_5O_2)_2}$  is precipitated by an ammoniacal solution of calcium chloride (Bottinger, Ber 1895, 28, Ref 327). Catechol can be separated from its isomeride by adding antimony fluoride to their aqueous solution, when only catechol antimonyl fluoride will be precipitated (Causse, Ann Chim Phys 1898, (vii) 14, 526, 538)

99

An alkaline solution of catechol becomes green, then black on exposure to air; catechol is also oxidised to a black insoluble substance by the action of Catecholase, a thermostable substance obtained from the young shoots of Salir purpurea (Weevers, Pioc K. Akad Wetensch, Amsterd 1909, 12, 193). Heated with ammonium carbonate to 140°, catechol yields protocatechuic acid C<sub>6</sub>H<sub>3</sub>(OH)<sub>2</sub>CO<sub>2</sub>H.

Catechol is used in photography, forming a very efficient developer in the presence of sodium sulphite or tribasic sodium phosphate as accelerator (Eder, J. Chem. Soc. Ind. 1890, 102., Bill. J. Photogr. 1900, 47, 676.) It can also be used as the starting-point in the preparation of a large number of valuable derivatives

Alkalı salts of catechol of the general composition OH  $\rm C_8H_4$  OM,  $\rm C_8H_4$  (OH)<sub>2</sub>, can be obtained by treating catechol with a solution of the theoretical quantity of alkalı hydroxide or of a salt with an alkalıne reaction, such as the sulphites. They form readily crystallisable salts, used in photography, and can be employed for producing pure catechol (Meister, Lucius and Bruning, D. R. P. 164666, 1904; Frdl. 1905–7, 129).

The mono- and di-ethyl others of catechol are prepared by heating under pressure a solution containing catechol, sodium hydroxide, and sodium ethyl sulphate or chloride in equivalent proportions. The ethers are then removed by steam distillation and separated by treatment with sodium hydroxide, in which only the monoether is soluble (J. Soc. Chem. Ind. 1896, 741, Eng. Pat. 16047, 1896). The diethers can be prepared by the action of alkalis on the monoethers (Fid. 1894-7, 123. D. R. P. 92651).

Catechol monoethyl ether forms large clear colourless crystals, mp 26°-27°, bp 215°, which have an odour similar to that of thymol, and are soluble in alcohol and ether, but not m water.

The monoalkyl ethers of catechol, when fused or treated in solution with various proteids, albumoses, and peptones, yield compounds which are applied therapeutically (Fehrlin, D. R. P. 162656, 1906).

Monoethyl catechol ether v Guaiacol. Dimethyl catechol ether v. Veratrol.

Catechol, when fused with aliphatic amines or heated with them in suitable solvents, yields stable amines which form useful photographic developers (D. R. P. 141101, 1903; Frdl. 1900-2, 1218). Other amino- and also nitroderivatives are described by Meldola, Woolcott and Wray (Chem. Soc. Trans. 1896, 1332); Heinisch (Monatsh. 1894, 15, 229); Nietzki and

100 CATECHOL.

Moll (Ber 1893, 26, 2182); Blankswa (Rec. trav. chim. 1905, 24, 40); Grischkewitsch-Trochimowski (J. Russ. Phys. Chem. Soc. 1909,

41, 1324); Dakın (l c.)

Good stable black, greenish, and bluish-black dyes, soluble in carbonates and alkaline sulphides, have been obtained by the action of aliphatic amines on catechol at 180°-222° (D. R. P. 84632; Frdl. 1894-7, 1048).

Methylene catechol ether CH<sub>2</sub>CO<sub>O</sub>C<sub>6</sub>H<sub>4</sub> is a colourless liquid; b p 172°-173° (Moureu, Bull. Soc. chim 1897, 15, 654, Mameli, Atta R. Accad Lincei, 1906, (v) 15, n 101; Perkin, Robinson, and Theorem. Robinson, and Thomas, Chem. Soc Trans 1909, 1977) A number of derivatives have been prepared (Moureu, lc 1898, 19, 507, Medinger, Monatsh, 1906, 27, 237; Barger, Chem. Soc. Trans. 1908, 563, 2081, Barger and Ewins, ibid. 735).

Catechol diphenylmethylene ether

$$CPh_2 < 0 > C_6H_4$$

is prepared by gently heating catechol with benzophenone chloride; colourless prisms, m p 93° (Sachs and Thonet, Ber. 1904, 37, 3327)

The methylene ethers of catechol derivatives can be converted into chlorine delivatives of their cyclic carbonates by being heated with thionyl chloride (Wellcome and Barger, Eng Pat 15987, 1907; J. Soc Chem. Ind 1908, 355)

287, 1907; J. Soc Chem. Ind 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 1906, 19

216° (110°-111°, 31 mm), is readily obtained by heating catechol with potash, ethylenic bromide and water in an atmosphere of hydro-Potassium permanganate, hydrogen iodide, and ammonia have an action on it, but it is oxidised by chromic acid to oxalic and carbonic acids It yields a number of substitution derivatives (Moureu, Compt. rend 1898, 126, 1426; Bull Soc chim 1898, (iii) 19, 507; Gattermann, Annalen, 1907, 357, 313, Lazennec, Bull Soc chim. 1909, (iv.) 5, 501, 509).

prepared by dehydrating orthohydroxyphenoxyaldehyde with phosphoric anhydride in presence of quinoline It is a colourless oil, boiling at 193°, and, when strongly cooled, forms brilliant white crystals, mp 16°-20° It forms a dibromide C<sub>6</sub>H<sub>4</sub>O<sub>2</sub>(CH)<sub>2</sub>Br<sub>2</sub>, mp 103°-104·5°, which, in contact with water, is converted into catechol, glyoxal, and hydrogen bromide (Moureu, Compt rend. 1899, 128, 559)

Catechol forms a number of acetals (Moureu, Compt. rend 1898, 126, 1656); also a vinyl derivative (Kurz Krause, Ber 1897, 30, 1617; Pauly and Neukam, *ibid* 1908, 41, 4151).

Catechol sulphonic acid C<sub>6</sub>H<sub>3</sub>(OH)<sub>2</sub>SO<sub>3</sub>H is conveniently prepared by stirring together a meta-halogen phenol sulphonic acid with about an equal weight of sodium hydroxide in aqueous solution, and heating the mass to 250° for 8-10 hours The mass is now dissolved in water and neutralised with a mineral acid such as sulphuric. The solution is evaporated and the sodium sulphate filtered off, whilst the concentrate solution of catechol sulphonic acid yields pure catechol when heated with mineral acids

(Frdl. 1897-1900, 150, 1902-4, 100; D. R. P. 9623; Ellis, Eng. Pat. 14931, 1896).

Catechol disulphonic acid is obtained by treating catechol with 5 times the amount of fuming sulphuric acid (Cousin, Compt rend. 1893, 117, 113), or by fusing phenol trisulphonic acid or its salts with alkalis and decomposing the alkalı sulphonate so obtained with dilute sulphuric acid (Frdl 1894-7, 118)

Halogen derivatives (Jackson and Boswell,

Amer Chem. J 1906, 35, 519; Dakin, lc.).

Monochlorcatechol C<sub>6</sub>H<sub>3</sub>(OH)<sub>2</sub>Cl, m p. 80°-81°, is obtained by the interaction of sulphuryl chloride with catechol in ethereal solution; by using a larger proportion of sulphuryl chloride, the duhlorcatechol, mp 105°-106°, is obtained (Paratoner, Gazz chim ital 1898, 28, ı 197)

Trichlorcatechol C<sub>6</sub>H<sub>3</sub>Cl<sub>3</sub>O<sub>2</sub> is obtained by the action of a chlorine solution in acetic acid or an acetic chloroform solution on catechol It forms colourless odourless prisms, mp. 104°-105°, with a burning taste Excess of chlorine yields tetrachlorocatechol (Cousin, Compt rend 1895, 120, 840) The corresponding bromoderivatives are obtained similarly (Cousin, lc).

The bismuth brominated catechols are recommended as a satisfactory substitute for tribromphenoxide, which is employed medically, under the name of 'xeroform' They are produced by adding an acid solution of bismuth nitrate to alkaline, tetra-, tri-, or di-biomocatechol, or by introducing precipitated bismuth hydroxide into an alcoholic solution of the bromocatechol (D. R. P. 107544, 1909)

Catechol carboxylic acid

$$C_6H_4(OH) O CO_2H, \frac{1}{2}H_2O$$

m p. 240°, is formed by the action of ammonium carbonate on catechol at 130°-140° under pressure, or by heating catechol with glycerol and potassium hydrogen carbonate at 180°-210° in an atmosphere of carbon dioxide (Praxmarer, Monatsh 1906, 27, 1199) The di-carboxylic acid can also be prepared Derivatives of catechol carboxylic acid, used in medicine, are obtained by the interaction of alcohols and also of primary and secondary bases with catechol carbonate; thus.

$$C_6H_4$$
 $O$ 
 $CO+C_2H_5OH$ 
 $=C_6H_4(OH)OCO_2C_2H_5$ 

by using anılıne, the compound C<sub>6</sub>H<sub>4</sub>(OH)O CONHC<sub>6</sub>H<sub>5</sub> is obtained, whilst with ethylene diamine it forms dicatecholdicarbethylenediamide  $C_2H_4(NH\cdot CO_2C_6H_4\cdot OH)_2$ (Einhorn and Lindenberg, Annalen, 1898, 300, 135; D. R. P. 92535; Frdl. 1894-7, 1110). A number of similar compounds are described by Einhorn and Lindenberg (l.c.); Einhorn and Pfeiffer (Annalen, 1898, 310, 218).

Methyl catechol dicarbonate, m.p. 41°, is described by Syniewski (Ber. 1895, 28, 1874).

Carbonyl esters of catechol of the type

CO(OC, H4OR), also used in medicine, are prepared by the action of phosgene on the corresponding alkyl catechol in sodium hydroxide solution (D. R. P 72806, Frdl 1890-4, 854).

¶Catechol monoacetic acid

C6H6(OH)O·CH2·CO2H

CATECHOL. 101

m.p. 131°, is obtained by the action of monochloracetic acid on catechol in aqueous or alkaline solution. When heated to 120°, it forms the anhydride C<sub>6</sub>H<sub>4</sub>CO, m.p. 56° (J Soc. Chem. Ind. 1896, 588), which, when treated with water, yields the acid in a very pure state (D. R. PP. 87336, 87668, 87669, 89593, Frdl 1894-7, 1106, 1107, 1108) The sodium salt of this acid is said to be a better remedy for phthisis and loss of appetite than guaiacol or its carbonate (Frdl. 1894-7, 1106). A large number of derivatives formed by the acid are described by Ludwig (J pr. Chem 1900, n. 61, 345). Catechol diacetates are described by Drezgowski (J. Russ. Phys. Chem Soc. 25, 157), and by Voswinckel (Ber. 1909, 42, 4561)

Catechol reacts with chloracetyl chloride or chloracetic acid, forming chloroacetyl catechol,

 $C_6H_4(OH)_2+ClCH_2COCl=C_6H_3(OH)_2COCH_2Cl$ which, with ammonia or a primary aliphatic amine, yields amino-acetyl compounds of the type RNHCH<sub>2</sub>CO C<sub>6</sub>H<sub>3</sub>(OH)<sub>2</sub>, and these ketocompounds can be readily reduced to the cor responding alcohol (Imray, Eng Pat 26480, 1903, J. Soc. Chem. Ind 1904, 1043, D R P 13209, Frdl 1890-4, 857) (see also ADRENA-

Aniline and chloroacetyl catechol form an andrde C611 (OH)2CO CH2 NHPh, which, with mitrous acid, yields catecholglycophenyl triazine [CeH3(OH)2]2CO CH2 N Ph N NCH2CO, mp. 115°, with decomposition The corresponding tolyl- derivative melts at 120°, and is prepared in a similar manner (Dzierzgowsky, Ber 1894, 27, 1983, D R P 71312, Frdl 1890-4, 857)

Acetocatechol C  $_{\rm 6}{\rm H}$  ,Ac (OH)  $_{\rm 2},$  m p  $\,$  116° ,  $\,$  dimethoxyacetcatechol C  $_{\rm 6}{\rm H}$  ,Ac (OMe)  $_{\rm 2},$  and catecholqlycothrocyanate C<sub>6</sub>H<sub>3</sub>(OH)<sub>2</sub>CO CH<sub>2</sub> SCN, m p 147°-150°, have been prepared by Dzierzgowsky (lc). According to Abderhalden and Kautsch, the chloracetyl derivatives of catechol, when treated with ammonia, are resolved into their components (Chem Zentr 1910, n 1356)

Alkyl acetyl catechol alkyl ethers, used in pharmacy, are obtained by the action of the alkyl acetyl chlorides on catechol monoalkyl ethers (J. Soc Chem. Ind 1906, 653, Eng Pat

25571, 1905; US Pat 822339, 1906).

A soluble tasteless product, C<sub>10</sub>H<sub>8</sub>N<sub>2</sub>O<sub>6</sub>, useful for medical purposes and as a substance from which other valuable technical products can be obtained, is formed by the condensation of catechol with alloxan in the presence of zinc chloride or mineral acids It forms prismatic crystals, which decompose above 200° (D. R. P. 107720. Frdl 1897–1900, 864).

Catecholdiantipyrine is obtained by mixing aqueous solutions of its constituents, and forms colourless needles, mp 78°-79° (Patein and

Dufan, Compt. end 1895, 121, 532)

C,H,1N,[C,H4(OH2] Prperidine catechol forms white crystals which rapidly become red and then brown on exposure to air. It melts at 80°-81° (Rosenheim and Schidrowitz, Chem. Soc. Trans. 1898, 140).

Catechol, when treated with phthalic anhydride and sulphuric acid at 150°, yields alizarin,

thus:

$$\begin{array}{c} {\rm C_6H_4} < {\rm OH(1) \atop OH(2)} + {\rm C_8H_4} < {\rm CO} \atop {\rm CO} > {\rm C} \atop {\rm OH(2)} \\ = {\rm C_6H_4} < {\rm CO} \atop {\rm CO} > {\rm C_6H_2} < {\rm OH(1) \atop OH(2)} \end{array}$$

(Baeyer and Caro, Ber. 1874, 7, 972; Liebermann and Hohenemser, ibid. 1902, 35, 1778) (v. ALIZARIN AND ALLIED COLOURING MATTERS)

Catecholphthalein C20H14O6 is prepared by heating phthalic anhydride (3 parts) with catechol (2 parts) and zinc chloride (3 parts) to 140°-150° for 3-4 hours. The aqueous extract of the product is boiled with animal charcoal, and the filtrate, on cooling, deposits yellowishwhite leaf crystals of the substance which sinters 80°-90°, but does not melt (Meyer and Pfotenhauer, Ber. 1907, 40, 1442, Bayer, Chem. Zentr. 1910, n. 1524).

Under certain conditions, catechol combines energetically with diazo- compounds yielding azodyes (Witt and Mayer, Ber. 1893, 26, 1072, Orton and Everatt, Chem Soc Trans. 1908, 1021) Thus Benzencazocatechol C<sub>6</sub>H<sub>3</sub>(OH)<sub>2</sub>N<sub>2</sub>C<sub>6</sub>H<sub>5</sub>, mp 165°, which dyes cotton mordanted with alumina a golden yellow, is formed by the interaction of an alcoholic solution of catechol and a concentrated solution of diazobenzene chloride, the mixture then being poured on to ice. The nitro- derivative NO<sub>2</sub> C<sub>6</sub>H<sub>4</sub>N<sub>2</sub>C<sub>6</sub>H<sub>3</sub>(OH)<sub>2</sub> colours alumina mordants ied, and iron and chromium mordants brown, the sodium sulphonate  ${\rm SO}_3{\rm NaC}_6H_4{\rm N}_2{\rm C}_6H_3({\rm OH})_2$  colours wool mordanted with alumina, yellow, with chromium, red-brown Similar toluene compounds have also been obtained Catechol also forms triazoor azoimido- compounds (Rupe and Majewski, Ber 1900, 33, 3401)

Catechol glycorsoquinoline

forms glittering orange-coloured crystals which give a red colouration with very dilute ferric chloride and a green colour in presence of excess of the latter, both the base and the chloride dye cotton mordanted with iron, aluminium, or chromium salts, black-yellow or reddish-brown respectively (Nencki, Ber 1894, 27, 1969).

 $Catecholylycotetrahydroquinoline = \mathrm{C_{17}H_{17}NO_3}$ crystallises in yellow lustrous plates, m p 170°

(Nencki,  $l \in$ )

Catechol, when heated with zinc chloride and formic acid, yields aurin dyes which give fast colours with metallic oxide mordants (Caro, Ber 1893, 26, 254)

Catechol tannins are employed in colouring leathers (J Soc Chem Ind. 1907, 423, 882, ibid 1909, 1151)

A number of products obtained by the condensation of catechol with ketones are described by Fabinyi and Széky (Ber. 1905, 38, 2307).

Catechol, when warmed with an alcoholie solution of picryl chloride containing sodium, yields 3 5-dinitro-o-diphenylene oxide,  $\rm C_6H_4O_2$   $\rm C_6H_2(NO_2)_2$ , mp 192° 192 5° (Hillyer, Amer. Chem. J. 1900, 23, 125)

Catechol heated with hippuryl chloride on the water-bath yields o-hydroxyphenyl hippurate NHBz CH<sub>2</sub> CO<sub>2</sub>C<sub>4</sub>H<sub>4</sub> OH, m.p 134°-136°, which with hydrogen chloride gives the anhydride  $C_{16}H_{11}O_{3}N$ , m p. 232°-233° (Fischer, Ber. 1905, 38, 2926). 102 CATECHOL.

When catechol is hydrogenated in the presence of finely divided nickel, cis-cyclohexane 1:2-diol, m.p. 75°-76°, b p. 225°, is formed (Sabatier and Mailhe, Compt. rend. 1908, 146, 1193).

A number of quinone and halogen quinone derivatives of catechol are described by Jackson and Koch (Amer Chem J 1901, 26, 10), Jackson and Porter (ibid. 1903, 30, 518), Jackson and Russe (ibid 1906, 35, 154, Ber. 1905, 38, 419) Other derivatives of catechol have also been prepared (Cousin, Ann Chim Phys 1898, (vii ) 480; 1899, (vii ) 18, 76; Bischoff, Ber 1900, 33, 1669; Wisinger, Monatsh 1900, 21, 1007; Bischoff and Hedenstrom, Ber. 1902, 35, 3452; Bischoff and Frohlich, Ber. 1907, 40, 2779, 2790; Barger and Ewins, Chem Soc. Trans 1909, 552, 1482; Fourneau, J. Pharm Chim 1910, (vii ) 1, 55, 97).

Catechol phosphines and chlorophosphines (Krauer, Ber 1894, 27, 2565); phosphites and sulphites (Anschutz and Posth, Ber 1894, 27, 2751); also a number of antimonyl catechol compounds (Causse, lc), some bismuth derivatives (Richard, Chem. Zentr. 1900, n 629), and a lead salt (Jackson and Koch, Ber. 1898, 31, 1458),

have been prepared.

Homologues of catechol, such as homocatechol (o-dihydroxytoluene), can be prepared by heating the corresponding alcohol with catechol in the presence of zinc chloride in open or sealed vessels (Merck, Frdl. 1894-7, 115, D R P. 78882), or by the interaction of persulphates and p-phenol derivatives in alkaline solution, the product then being warmed with acid (Frdl 1894-7, 121; D R. P. 81298).

$$\begin{split} \mathbf{C_6H_4} & \stackrel{OH(1)}{\underset{R}{\bigcirc}} + \mathbf{K_2S_2O_8} + \mathbf{KOH} \\ & = \mathbf{C_6H_3} \stackrel{OK(1)}{\underset{OSO_2OK(2)}{\bigcirc}} + \mathbf{K_2SO_4} + \mathbf{H_2O} \\ \mathbf{C_6H_3} & \stackrel{OK(1)}{\underset{R(4)}{\bigcirc}} \\ \mathbf{C_6H_3} & \stackrel{OK(2)}{\underset{R(4)}{\bigcirc}} + \mathbf{H_2SO_4} + \mathbf{H_2O} \\ & = \mathbf{C_6H_3} \stackrel{OH(1)}{\underset{R(4)}{\bigcirc}} \\ \end{split}$$

This method can be applied to the production of a large number of various derivatives.

CATECHU or CUTCH. There are several varieties of catechu or cutch bearing different names according to the country or plants from which they are obtained The following are those principally employed by dyers and tanners: Gambier catechu, Bengal or Acacia catechu, Bombay or Areca catechu, and Mangrove cutch

Although catechu has perhaps received greater attention than other natural dyes, the results have been so varied that the chemistry of the subject was for a long time in a most unsatisfactory Some confusion has arisen from the condition non-appreciation of the fact that the main constituents of Gambier and Acacia catechu are not identical, and some uncertainty has also apparently existed as to the botanical origin of the commercial varieties. Bombay catechu 18, for instance, occasionally referred to as originating from the Acacra catechu, and Bengal cutechu from the Areca catechu (Linn.); and in many cases, at the present time, it is impossible

to ascertain the botanical derivation of commercial brown cutch preparations.

Gambier catechu.—Gambier, yellow cutch, cubical cutch, cube gambier, or terra japonica, is obtained from the Uncaria gambier, an extensive scandent bush which is met with, both wild and cultivated, in Malacca, Penang, and Singapore. The catechu is isolated by extracting the leaves and twigs with hot water until the liquid becomes syrupy, the insoluble matter being removed from time to time by means of a strainer. On cooling, the pasty mass is cut into cubes with sides I inch in length and dried on bamboo trays

Catechin C<sub>15</sub>H<sub>14</sub>O<sub>6</sub>,4H<sub>2</sub>O, the crystalline principle, was first described by Nees van Esenbeck (Annalen, 1832, 1, 243), was subsequently examined by Berzehus in 1837 (J 14, 235), and more recently by numerous chemists isolate catechin, Lowe (Zeitsch anal. Chem 13, 113) devised the following method: catechu is washed with cold water to remove catechu tannic acid, well pressed, allowed to dry, and dissolved in hot acetic ester The filtered solution is evaporated and the residue crystal-

hsed from hot water

According to Perkin and Yoshitake (Chem. Soc Trans. 1902, 81, 1162), a combination of this method and that of Berzelius (lc) gives good results

The finely powdered catechu is extracted with 10 times its weight of boiling ethyl acetate, the solution is evaporated, and the residue crystallised from 10 times its weight of water The product is again dissolved in boiling water, and lead acetate solution added, drop by drop, until a coloured precipitate is no longer formed, and the filtrate is almost colourless, the latter, while hot, is treated with sulphuretted hydrogen, the lead sulphide removed, and the crystals, which separate on cooling, are collected, washed, and allowed to dry at the ordinary temperature. The substance is now practically colourless, and the yield greater than if the purification had been effected by frequent crystallisation from water

The formulæ which have been assigned to catechin are very numerous It has been shown by v Kostanecki and Tambor (Ber 1902, 35, 1867), and simultaneously by Perkin and Yoshitake (lc), that it is correctly represented

as C<sub>15</sub>H<sub>14</sub>O<sub>6</sub>,4H<sub>2</sub>O

Catechin forms colourless needles, and when crystallised from water the air-dry product melts at 96° (Clauser, Ber 1903, 36, 101). After standing over sulphuric acid, it possesses the formula C<sub>15</sub>H<sub>14</sub>O<sub>6</sub> H<sub>2</sub>O, and melts at 176°-177°, and this is also the melting-point of the anhydrous substance. Catechin is readily soluble in boiling water and cold alcohol, and gives with lead acetate solution a colourless precipitate, and with ferric chloride a deep-green liquid. With pine wood and hydrochloric acid, it gives the phloroglucinol reaction.

On fusion with alkali, protocatechuic acid, phloroglucinol, and probably acetic acid are produced, and it is interesting to note that catechu has been considerably employed for the commercial preparation of the former compound.

Schutzenberger and Rack (Bull. Soc. chim. 4, 6) have described a dibenzoyleatechin; and Liebermann and Tauchert (Ber. 1880, 13, 695), diacetyl catechin, diacetyl dichloreatechin, and diacetyl dibromeatechin; but their formulæ for these compounds are now known to be incorrect.

Penta - acetyl - catechin  $C_{15}H_{9}O_{6}(C_{2}H_{3}O)_{5}$ ; colourless needles, m.p.  $124^{\circ}-125^{\circ}$  (v. Kostanecki and Tambor); pentabenzoyl catechin,  $C_{15}H_{9}O_{8}(C_{7}H_{8}O)_{5}$ , colourless needles, m.p.  $151^{\circ}-153^{\circ}$ , tetrebenzoyl catechin,  $C_{15}H_{10}O_{6}(C_{7}H_{5}O)_{4}$ , prisms, m.p.  $171^{\circ}-172^{\circ}$  (Perkin and Yoshitake), disazobenzene catechin,  $C_{15}H_{12}O_{8}(C_{5}H_{5}N_{2})_{2}$ , salmon - red needles, m. p.  $193^{\circ}-195^{\circ}$  (Ett. P. and Y.), acetyldisazobenzene catechin, orange red needles, m.p.  $253^{\circ}-255^{\circ}$  (P. and Y.); catechin tetramethylether  $C_{15}H_{10}O_{3}(OCH_{3})_{4}$ , needles, m.p.  $141^{\circ}-146^{\circ}$  (K. and T.), acetyl catechin tetramethylether  $C_{15}H_{9}O_{2}(OCH_{3})_{4}C_{2}H_{3}O$ , needles, m.p.  $92^{\circ}-93^{\circ}$ , and catechin pentamethylether  $C_{15}H_{9}O(OCH_{3})_{5}$  (K. and T.), have been prepared M.

When catechin tetramethylethor, suspended in water, is oxidised with potassium permanganate, it gives veratric acid, and most probably phloroglucinol dimethylether (Chem Soc Trans 1905, 87) As the result of this investigation, Perkin considered that catechin was possibly a reduction product of quercetin

and indeed a small quantity of the latter colouring matter is present in catechi (Lowe Perkin, *ibid* 71, 1135)

More recently, v Kostanecki and Lampe (Ber 1906, 39, 4007) have shown that when catechin tetramethylether is brominated in the presence of sunlight, only a monobromeatechin tetramethylether, mp 173°-174°, is produced, whereas the above constitutional formulæ require the formation of a dibromo-compound. When oxidised with permanganate, bromeatechin tetramethylether gives veratric acid, so that the bromine must have replaced one hydrogen of the phloroglucinol nucleus. When alcoholic solutions of catechin-tetramethylether and of iodine and iodic acid are mixed, long colourless needles of whours:—

$$\begin{array}{c} \text{MeO} \\ \text{MeO} \\ \text{MeO} \\ \end{array} \begin{array}{c} \text{H} \\ \text{CH}_2 \\ \text{OH} \\ \text{OMe} \end{array}$$

m.p.  $192^{\circ}$ - $193^{\circ}$ ; this yields an acetyl derivative  $C_{21}H_{23}O_{,}I$ , m p.  $189^{\circ}$ 

Iodocatechin-tetramethylether when treated with zinc-dust and alkali yields the original catechin-tetramethylether. this elimination of reduced being also noticed with other members of the maclurin type (v Kostanec'i and Lampe, Ber. 1907, 40, 4910). v Kostanecki and Lampe

have assigned the following constitution to catechin:—

and this is in harmony with many of the properties of this substance. When catechin tetramethylether is oxidised with chromic acid, catechone trimethylether, orange-yellow needles, m p 210°, is produced (K and T).

$$\begin{array}{c|c} CH_3O & CH_3O \\ \hline \\ CH_3O & -CH(OH) - \\ \hline \\ \end{array}$$

whereas catechin pentamethylether gives the tetramethyl compound.

and this behaviour is analogous to that of leucomaclurin pentamethylether (see MACLURIN)

Acetyl catechone by reduction with zinc-dust and glacial acetic acid, and hydrolysis of the product, gives hydroxy-catechin, yellow needles, melting at 284°–285°—

The hexamethylether has mp 102° (Nierenstein Annalen 1903, 396, 194).

stein, Annalen, 1903, 396, 194).
When catechone trimethylether is nitrated, a mononitro- derivative (1)

$$(2) \quad \begin{array}{c} \text{CH}_3\text{O} \\ \text{CH}_3\text{O} \end{array} \begin{array}{c} \text{NO}_2 \\ \text{-COOH} \end{array}$$

m p. 141°, is obtained, and on oxidation yields nitroveratric acid (2) Finally, by the reduction of catechin tetramethylether with sodium and alcohol, an oil is produced which, on treatment with methyl sulphate, gives pentamethoxyethyldiphenylmethane

a reaction which points clearly to the presence of the cumaran ring in catechin.

Ryan and Walsh (Proc. Roy. Dub Soc.

1916, 15, 113) have attempted to decide between the chroman structure of Perkin and Yoshitake and the coumaran formula of v Kostanecki and Lampe. To this end they have synthesised  $2.4 \cdot 6:3' \cdot 4'$ -penta-methoxy-3-ethyl-diphenylmethane, in order to ascertain whether this was identical with the deoxy-hydro-catechin-pentamethyl-ether obtained from catechin, as described above by v Kostanecki and Lampe

The synthesis is made clear by the following scheme :-

They were, however, unable to obtain the resulting product in a crystalline conditionthe addition of a crystal of the product obtained catechin (deoxy-hydro-catechin-pentamethyl-ether) failed to cause it to crystallise —hence they were not able to obtain a definite settlement of this point

Catechin is oxidised in aqueous solution by potassium ferricyanide in the presence of potassium acetate with formation of an orangecoloured amorphous compound (Perkin), which dyes mordanted calico orange-brown shades which are fairly fast to soap It is probable that this dyestuff is related to the catechone of v Kostanecki and Tambor, and which was obtained by these authors in the form of its tri- and tetramethyl ethers

When catechin is treated with carbon tetrachloride and aqueous potassium hydroxide, it yields catechin carboxylic acid, colourless needles, m.p. 274°-277° (decomp).

COOH 
$$C_6H_2(OH)_2$$
— $CH(OH)$ — $OH$ 

The annexed constitution has been assigned to it on account of the fact that its pentamethyl-ether methyl-ester C22H26O8, mp 92°, when oxidised with alkaline permanganate, yields hemipinic acid.

Catechin carboxylic acid has been resolved, and the *d*-acid has  $[a]_D^{18} = +76 \, 4^\circ$ , and mp. 273° (decomp), whilst the *l*-acid gave values  $[a]_D^{18} = -68 \, 22^\circ$ , and m.p. 270°-273° (decomp.) (Nierenstein, Annalen, 1913, 396, 194)

Catechutannic acid. In addition to catechin.

gambier catechu contains a small amount of catechutannic acid, and this substance is present in considerable quantity in the browner varieties To isolate it, the following method of cutch has been employed .-

A hot aqueous extract of catechu is allowed to stand until no more catechin is deposited, and the clear liquid is evaporated to dryness. residue is dissolved in alcohol, the solution treated with ether to precipitate impurities and then evaporated to diyness

Catechutannic acid consists of an amorphous reddish-brown powder, readily soluble in water According to and alcohol, insoluble in ether Lowe (Fr. 13, 121), it possesses the formula C21H18O8, and gives a lead salt 3PbO,2C21H18O8,

but this most probably requires revision According to Etti (Annalen, 186, 332), catechutannic acid is an anhydride of catechin, and is derived from this substance by elimination of It is said to be produced when an aqueous solution of catechin is heated to 110° (Lowe, *ibid* 12, 285), or by boiling catechin with solutions of the alkali carbonates Again, catechin is decomposed at its melting-point with evolution of water and formation of a product resembling catechutannic acid, and aqueous solutions of catechin on long standing become brown-coloured with apparent formation of this That the products obtained by these compound methods resemble catechutannic acid is certain, but the subject has not been fully investigated.

Catechutannic acid solution gives a precipitate with lead acetate, and also resembles catechin in giving a green colouration with ferric chloride, and the phloroglucinol reaction with pinewood and hydrochloric acid It is a powerful tanning agent, and appears to differ but little from the so-called 'catechol' tannins

Three other catechin anhydrides have been described, viz the second anhydride ('42H34O15(?), (Etti), which is produced by heating catechutannin to  $162^{\circ}$ , the third anhydride  $C_{21}H_{16}O_{7}(?)$ , formed by digesting catechin with boiling dilute sulphune acid for several hours, and the fourth anhydride, which is obtained by heating catechin with hydrochloric acid at 160°-180°. These compounds consist of reddish-brown powders, and the fourth substance is insoluble, both in alkaline solutions and all solvents A product similar in properties to Etti's fourth anhydride is readily formed by adding sulphuric acid to a hot acetic acid solution of catechin (Perkin). A bright orange powder almost immediately separates, and this, on analysis, gave C=63 26 p c, H= 3 89 рс It is interesting to note that the formation of these red anhydrides, or phlobaphenes is characteristic of all the catechol (phlobo) tannins

According to Perkin and Yoshitake, gambier catechu contains a small quantity of a second catechin, which crystallises in small prisms. devoid of water of crystallisation, and melts at 235°-237° Its general reactions are identical with those of ordinary catechin, and by fusion with alkali it also gives phloroglucinol and protocatechnic acid. The azobenzene compound  $C_{15}H_{12}O_6(C_6H_5N_2)_2,$  orange-red needles, melts at  $215^\circ\text{--}217^\circ$  .

Finally, there are present in catechu, certain brown substances known as rubinic and japonic acids, which, according to some writers, appear to have been formed by the oxidation of the and also of their derivatives, differ widely, as is Their chemical nature is, however, catechin unknown.

Catechin, though largely employed for tanning purposes, does not precipitate a gelatine solution, and is not itself a tannin matter. On the other hand, it is absorbed by the hide, and there gradually passes into catechutannic acid

Dyeing Properties -On cotton, catechu is largely used for the production of the wellknown 'catechu brown,' which is exceedingly fast to light, acid and alkaline solutions, and also to bleaching powder. To obtain this, cotton is steeped in a hot solution of catechu (1-2 pc) to which has been added about 6 pc of copper sulphate, reckoned on the weight of the catechu employed The material is allowed to remain in the bath as it cools, and without washing is then treated in a warm or boiling second bath containing 1 or 2 grams of bichromate of potash per litie According to Hummel and Brown (J Soc Chem Ind 1896, 15, 422), in this operation the copper sulphate probably converts the catechin into catechutannic acid, and this is subsequently oxidised to japonic acid by the action of the bichiomate The colour is apparently intensified by the formation of a basic copper chromate Gambier catechu is also employed in dyeing compound shades with log-wood, fustic, and alizarin in conjunction with bichrome, and with bismarck brown, magenta, In the latter case catechu-tannin forms the mordant for the basic colour

Wool may be dyed with catechu in a similar manner to cotton. In silk-dyeing, catechu is largely used for weighting purposes. The silk is steeped in basic ferrous sulphate solution, then in potassium feriocyanide and hydrochloric acid, which causes the production of Prussian blue on the fibre It is then worked in a strong solution of gambier to which stannous chloride solution has been added.

Bengal or Acacia catechu.—Bengal catechu is derived from the Acacia catechu, a tree 15 to 20 feet high, which is common in most parts of India and Burma To isolate the catechu which is present in the red heartwood, the tree is cut down while it is fullest of sap, and the internal portion is sawn into small sticks and extracted with boiling water The liquid thus obtained is concentrated over a fire, and then allowed to evaporate spontaneously in shallow dishes extract thus obtained comes into the market as Pegu catechu, Brown cutch, and Brown catechu (Crookes, Dyeing and Calico Printing)

A purer substance, kath, or the pale catechu of India, is prepared by suspending twigs in the hot concentrated extract and collecting the

crystals which thus separate

Acacatechin  $C_1$ ,  $H_{14}^{\dagger}O_6$ 3 $H_2O$  can be obtained from the acacia kath by methods identical with those which are employed for the isolation of catechin from gambier catechu. It melts at 204°-205°, is somewhat more sparingly soluble in water than catechin, and when fused with alkalı gives phloroglucinol and protocatechnic acid. The reactions of acacatechin and catechin, in so far as they have been observed, are identical, and there is no difference in the composition of their derivatives when prepared under similar conditions. On the other hand, the melting-points of the substances themselves.

evident from the following table (Perkin and Yoshitake) :-

	Acacatechin	Catechin
Pentaacetyl derivative		124°-125°
Pentabenzoyl ,,	181°-183°	151°-153°
Azobenzene "	198°-200°	193°-195°
Tetramethyl ,,	152°-154°	144°-146°
Acetyl ,,	135°-137°	92°93°

It appears certain, therefore, that catechin and acacatechin are isomerides, and it is possible that the latter may, on the basis of v Kostanecki and Lampe's formula for catechin, be represented thus (Perkin, private communication):

a point which should not be difficult to determine

Bombay or Areca catechu. This variety is obtained from the fruit of the Arcca catechu, or betel-nut palm, a tree which is common in tropical Asia. Though its chief constituent resembles catechutannie acid, catechin itself has not been isolated from this product possesses a bright-chocolate and sometimes an orange-brown colour, and yields, on dyeing, very similar results to the ordinary cutches

Mangrove cutch. Mangrove cutch is obtained from the bark of the mangrove Cerups candolleana, and is of somewhat recent employ-In its preparation it is preferable to extract the fresh bank, which is of a light colour internally, rather than the stored product which has become red, or is said to have 'sweated' The extract, on evaporation, becomes deep-red in colour, and the object of the manufacturer is to prevent this anhydride formation from going too far, otherwise a certain portion of the extract is rendered insoluble in water

By fusion with alkali, it gives protocatechnic acid, but at present no catechin has been isolated from it (Perkin, private communication) dissolved in sodium bicarbonate solution, acetic ester extracts an almost colourless tannin, which possesses the properties of a catechol tannin

For many purposes, mangiove cutch is competing closely with the other varieties of catechu, and this competition will no doubt become keener if its quality can be further improved

Mahogany. According to Caseneuve (Ber. 8, 828), mahogany wood contains a catechin

Kino or Gum kino (see under Kinos).

CATELLAGIC ACID C<sub>14</sub>H<sub>6</sub>O<sub>6</sub>. Schiff (Ber 12, 2590), on heating protocatechnic acid with arsenic acid, obtained a substance which he named catellagic acid, and to this he assigned the formula C<sub>14</sub>H<sub>10</sub>O<sub>7</sub> or C<sub>14</sub>H<sub>8</sub>O<sub>7</sub> Perkin and Nierenstein (Chem Soc. Trans 87, 1417) obtained apparently the same substance by the oxidation of protocatechuic acid, and also parahydroxybenzoic acid with potassium persulphate and sulphuric acid. According to the latter authors, catellagic acid crystallises from pyridine in colourless needles, which melt above 360°, and sublime with but moderate carbonisation at higher temperatures. Solutions of the alkali hydroxides dissolve it with a pale-yellow colour,

and with nitric acid it gives a magenta-coloured hquid Diacetylcatellagic acid, colourless prismatic needles, melts at 322°-324°.

Catellagic acid, by distillation with zinc dust, gives fluorene, and is closely related to ellagic Its constitution (P. and N.) may be expressed as follows -

From the oxidation products of parahydroxybenzoic acid, Perkin and Nierenstein isolated, in addition to catellagic acid, compound,  $C_{14}H_8O_6$ , colourless needles, mp above 360° This, which gives the diacetyl derivative  $C_{14}H_6O_6(C_2H_1O)_2$ , colourless needles, mp 267°–268°, and by distillation with zincdust fluorene, possesses the formula .

and evidently originates from the interaction of one molecule of protocatechuic acid and one of parahydroxybenzoic acid

CATHARTIC ACID v SENNA LEAVES.

CATHARTIN v. SENNA LEAVES.

CATHARTOGENIC ACID v SENNA LEAVES CATHARTOMANNITE v SENNA LEAVES

CAULIFLOWER. A variety of Brassica oleracca, in which numerous imperfect flowers form a compact head, which forms the main edible portion

An American analysis shows the edible portion to contain:

Soluble Water Protein Fat carbohydrates Ash 908 1.6 08 6 Ö 0.8 H I

CAULOPHYLLINE v CYTISINE

CÂY CÂY FAT or COCHIN CHINA WAX v. WAXES

CAYENNE PEPPER v Resins.

CEANOTHUS WAX v Snowbrush WAX, art. Waxes

CEDAR CAMPHOR v CAMPHORS

CEDAR OIL v OILS, ESSENTIAL

CEDRA. (Cedrat, Fr.) The fruit of a species of orange, citron, or lemon The peel is very thick, covered with an epidermis containing a fragrant essential oil, used for flavouring preserves, also used whole for wet comfits, and cut in quarters for dry comfits A liqueur is made from it by gathering the fruit before it is ripe, and grating the peel into brandy

CEDRELA TOONA. The Cedrela toona, the Toon or Indian mahogany tree, is a large tree 50-60 feet, although occasionally reaching 100 feet in height, the wood of which closely resembles mahogany and is imported into England under the name of 'Moulmein Cedar,' and much used for making furniture It occurs in the tropical Himalaya from the Indus eastward, throughout the hilly districts of Central and Southern India to Burma, and is also found in Java and Australia. The flowers constitute one of the less important Indian natural dyestuffs, and are reputed to yield both a red and a yellow dye (known in Bengal as 'Gunari,' which is applied without mordants). Although employed for dyeing purposes alone, the flowers are also used in Burma in conjunction with safflower and together with turmeric to produce the sulphur-yellow colour or 'basanti' of Cawnpore.

To isolate the colouring matters, Perkin (Chem. Soc Trans. 1912, 101, 1539) digested an aqueous extract of the flowers with a little hydrochloric acid at 70°-80°, which caused the separation of a reddish-brown precipitate. This collected and dried was exhausted with boiling alcohol, and the solution on evaporation deposited a small amount of a red microcrystalline powder By re-crystallisation from pyridine and removal of an insoluble amorphous impurity, this separated in large orange-coloured leaflets which contained pyridine, and became red and opaque when washed with benzene or alcohol,

the pyridine being thus eliminated.

It melted at 285°-287°, and with cold concentrated sulphuric acid gave a deep indigo blue liquid, resembling in this property bixin, the colouring matter of annatto, Bixa orellana (l.c.). This compound proved to be identical with the red colouring matter nycanthin isolated by Hill (*ibid.* 1907, 91, 1501) from the flowers of the Nycanthes arbor-tristis, to which the erroneous m p 234°-235° has been assigned. The amount which is present in the Toon flowers is very small and does not seem to average more than 0 1 p c. Though there appears to be little doubt that nycanthin and bixin are closely related, the connection between the two compounds cannot be predicted with any reasonable certainty until chemists are in agreement as to the correct The analyses of Hill and formula of bixin of Perkin indicate that nycanthin contains approximately C=7268, H=775, and the simplest formula to which this corresponds is C<sub>15</sub>H<sub>18</sub>O<sub>3</sub> Among the numerous expressions proposed for bixin is, however, that of van Among the numerous expressions Hasselt (cf Annatto), C<sub>29</sub>H<sub>34</sub>O<sub>5</sub>, and should this eventually prove to be correct, then nycanthin is possibly an oxy- or hydroxy-bixin,  $C_{29}H_{34}O_{6}$  (C=72 8, H=7·1).

Addition of zinc-dust to the hot orangeyellow coloured alkaline solution of nycanthin causes decolorisation From this by acidification a colourless or faintly yellow precipitate separates, and this, as is well known, is a property also possessed by bixin

Cotton on immersion in a boiling dilute solution of nycanthin in sodium carbonate, and subsequently rinsing with acidified water, is dyed an orange shade indistinguishable from that given in these circumstances by annatto, a fact which again points to a relationship between the two colouring matters

The flowers of the Cedrela toona contain in addition to nycanthin a fair amount of quercetin probably as glucoside, and also a second flavone or flavonol dysetuff, the identity of which was not ascertained A sugar, C<sub>12</sub>H<sub>22</sub>O<sub>11</sub>, is also present, and this after purification melted at 165°-168°

Cotton and woollen fabrics can be dyed a dull yellow colour by mere immersion in a boiling extract of Toon flowers. This, however, is not permanent, and is removed, although much more quickly from cotton than wool, by the actior of soap or d.lute alkalı. Better results are obtained by the employment of mordants, and

the following shades were obtained with mor danted woollen cloth :-

Chromium Aluminium Dull brownish- Full golden- Bright Dull yellow. yellow. yellow olive-brown.

During these operations, nycanthin or its glucoside apparently plays no part, and the colours obtained are due to the flavone glucosides present Not only the flowers but the seeds of the Cedrela toona are stated to give a red dye

A. G. P. CEDRIRET. A substance found in woodtar by Reichenbach and recognised by Liebeimann as a quinone-like substance and termed by him cærulignone. Hofmann showed that it was tetramethoxydiphenyl quinone, formed by the oxidation of pyrogallol dimethyl ether (v CERU-LIGNONE and QUINONES)

CELERY. A prum graveoleus The blanched stems are used for food

The composition, as given by American analyses, is .

Water Protein Fat Carbohydrates Ash

A more detailed analysis is given by Church (Foods, 1889)

Starch and Water Protein mucilage Sugar Cellulose Ash 20 16 0.9

Mannitol is one of the chief carbohydrate Asparagme (about 05 pc) and constituents tyrosine, are among the nitrogenous constituents (Bamberger and Landsiedl, Monatsh 1904, 25, 1030).

The characteristic odour and flavour of celery are due to an essential oil, which, according to Ciamician and Silber (Ber 29, 1799, 1897, 30, 492, 1419), consists of a terpene, probably  $C_{13}H_{24}$ , and two acid bodies, sedanonic acid  $CO_2H$   $C_6H_5$  CO  $C_4H_9$  and sedanolic acid

 $CO_2H C_6H_8 CH(OH) C_4H_9$ the anhydride  $C_6H_8 \subset C(C_4H_8) O$  of the former and the lactone  $C_6H_8 < C_6C_4H_9 > 0$ 

of the latter appear to be the constituents upon which the smell of the celery depend acid and a phenolic substance are also present.

CELERY OIL v. OILS, ESSENTIAL CELESTINE BLUE v OXAZINE DYESTUFFS CELESTITE or Celestine. Native strontium sulphate (SrSO<sub>4</sub>), forming orthorhombic crystals isomorphous with barytes (BaSO<sub>4</sub>) The crystals are colourless or yellowish, but sometimes they show a pale tinge of sky-blue, and on this account the mineral receives its name. The mineral is often very like barytes in appearance, and it is also heavy (sp gr 39, of barytes, 4.5), it is most readily distinguished by the colour the powdered mineral moistened with hydrochloric acid imparts to the Bunsen flame. Numerous finely crystallised specimens have been found in the red marls of Triassic age in the neighbourhood of Bristol, and in the sulphur-mines near Girgenti in Sicily. Deposits of celestite occur in beds of Cretaceous age over very wide area in Russian Turkestan; and the mineral is found also in Baluchistan. The

largest crystals, measuring a foot across, are from a cave in limestone on Strontian Island, Lake Erie, Ohio. Workable deposits are mined in Arizona and California. The mineral is dug in numerous shallow pits in Gloucestershire and Somersetshire, the production amounting to about 20,000 tons per annum, valued at about 11 per ton Most of this was exported to Germany, where in the form of strontium hydroxide, it was used in the refining of beet-It is also converted into strontium nitiate for making red fire in pyrotechny. For details respecting the British occurrences, see Special Reports on the Mineral Resources of Great Britain, vol III. (Mem Geol Survey), 1915, 2nd ed 1918 L. J. S.

CELLOIDIN. Trade name for a purified

form of pyroxylm.

CELLOSE (CELLOBIOSE) v. CARBOHY-DRATES.

CELLOTROPIN. Trade name for benzoic ester of arbutin

CELLULASE v ENZYMES

CELLULOID (Pyroxylin Plustic) is a colloid composed of soluble mitrocellulose, approaching  $C_{12}H_{16}(NO_2)_4O_{10}$  in composition, together with camphor—It is obtained by gelatinising nitrocellulose by means of a solution of camphor in ethyl alcohol or a similar menstruum. The word 'celluloid' is a registered trade-mark in the United States The substance was first produced by Alexander Parkes, of Birmingham, in England, under the name of 'Parkesine.' Parkes was succeeded by Daniel Spill, of Hackney, London, who adopted the name of 'Xylonite,' under which name it is still well known in Great Britain Other trade names are Fiberoid, Py-ra-lin, Viscoloid, &c Great improvements in the manufacture, especially in mechanical features, were made by John W. Hyatt, of Newark, N.J., U.S.A., and the material first became a commercial success in the United States.

The introcellulose employed is preferably made from tissue paper by subjecting it for 20 minutes or longer to the action of a bath of mixed sulphune and nitne acids containing 19-20 p c of water, at a temperature of 30° or more The resulting nitrocellulose is thoroughly washed with water to free it from acids, and bleached The surplus water is then removed

The nitrocellulose is then mixed with alcohol, camphor, and if necessary, pigments and fillers, and thoroughly incorporated in a kneading Transparent material receives a small The doughpercentage of urea as a stabilizer like mass is worked and formed into sheets between slightly heated rolls. These sheets are consolidated in hydraulic presses heated to about 75°C, into a solid cake, from which after cooling sheets of the desired thickness are cut, or the mass taken from the rolls is placed in a heated cylindrical hydraulic press, provided with suitable nozzles and dies, from which it emerges in the shape of tubes, rods, or the like, of any desired cross-section Rods may also be made out of the solid cake previously mentioned, by forcing a cutting tool through it. All this material has to be freed from its excess of solvent, and is seasoned in rooms, heated to 30°, where it is kept for a period of days, weeks, or months, according to thickness. The camphor solvent

108 CELLULOID.

usually employed is denatured alcohol, owing to the fiscal policy of the countries concerned, but wood alcohol, pure grain alcohol, and a mixture of one or both of them with fusel oil, or its various constituents, have also been widely used. Owing to the great fluctuations in the price of camphor in recent years, the attempts to make this substance synthetically, and to find a substitute for it, have been pursued with vigoui. Synthetic camphor in commercial quantities is an accomplished fact, and is the equivalent of the natural product. The search for substitutes was begun in the early eighties, the most suitable found so far being acid derivatives of aromatic amines.

Celluloid is coloured by means of mineral colours, lakes, and coal-tar dyes, to reproduce the appearance of some more expensive substances, such as ivory, tortoise-shell, leather, coral, amber, &c, or to replace glass in the manufacture of articles in which brittleness is a serious disadvantage. A special variety of celluloid is used in the manufacture of cinematograph film. This contains a higher proportion of introcellulose than ordinary celluloid, and the nitrocellulose is more highly intrated.

Celluloid, while highly inflammable, is non-explosive under any conditions to which it may be subjected in the work of cutting, turning, or moulding, or indeed under any normal conditions. Its specific gravity varies with its composition. It is about 1.35 for the unpigmented material.

Celluloid is plastic at a temperature of 75°, and in practice it is usually softened in boiling water or on a steam table preparatory to moulding. This property of turning plastic at comparatively low temperatures, and its hardness and elasticity at ordinary temperatures, as well as its resistance to the action of water, dilute acids and many other agents, constitute its great technical value. It is used extensively in the manufacture of combs, and other toilet articles, knife handles, piano keys, collars, toys, and for a great variety of other purposes. A relatively less important branch of the

A relatively less important branch of the celluloid industry is concerned with the manufacture of artificial leather by spreading a solution of celluloid on fabric. Celluloid solutions are also used in the manufacture of patent leather, and for metal lacquers, wood enamels, incandescent mantle dips, and a variety of other purposes where a quick drying water-proof transparent or pigmented coating is required, which may be either hard or flexible

For a method of analysing celluloid, sec Hervé, Caoutchouc et Gutta Percha, 1918, 15, 9601; J Soc. Chem Ind. 1918, 686 A.

CELLULOSE, considered physiologically, is the main product of vegetable life. It is the preponderating constituent of all vegetable tissues, and essential to the cell as the structural unit. For while the synthesising activity of the cell is identified with its protoplasmic contents, its main function is the building up of non-introgenous substances, of which cellulose is the chief, elaboration of cellulose, in fact, is synonymous with growth. As an organic product it is known to us in the specialised and diversified forms of plant structures, which are employed in industries either in their original

form or after treatment for separation of their fibrous components.

Cellulose is the basis of our staple textile and paper-making industries, and, when modified by various chemical treatments, of modern high explosives, 'celluloid' products and 'artificial silk'

Cellulose, as a component of vegetable foodstuffs, and in connection with agriculture, is economically important, and is a dominant factor of the cycle of processes, organically interdependent, of the vegetable and animal worlds.

By cellulose, as a chemical individual, we understand usually the residue from the exhaustive alternate treatment of vegetable tissues with alkaline solvents and weak oxidants. Generally, no cellulose is isolated on the large scale except as the result of a chemical treatment, more or less drastic, of fibious raw materials; and all that we know of cellulose as a chemical individual results from the study of products so The typical cellulose is the substance of bleached cotton, the bleaching process such as above described removing the substances other than cellulose with which it is associated in the plant. So obtained, it is a white substance, translucent when viewed under the microscope, but more or less opaque in the mass. This appearance is a consequence of the peculiar form of the cotton fibre, a flat thin-walled tube, the fibrillæ of which are membranously disposed.

The following brief outline of the special chemistry of cellulose necessarily precedes an account of its industrial applications, so far as they involve chemical principles or processes of treatment

CELULOSE —Generally, the non-nitrogenous skeleton of plant structures Type the fibre substance of cotton, freed from associated 'impurities' by processes of (1) alkaline hydrolysis and oxidation (bleaching), (2) digestion with hydrofluoric and hydrochloric acids, to remove mineral impurity or ash constituents

Composition — Elementary C 444, H, 62; O, 494, whence the empirical formula,  $C_6H_{10}O_5$ 

Constitution.—By solution in sulphuric acid as disulphuric ester  $n [C_6H_8O_3(SO_4H)_2]$  and ultimate hydrolysis, the colloidal aggregate is resolved with formation of dextrose in large proportion (Flechsig Zeitsch physiol Chem. 7, 523) The identity

$$[n C_6 H_{10} O_5] + n H_2 O = n C_6 H_{12} O_6$$

which has been assumed, has not been verified experimentally, a maximum yield of 90–100 p c. dextrose [theory, 111 11], but only indirectly estimated and accompanied by acid products, leaves the problem undetermined (Ost and Wilkening, Chem. Zeit 34, 461) See also recent critical discussions (Chem. Soc. Trans. 1918, M. Cunningham. Cross and Bevan). Cellulose is thus variously regarded.

- 1 As a polyhexose anhydride, (a) aldose, (A. G. Green, Zeitsch. Farb. Chem. 3, 97), (b) ketose (Fenton; Cross and Bevan, Chem. Soc. Trans. 82, 361, 366).
- 2. As a polycyclohexane derivative, this view is based on further considerations of density and molecular volume (Cross and Bevan, Ber. 1909, 42, 2198.
  - 3. As an essentially labile aggregate, that is

of variable constitution or configuration, varying according to the action of reagents (Cross and Bevan, Chem. Soc. Trans. 85; Cellulose Researches, n 1905).

Cellulose and water.—Hydration Constitutional water is retained by cellulose in the airdry condition Cotton holds 6-8 pc, varying with temperature and moisture of atmosphere Cotton which has been hydrated by treatment with alkalis (mercerisation) or solvents (infra) or by prolonged attrition in presence of water, shows an increased capacity for moisture when air-dry, and retains 9-11 pc Conversely, the action of condensing acids (HCl, HBi) produces modified aggregates ('hydrocellulose') with a lower capacity (3-5 pc.) Cellulose separated from its solutions, or regenerated from its derivatives by the action of reagents, shows a maximum hydration capacity; the colloidal or gelatinous hydrates having the composition (in contact with water at ordinary temperatures)

20-10 p c. Cellulose Water 80 - 90

Cellulosesolvents -Insoluble in all andneutral solvent liquids, cellulose is dissolved by .

1. Concentrated solutions of zinc chloride (40-50 p c ZnCl<sub>2</sub>), on heating at 80°-100°, when previously hydrated, at lower temperatures.

2 Solution of zinc chloride in twice its weight of HCl Aq (35 pc HCl) this reagent rapidly attacks and resolves the aggregate. Aqueous hydrochloric acid of maximum concentration (>40 pc HCl) acts similarly (Wilstatter, Berl. Ber 46 (1912) 210) but with fixation of negative groups (Cl) in stable union with the products (M Cunningham, Trans Chem Soc lc).

3. Solutions of cuprammonium hydrate containing .

Cu, as CuO  $n{\rm H}_2{\rm O}$  . . 2 5–3 5 p c NH  $_3$  (as NH  $_4{\rm OH}$ ) . . 15 p c

Ethylene-diamino-cupiic solutions act more powerfully (W Traube, Berl Ber. 44, 3319 (1911)

From solutions 1 and 3, the cellulose may be recovered quantitatively, but as a hydrate and otherwise modified in constitution

4 Concentrated solutions of certain metallic sulphocyanides at high temperatures, 120°-140°. Reactions —The above reactions resulting in solution of the cellulose are characteristic; otherwise it is exceptionally non reactive dilute solutions of iodine, in presence of certain dehydrating agents, it is coloured blue

Cellulose compounds A. Synthetical derivatives. Esters.

(a) Nitrates. By direct reaction with nitric acid, usually in presence of sulphuric acid, in which case unstable mixed esters are formed as a stage in the reaction, the NO<sub>3</sub> displacing the SO<sub>4</sub>H residues (Cross, Bevan and Jenks, Berl. Ber. 34 (1902) 3496) The esters are formed without sensible structural modifications are purified from residual SO<sub>4</sub>H by prolonged boiling with water, and are then 'stable.' A series of these esters is known, the highest approximating to the trinitrate (C<sub>6</sub>) (gun-cotton); the intermediate terms—dinitrate—being soluble in ether-alcohol (collodion cotton), the lowest having physical properties but little different from the original cellulose.

These esters are variously formulated as

nitrates of a reactive unit of C<sub>6</sub>-C<sub>12</sub>-C<sub>24</sub> dimensions.

Solvents.—The special solvents of these esters are acetone, ether-alcohol, nitrobenzene.

A diversified range of solvents is enumerated in a paper by H. dc Mosenthal (J. Soc. Chem. Ind. 1907)

Saponification.—By certain alkaline and reducing agents (alkaline sulphydrates) the nitric groups are eliminated and cellulose regenerated.

(b) Acetates. By reaction with acetic anhydride under various conditions. (1) at 110°. direct formation of monoacetate (C, insoluble in all neutral solvents and in the solvents of cellulose (2) At 140°-160° · formation of higher acctates, attended by solution in the reaction mixture (3) In presence of catalytic agents  $(ZnCl_2-H_2SO_4-H_3PO_4)$  at intermediate temperatures, H<sub>2</sub>SO<sub>4</sub> determines reaction at 25°-30° The extreme products are mixtures of tri- and higher acetates (4) When the reaction mixtures are diluted with hydrocarbon, the fibrous cellulose may be acetylated without solution or visible structural change

Industrially important acetates are the acetone soluble esters C<sub>12</sub>H<sub>15</sub>O<sub>5</sub> OAc<sub>5</sub> produced by acetylation with mixtures of Ac2O and H2SO4. These are the basis of aeroplane varnish-dopes

Solvents of the higher acetates, are chloro-

form, acctone, phenol

For an exhaustive account of the industrially important types, see E C Worden, J Soc Chem, Ind 1919.

Saponification -The acetyl groups may be removed by boiling with alkaline solutions, the cellulose being regenerated In quantitative determinations the saponification may be effected by boiling with normal sodium hydroxide diluted with an equal volume of alcohol

(c) Formates—Cellulose and formic acid interact at 60°-100°, in presence of catalysts the reaction proceeds to complete solution limit of esterification appears to be the diformate (C<sub>6</sub>), but the product is unstable, decomposing spontaneously with liberation of formic acid (1 mol). The reactions are not those of simple ester (anhydride) formation; the celluloses in reaction appear to undergo constitutional change (Cross and Bevan, J. Chem. Soc. Ind. 1911, 99, 1450, Berl and Smith, Berl Ber 1907, 40, 906, Woodbridge, J. Amer Chem Soc 1909, 31, 1067, Dewing, ibid 1911, 33, 1179)

(d) Acid-sulphuric esters By the action of sulphuric acid an extended series of esters is formed, which have been described as cellulose sulphune acids But they are certainly derivatives of products of resolution. The first stage results in the formation of a disulphuric ester  ${\rm C_6H_8O_3(SO_4H)_2},$  but its relationship to the parent complex is doubtful. The ester is soluble in water, the Ca, Ba, and Pb salts are insoluble alcohol By progressive hydrolysis the cellulose is ultimately resolved in the direction of dextrose (see M. Cunningham and Cross and Bevan, l.c).

(e) Aceto-sulphates and mixed esters, con taining the SO<sub>4</sub>H residues associated with acetyl and other negative groups in combination, are obtained when sulphuric acid is allowed to act under regulated conditions simultaneously with other esterifying agents. Thus a mixture of acetic anhydride (50 parts), glacial acetic acid (50 parts), and sulphuric acid (4-6 parts), acts rapidly at 30°-40°. The first product appears to be a neutral body of the empirical formula

$$(4C_6H_7O)SO_4(C_2H_3O_2)_{10}$$

and under the action of water to undergo an internal hydrolysis, the SO<sub>4</sub> group becoming SO4H, which forms a stable combination with bases The Mg, Ca, Zn salts are insoluble in water, but soluble in acctone

(f) Benzoates result from the action of benzoyl chloride in presence of alkaline hydroxides monobenzoate (C6) is obtained by treating cellulose with a solution of sodium hydroxide of 10 pc. (NaOH) strength, and shaking with benzoyl chloride This benzoate is formed with only slight structural change. The dibenzoate (C<sub>6</sub>) is obtained by the interaction of benzoyl chloride and alkali cellulose (mercensed cotton) in presence of sodium hydroxide solution (15 p.c. NaOH) Its formation is attended by structural change; the fibrous cellulose is disintegrated, the dibenzoate being an amorphous substance The dibenzoate is soluble in acetic acid and chloroform

Mixed esters, containing the henzoyl and nitric residues, result from the action of nitric acid upon the benzoates Simultaneously a nitro- group enters the benzoyl residue.

Alkalı cellulose The fibrous cellulose undergoes considerable structural modification under the action of solutions of sodium hydroxide of 12-15 pc NaOH These reactions and phenomena were first studied by Mercer They are the basis of the process of mercenisation (q v)under which cotton-yarn and cloth assume a special lustro and silky finish. There is a definite synthetical reaction in the ratio C<sub>6</sub>H<sub>10</sub>O<sub>5</sub> · 2NaOH, which is a stage in the formation of the dibenzoate (supra)

The compound is completely dissociated by water; by treatment with alcohol an equilibrium is reached when the reagents are associated in the ratio  $C_{12}H_{20}O_{10}\cdot NaOH$ The alkali-cellulose hydrate, of composition  $\cdot$ 

 $\begin{array}{cccc} \text{Cellulose} & . & . & 30\\ \text{Sodium hydrate} & 15\\ \text{Water} & . & . & 55 \end{array} \right) \begin{array}{c} \text{cellulose} \cdot \text{ sodium hydrate} \\ \text{C}_6\text{H}_{10}\text{O}_5 & 2\text{NaOH} \end{array}$ 

is the first stage in the synthesis of

Cellulose xanthogenic acid, which results from the interaction of the alkali cellulose and carbon disulphide at ordinary temperatures sodium salt is soluble in water. It is an unstable compound, the solution undergoing spontaneous progressive change. The solution, which is highly colloidal, finally solidifies Bymeans of the characteristic reaction of the xanthates with iodine

$$\begin{array}{c}
\text{CS} & \text{OX XO} \\
\text{SNaNaS} & \text{CS} + \text{I}_2 \\
= 2\text{NaI} + \text{CS} & \text{S} & \text{CS}
\end{array}$$

the progress of the change may be followed, the essential feature being the elimination of the CS<sub>2</sub> residues with reaggregation of the cellulose units Well-marked stages in the series occur at the points denoted by the empirical formulæ  $C_{12}H_{19}O_9CSSNa$ ,  $C_{24}H_{39}O_{19}CSSNa$ . The former represents an equilibrium attained after the solution has remained for some hours at the solution has remained for some hours at the of the hypochlorites, permanganates; but when ordinary temperature; the latter is reached in the limit is pussed the oxidations which result

from three to four days. The cellulose under the reaction acquires a more acid character, an additional OH group combining with alkali. The lower terms of the series, e.q. C<sub>48</sub>H<sub>79</sub>O<sub>38</sub>. CSSNA, though insoluble in water or dilute saline solutions, are dissolved by the addition of sodium hydroxide The sodium atom in combination with the CSS residue is not attacked by By double weak acids such as acetic acid decomposition with soluble salts of Cu, Zn, &c, the corresponding xanthates are produced as insoluble colloidal precipitates.

In the above reactions the cellulose aggregate is maintained, the solutions of the derivatives are viscous and colloidal, but in the following

B Reactions of decomposition, which are determined by hydrolytic and oxidising agents, the directions of resolution are extremely various, and the relationships of the products to the original aggregate are undetermined

(a) Sulphuric acid dissolves the cellulose as a disulphuric ester, but decomposition attends the reaction, and on diluting and boiling, the hydrolysis is carried to the extreme molecular limit, the final product being dextrose (supra); but the reactions are not simple as generally stated, they are complicated by relatively stable union of the SO4H with the resolved cellulose 'residues,' and by tendency to reversion or condensation

(b) Hydrobromic acid in ethereal solution attacks the cellulose profoundly with production of brom-methyl furfural The formation of this compound indicates a previous or intermediate stage in which the products of resolution are molecular ketonic bodies of carbohydrate constitution (Fenton, Chem Soc Trans 1901, 361).

(c) Hydrochloric acid, in presence of water, dilute sulphuric acid, and acids generally, attacks the cellulose aggregate with production of a variety of derivatives (1) Insoluble: these are generally termed 'hydrocelluloses' They are disintegrated residues of the original fibres, they differ chemically from the parent aggregate in the presence of free aldehydic groups, and in readily yielding to the action of alkalis (2) Soluble molecular products, chiefly dextrines and dextrose.

(d) Alkaline hydroxides and alkalis generally in the form of dilute solutions have little apparent action on cellulose—even when treated at elevated temperatures Sodium hydroxide in solutions of concentrations of 12 p c. NaOH and upwards, combines with the cellulose, producing profound structural modifications (mercerisation), but without resolving the aggregate.

At higher concentration and temperature the cellulose is partially dissolved; but even under the conditions of a 'fusion' at 180° the resolution is limited to the conversion into alkali soluble modifications, which are precipitated in the colloidal form on diluting and acidifying. At higher temperatures (250°) and with larger proportions of the alkaline hydroxides, the cellulose is resolved into acid products of low molecular weight, chiefly acetic acid and oxalic acid

(e) Oxidants. The directions of oxidation of cellulose are likewise extremely diversified. The aggregate manifests considerable resistance to alkaline oxidants in dilute form, eg. solutions

CELLULOSE

are drastic in the sense that the soluble products are of low molecular weight, chiefly carbonic and The insoluble fibrous residues, oxalic acids. more or less disintegrated, are known as oxycelluloses. They contain free aldehydic groups, are easily attacked by hydrolysing agents, and on boiling with hydrochloric acid (106 sp gr) are decomposed with production of some furfural

Resolved by the action of concentrated solutions of the hypochlorites, cellulose yields chloroform and carbon tetrachloudes The hypobromites give the corresponding bromine derivatives Nitric acid (1 25 sp gr ) at 80°-100° converts cellulose into a series of coxycelluloses, which are resolved on boiling with calcium hydroxide into acid products, among which isosaccharinic and dioxybutyric acids have been identified. In the original oxidation small quantities of the higher dibasic acidssacchanic and tantanic acids-are produced, but the main products are oxalic and carbonic acids

With chromic acid an endless series of oxidations may be effected, the degree of action depending upon the proportion of the active oxidant and the associated hydrolytic action of The oxycelluloses produced are mineral acids distinguished by relatively large yields of furfural when decomposed by boiling HClAq (1 06 sp gr) In presence of sulphuric acid there ensues complete combustion, and the reaction is the basis of quantitative analytical methods.

(f) Resolution by ferment actions Under the actions of specific organisms the cellulose complex is totally resolved, the main products being methane, hydrogen, and carbonic and The decomposition may be associfatty acids ated with the action of an enzyme, but a remarkable feature of the process is the absence of intermediate products, at least in the cases hitherto investigated In the digestive tract of the herbivoia, cellulose is resolved, and from the investigation of the process, necessarily by indirect observations, it appears that, in addition to a destructive resolution to ultimate gaseous products, there occurs a resolution to proximate groups of high nutritive value, which are assimilated by the animal organism

(q) Resolution by heat · destructive distillation Cellulose heated at 100°-120° is dehydrated at 150° decomposition is evidenced by change of colour. At this early phase maltol appears to be formed The decompositions of cellulose at temperatures exceeding 250° are necessarily

extremely complex

The groups of products show an average proportion:

Solid 30 p.c.	Liquid 50 p.c.	Gaseous 20 p.c.
Charcoal or pseudo-car- bon	Containing acetic acid(2p c.), methyl alcohol (7 p.c.), acetone, furfural (12 p.c.)	Chiefly CO and CO,

the actual proportions and composition of these mixtures varying with the temperature and duration of their heating

By 'dry' distillation in value of cellulose

(and starch) large yields of lavoglucosan are obtained. Pictet and Sarasin, Compt Rend. 166 (1918) 28.

111

General view of the decompositions of cellulose. It is clear that the cellulose complex breaks down under destructive influences, in directions depending upon the nature of the attacking agent, its concentration, and all the surrounding physical conditions. The study of surrounding physical conditions these decompositions has thrown but little light on the actual nature and constitution of the cellulose aggregate. for the reason, perhaps, that we have endeavoured to maintain a basis of interpretation such as is applicable to ordinary molecular compounds or complexes. Cellulose is a typical amphoteric colloid the reactions with hydrolytic reagents suggest many points of analogy with the state of a complex salt in solution (in water) Its component groups of unknown, but possibly small dimensions, appear to exist under a certain internal stress which determines migrations of H and OH under reaction. While, therefore, we have reduced the reactions of cellulose to a short systematic expression, it is clear that the main aspect of the subject cannot effectually be so treated, because it involves as theoretical basis the actual state of matter and the dimensions and distribution of the reactive unit-groups in the cellulose complex, and this basis is, as yet, largely undetermined (see Cross and Bevan, Cellulose Researches, 1905, 1910)

the typical The cellulose group.  $\mathbf{From}$ cellulose we pass to the diversified group of Then general characteristics are those of the prototype, the variations they present are especially such as involve the unde-termined factors of constitution. With these there are certain correlative variations which afford an empirical basis of classification. These are (a) the degree of resistance to hydrolytic and to oxidising agents, (b) the percentage yield of furfural when decomposed by boiling HClAq, (c) elementary composition, in respect of the ratio C O

The fibrous celluloses are grouped as follows.

Туре	Cotton sub-group A. Bleached cotton.	Wood cellulose sub-group B Juta cellulose.	Cereal cellulose sub-group C Straw cellulose
Hygroscopic moisture Elementary composition C O Furfural Other cha- racteristics	6-8 p c.  { 44 0-44 4   50 0   0 1-0 4   No active CO groups	9-11 p c 43 0-43 5 51 0 3 0-6 0 Some free CO groups	9-12 p c 43 5-44 5 52-50 12 0-15 0 Variable reactivity of CO groups.

See Esparto Cellulose and the Problem of Constitution: Cross and Bevan, Chem. Soc. Trans. 113 (1918) 182.

Of these groups the following points may be noted.

A. Comprises, in addition to cotton, other industrially important celluloses, e.g. flax, hemp, and rhea. They occur in the plant-world in association with compounds easily removed by the action of alkalis. They pass through the

cycle of reactions involved in their solution as xanthates, without hydrolysis to soluble derivatives

B These celluloses are obtained as products of decomposition of a compound cellulose. They may be regarded as partially hydrated or hydrolysed. They are more readily attacked by hydrolysing agents and, in the xanthate reactions, are partially resolved to alkali-soluble, derivatives.

U These celluloses are in most cases a complex of structural elements, and not homogeneous chemically They are still less resistant than the preceding group, and more especially the furfural-yielding components, which are selectively attacked under certain conditions

The cellulose groups, as above, pass by imperceptible gradations into a heterogeneous class of natural products, which, while possessing some of the characteristics of the celluloses proper, are so readily resolved by hydrolytic treatment that they must represent a very different constitutional type or types. To this group of complex carbohydrates the class-name hemicellulose has been assigned. They are structurally different from the fibrous celluloses, occurring mostly in the cellular form (parenchyma, &c.). They differ in physiological function, and in being readily resolved by hydrolysis into the crystalline monoses.

The foregoing exposé will enable us to group the industrial and manufacturing applications of cellulose in reference to first principles as

follows .—

GENERAL.—The uses of the fibrous celluloses, more particularly of cotton and the cotton group, in which we may include flax, hemp, and ramie, depend, apart from the primary condition of length of ultimate fibre, upon the extreme chemical resistance of the fibre substance, which is a function both of the constitution of the ultimate groups and of their mode of union to constitute the aggregate itself

Insensitiveness to oxidation is an obvious condition of such stability as is required for textile fabrics and paper, and, as evidence of resistance to atmospheric oxygen, we have the fact that flax and cotton fabrics and papers composed of these fibres have been handed down to us from antiquity, with little change. Next in order of importance is resistance to water and alkaline hydrolysis. This resistance enables textile fabrics to withstand periodical cleansing or laundrying, in which alkalis are the principal agents. In the purifying of textile fabrics by the bleaching processes and the preparation of paper pulps, the same negative qualities are of first importance.

Textules are subjected to severe processes of alkali treatment, and to the action of bleaching agents, such as hypochlorites, without evident

chemical or structural modification.

On the other hand, there is a limit of the resistance to exidation, and any unduc action of the ordinary bleaching solutions leads to the formation of 'oxycellulose,' and structural weakening as an attendant result.

While extremely resistant to alkalis, the celluloses are sensitive to acids, and here again in bleaching, finishing, and dyeing processes, the incidental acid treatments require careful adaptation to the limit of sensitiveness of the cellulose.

SPECIAL.—Constitutional moisture and hydration effects. These involve a range of phenomena of obvious industrial importance. The normal moisture of cellulose has to be taken into account in the finishing of textiles, and their package for shipment. The condition of the fibres as regards hydration, of which the capacity for combining with atmospheric moisture is an index, directly affects the finishing processes which are chiefly the mechanical operations of mangling, calendering, and beeting.

The further hydration of the celluloses which takes place in the beating operations of the papermaker is of considerable practical importance, and affect the quality and character

of the papers in a very great degree

Cellulose and ash constituents. The normal ash of the cellulose of the cotton group is small in proportion, and we are not able to affirm that these inorganic constituents have any determining relationship to the constitution of celluloses, though this is an accepted probability.

It is a problem for colloidal chemistry to establish this relationship in specific terms. Industrially, the question arises only with regard

to the aggregate.

Thus in the purest form of cellulose required as filter paper for the quantitative separations by chemists, it is of importance that the ash components should be reduced to a minimum

This minimum of 0.05 p.c. by weight, is attained by digesting the cellulose with hydrofluoric acid and hydrochloric acid, and thoroughly

washing the paper in pure water.

Pure unsized cellulose paper thus treated constitutes the well-known 'Swedish' paper, so called from its country of origin, but now produced in this country and other centres

Cellulose as a typical colloid enters into characteristic combinations with inorganic oxides, and this property is an important basis of the processes of the dyer and printer.

Oxides of the polyvalent metals, notably of aluminium, chromium, iron, tin, and lead, are taken up by the celluloses from solutions of their salts, and the cellulose thus mordanted has increased special affinities for colouring matters

A more special industrial application of this property is the method for making the mantle, now in common use for intensitying coal-gas illumination (Auer-Welsbach). The colloidal oxides of thorium and cerum in suitable proportions are fixed upon cellulose fabrics, which are then dried and ignited. The result is an inorganic skeleton of the original fabric, prepared in any desired form, and composed of the oxides in question

The particular form fulfils the conditions of maximum illuminating surface, together with the desired degree of mechanical resistance to stand shock and wear and toai under the particular conditions of employment

Cellulose and solvents It is in the solutions of cellulose or its derivatives that the particular properties of the cellulose aggregate are evident

In the case of the aqueous solvents observation shows that the cellulose, employed as fibre, passes through phases of progressive hydration with considerable distension until the final stage of homogeneous structureless solution is reached. The general character of the solutions is their high viscosity, which imposes a limit of from 7 to 9 p.c. cellulose for solutions which

require filtering.

The technical applications of these solutions depend upon the fact that the cellulose is brought into the plastic homogeneous structureless condition, in which it may be formed or shaped at will, and in finally reverting to the solid state preserves its structural continuity through the successive phases of dehydration.

The solution in zinc chloride has been used for making threads to be carbonised for electric

incandescence lamps.

The solution is forced through narrow orifices into alcohol, which precipitates the cellulose as a transparent hydrated solid, retaining zinc oxide (hydrate) in combination. The solid hydrate is formed and manipulated in continuous length, and, when freed from zinc oxide and dried, is a structureless cylinder of cellulose. Heated out of contact with air, it is converted into a 'pseudocarbon,' which constitutes the filament in question.

The solution of zinc chloride in hydrochloric acid has been employed for converting cellulose papers into a special agglometated product or board, which is used as an insulating material and for structural purposes. The sheets or webs of paper are treated with the solvent by immersion, and the material thus attacked is then welded into the composite fabric by means of the adhesion of the viscous cellulose solution resulting from the attack.

The composite sheets or webs so produced are finally compacted by pressure, and then exhaustively washed to remove the solvents

Cuprammonium There are various industrial applications of this characteristic solvent Textile materials are treated by passing through the solution. The cellulose is attacked superficially, and under the pressure of rolls the gelatinised product is distributed uniformly, the fabric is then dried. The fabric is thus coated with a variush composed of cellulose and the hydrated copper oxide, of greenish colour which renders the fabric impervious to water and rotpicof.

Papers are similarly treated, the sheets of webs being welded together under pressure. These tabries have been known for a number of years as the 'Willesden' waterproof fabries.

The most important industrial application of the solution is in the manufacture of artificial cellulose threads, which are produced in various grades of fineness, and known as 'Artificial Silk,' 'Monofil' (Lustra Cellulose, Soie Artificielle, Glanzstoff, Crin).

The process in its simplest form consists of the production of the solution by treating bleached cotton with the cuprammonium solvent, and filtering through fine metal-wire cloth to remove incidental impurities

The solution is projected through orifices of varying diameter, according to the size of the

threads to be produced, into solutions which

precipitate or coagulate the cellulose.

The setting solutions are of two types, acid and alkaline.

The cellulose is precipitated as a hydrated solid, in continuous length, and is drawn forward at speeds varying from 20 to 50 metres per tures. Vol. II – T.

minute, according to the diameter of the thread and the conditions of the precipitation

In the case of fine filaments, constituting artificial silk, several of the threads so produced are twisted together to form a compound filament or yarn suitable for weaving purposes. The products are dried under special conditions, to secure maximum lustre and elasticity

Cellulose esters The application of the nitrates to high explosives is an application of cellulose that stands apart and depends, of course, upon the fundamental chemistry of the product.

The ratio of oxygen is such that the products contain the elements for their complete conversion into gaseous products when raised to the reactive temperature.

The nitrates in the fibrous form in which they are produced, are explosives of the disruptive or blasting type, and were exclusively

so used for many years

The type of explosion required for the propulsion of projectiles, is a restrained or graduated combustion, which is determined by a change of form of the intrates. These are convertible into plastic modifications under the action of their specific solvents, and in this state they may be formed or fashioned into threads, cylinders, or solids of any desired form or dimension. The combustion of these structureless solids, in its aggregate explosive effect, may be made to fulfill any desired ballistic conditions.

The most interesting case is that of the employment of nitroglycerine, itself a high explosive, and the basis of dynamite, to reduce the cellulose nitrate, acting as a solvent, to the structureless condition.

Mixtures of introcellulose and introglycerine, in suitable proportions, are drawn to threads and constitute with certain admixtures the modein explosives cordite, ballistite, &c. (see Explosives)

The collulose intrates, treated with neutral solvents and subjected to a process of milling, are reduced to a structureless plastic mass. This may be reformed into solid substances which may be produced in any desired form or dimension. In sheets or film they constitute the basis or transparent carrier of photographic emulsions.

In solid form they are known as celluloid, xylonite, &c., and find endless applications both useful and ornamental (v Celluloid).

The solutions of mitrates in neutral solvents, such as ether-alcohol (collodion) or amylacetate, are used as varnishes and lacquers for various purposes

purposes

The cellulose intrates in ether-alcohol solution are employed industrially in the manu-

facture of artificial silk

This, in fact, was the pioneer invention 'of Chardonnet,' and dates from 1883

The process of spinning consists in forcing the solution through capillary glass jets, either into air (Chardonnet) or into water (Lehner).

The thread is thus formed and obtained as a nitrate, in which form it is twisted into compound textile filaments, which are reeled into

skeins of yarn.

A process of saponification for removing the nitric groups follows. This consists in digesting the nitrate yarn in solutions of ammonium-magnesium sulphydrates at ordinary temperatures.

114 CELLULOSE.

As a result of the cycle of operations, the denitrated cellulose is obtained and constitutes the artificial silk of commerce.

The xanthogenic esters of cellulose in aqueous solution (viscose) are the basis of the production of artificial textile fibres, and the viscose artificial silk has displaced the pioneer product as well as to a great extent the cuprammonium product (Glanzstoff) The manufacturing process comprises the following operations:—

(1) Wood cellulose is converted into alkalicellulose (hydrate).

(2) After ageing, the product is treated with carbon disulphide in closed vessels

(3) The xanthate is dissolved and filtered, and after ageing is projected through fine apertures into acid solutions, which cause rapid decomposition and reversion to 'cellulose'

(4) The reprecipitated cellulose hydrate is

dried and dehydrated under strain.

For a full description, see L P. Wilson,

J. Soc Chem Ind. 1917, 817.

Cellulose acetates are the analogues of the nitrates with the radical distinction of being non-explosive, and, in fact, eminently stable compounds.

By treatment with their special solvents, they are dissolved to homogeneous viscous solutions, and they may be fashioned into films and solids as are the nitrates.

So far the industrial applications of the acetates have been limited chiefly by the

prohibitive costs of production

One important application, however, produces results so very much sui generis and in an arena where costs of production are a minor consideration, that it has led to extensive developments of the manufacture. Solutions of the acetate (6–8 pc) in 'organic' solvent liquids constitute a viscous varnish-dope, which when applied to a (stretched) fine textile, cotton or flax cloth, produces a considerable shrinkage, and this under strain, as on the wing planes of the aeroplane, gives a taut, smooth surface, at the same time waterproofing the fabric and thus fulfilling the exacting technical specification of the effect required for these special and highly specialised structures.

The acetate is also used as a varnish covering of fine wire used in electrical construction. The acetate is a high insulator with exceptionally low

inductive capacity.

Cellulose acetate has already been spun to artificial silk and coarser textile threads, but there has been so far no industrial development of the processes

The technical interest of such a product is that it is employable as an ester, whereas the nitrate is entirely unsuitable, as such, for textile

applications.

Cellulose and alkalis (Mercerisation). The action of alkaline hydroxide in strong solution (15-20 p c. NaOH) upon cotton textiles, is the basis of a special industry. By converting the cotton fibre into the modified form, cotton yarns and fabrics are changed in appearance and acquire a silky lustre and touch.

The goods to be 'mercerised' are passed on the nature of the fibre substance. So too through a solution of caustic soda in the cold. This produces the effect of considerable shrinkage accompanying the change of form and treated for the isolation of the fibres. We must

dimensions of the ultimate fibre, from a flat membranous, to a thick-walled cylindrical homogeneous tube.

This shrinkage is resisted by placing the goods under the condition of mechanical strain, either during the process of alkaline treatment, or, after allowing the shrinkage to take place, the goods may be afterwards stretched to their original length.

The fundamental observations which condition this process were made by J. Mercer (1850–1860), but they remained undeveloped until late in the century (1880–1890).

The industry is now a considerable one, and is to a certain extent independent of fashion

(see MERCERISING).

Cellulose and sulphuric acid. Whereas cellulose reacts with the more concentrated acids ( $H_2SO_4-H_2SO_4,H_2O$ ) to form sulphuric esters, the acids of 670 to 780 pc  $H_2SO_4$  (approximately constant) matelyH2SO4,2H2O-H2SO4,3H2O) hydrate, and dissolve the cellulose to a colloidal solution, from which, if immediately diluted, the cellulose is precipitated as a gelatinous hydrate ('Amyloid').
These reactions are industrially applied in the preparation of 'parchment paper,' or 'vegetable parchment' A pure cellulose paper is passed through a bath of acid, and immediately, in continuous length, into water, which arrests the action of the acid and reprecipitates the cellulose superficially dissolved as a structureless colloid. After washing from the last traces of acid, the web of now parchmentised paper is dried under special conditions of strain to control the shrinkage of width (10-13 pc), so as to maintain an even surface and prevent deforma-To overcome the brittleness product, which would result from total drying, it is treated with solutions of neutral hygroscopic substances, such as glycerol or glucose, before passing on to the drying cylinders. A sufficient proportion is retained in the finished product to ensure a normal 'humidity.

The total hydrolysis of cellulose to fermentable 'sugars' is effected by dissolving in the more or less concentrated acid, and, after allowing the acid to act until the solution becomes limplied, diluting and heating the dilute solution. The acid is neutralised with chalk, filtered from the insoluble calcium sulphate, and concentrated. The industrial value of this piocess is obviously limited by the relatively low values of starches and the more economic conversion of these by simpler means and to superior products.

simpler means and to superior products

The compound celluloses (Vegetable fibres).

While the simplest form of vegetable life is
the cell, and the cell is, moreover, the universal originating unit, we observe, as we
ascend the scale of plant organisation, an increasing variety of differentiations of this simplest structural unit graduating into the fibres
and vessels of the stems of the higher flowering
plants. It is to the presence of such elongated
cells as warrant the designation 'fibre' that
these stems mainly owe their powers of bearing
strains and resisting fracture. The uses to which
these fibres are put in the arts depend upon the
same characteristics of form, and obviously also
on the nature of the fibre substance. So too
the anatomy of fibrous stems is necessarily
a main factor of the processes by which they are

CELLULOSE 115

here except from the general anatomical view we are about to take the most important of the vegetable fibres, viz cotton, which as a seed hair is distinct physiologically, and differs structurally from all other fibres employed for textile

purposes.

The 'ultimate' fibre is a hollow tube, the walls being thin and membranous, it is attached at one end to the testa of the seed, the other being free, and there is no adhesion of the fibres to one another. The preparation of the textile fibre involves, therefore, only a mechanical treatment, and that of the simplest kind, for separating it from the seeds. The other vegetable fibres employed in the arts are without exception constituents of complex structures (stems and leaves) which require a more elaborate mechanical operation for their separation, in addition in many cases to a preparatory chemical treatment

The fibres of stems are arranged according to the two main structural types of growth, the exogenous and endogenous In the exogenous stem of annuals (dicotyledonous) they constitute a localised tissue, the bast, which is an annular ring external to the wood and beneath the cortex. In the endogenous stem the fibres proper (bast fibres) are generally aggregated together with vessels into bundles known as fibrovascular bundles, which are scattered more or less irregularly throughout the cellular matrix

In regard to the leaf, the two great divisions of the phanerogams are also contrasted, the fibro-vascular bundles of the former are not only nregularly disposed, but interlaced (reticulate venation), whereas the leaves of the typical monocotyledon are characterised by a parallel arrangement of the bundles, and fulfil, theretore, a necessary condition of separation for tex-Fibres of this class are amongst tile purposes the most useful that we have There is a distinction to be noticed, though rather of a technical than anatomical nature, between the vegetable fibres and 'fibrous substances' former we understand isolated bast fibres or fibro-vascular bundles, such as can be spun into a continuous length or yarn A fibrous substance is any vegetable structure containing fibres Many of these do not admit of being economically treated for the isolation of a textile fibre, but, on the other hand, are resolved by suitable chemical treatment into a fibrous mass or pulp, available for paper making. Many of our most valuable raw materials for this industry are of this nature. We may further distinguish, according to the above classification, (1) evogenous bast tissues, such as those of the Adansonia and Broussonetia (paper mulberry) and entire stems (woods), and (2) endogenous stems (straws and bamboo), and leaves (esparto). In this more miscellaneous group also we should include the refuse from the preparation of textile fibres, such as the root ends of jute (butts), the waste from the flax-scutching process

(infra), &c.
We have already excepted the cotton fibre from the above classification, indicating a structural as well as a physiological distinction from other textile fibres. These are, in fact, always obtained and spun in the form not of ultimate fibres, but of bundles of these. The ultimate bast fibre is also a hollow tube, but more or less

thick walled and with tapering extremities, in section it is seen to be cylindrical or polygonal The dimensions are remarkably uniform for the bast of any given plant or species, but exhibit wide variations from species to species. Thus the average length of the bast cell of jute is 3 mm, and of flax 28 mm. The textile 'fibres' are aggregates of these ultimate fibres, and it is convenient to employ for them the special designation of *filament* This complex spinning unit varies in the number and degree of cohesion of the constituent fibres These variations even in the same plant or species are very considerable, but more so as we pass from species to species. Expressed in another way, the textile fibres vary very much in regard to fineness and divisibility of the filaments. These, it is scarcely necessary to say, determine in a very important sense their spinning qualities. The nature of the fibre substance is a self-evident factor of the mechanical properties of the filaments, and lastly, though less obviously, the length of the ultimate fibre, which greatly influences the strength and durability of the yarn.

To the spinner the chemical composition and properties of the fibre substance may appear of altogether secondary importance; but they are obviously of first importance in regard to the application of the yarn, as of the goods woven from it. Supposing them put into use without further preparation, the durability of the fabrics will depend upon their resisting the disintegrating action of air (oxygen) and water, reinforced by heat and light But a large proportion of the textile fabrics of commerce are supplied to the consumer in the bleached state, the process of bleaching consisting in the removal, by a more or less drastic treatment with reagents of those fibre constituents to which the colour of the raw material is due These processes being the subject of a special article, we shall not require to deal with them at all in detail. The principles underlying them, however, have a close and obvious connection with the properties of cellulose, and the relationships subsisting between the cellulose of the vegetable fibres and the non-cellulose constituents with which each is associated in the plant, and from this point of view we proceed to give a short account of the

## CHEMISTRY OF THE COMPOUND CELLULOSES.

There are many reasons for regarding cellulose and the non-cellulose constituents of vegetable tissues and fibre substances as united chemi-While this is certainly true of the cutocelluloses (infra) there is evidence that in the ligno celluloses the bond of union is rather that of mutual interpenetration or 'adsorption' At the same time the combination is equally resistant to reaction as that of a union of 'residues' in the strictly chemical sense. Taking cellulose as the constant, the basis of our classification of the compound celluloses will be the nature of the non-cellulose, the characteristics of which are as distinct as they are general Physiologists recognise three 'modifications' of cellulose in the plant, and these we term 'compound celluloses.' We shall find the compound celluloses.' distinguishing chemical features of the three groups of compound celluloses as well marked 116 CELLULOSE.

as their functional correlations, and the corresponding classification has a 'natural' in addition to its chemical significance. We shall consider first the group which is of least, because of only incidental, importance in relation to our subject.

Cutocelluloses (Adipocelluloses). The protective tissues of plants, which are, moreover, cellular rather than fibrous, viz cork and cuticle, are composed of a substance of marked water-resisting characteristics. In this property, as well as in empirical composition, the cuticular substance designated cutose by Fremy resembles many of the waxes. The following percentage numbers are the results of the analysis of the cuticle of the apple purified from wax and adventitious matters: C, 73 66, H, 11 37, O, 14 97.

Cork is not a simple substance, but contains a number of products, wax, fatty esters and anhydrides, proteid residues, and tannins, &c, associated with the matrix or skeleton substance, which is of the nature of cutose Both cutose and cork yield a residue of cellulose when treated with special reagents (sulphites) for the resolution of its union with the wax-like non-cellulose The latter 1 is resolved by boiling with strong solutions of the alkalis into two fatty acids, a solid acid designated stearocutu and a liquid called oleo-The investigation of these cuticular substances has not been sufficiently extended to warrant our entering into further detail in regard to their composition and properties We may regard them as compound celluloses resolved by alkaline saponification into cellulose and a mixture of fatty acids of peculiar properties, but altogether unknown constitution They may be conveniently grouped under the term adipocelluloses, which broadly expresses their chemical relationship As regards their distribution, they occur chiefly in the epidermal and cortical tissues of leaves and stems, but the observations of Fremy lead to the conclusion that they are by no means confined to these, and there is evidence of their presence, if only in minute proportions, in the fibres themselves, but their occurrence, chemically speaking, may be regarded as adventitious, the fibre substances belonging to essentially different classes of compounds. These adipocelluloses, moreover, in most of the technical applications of vegetable materials which come within the province of this article, have to be got rid of An instance of an epidermal tissue (cutocellulose) used as such is the Raffia, which consists of the cuticular tissues of Raphia ruffia, which in horticultural work replaces the linden bast or 'bass' of a former age A more exhaustive investigation of Raffia as a type of cuticularised tissue has established the constitution of the cuto-cellulose of the mixed tissue as an ester of an oxidised 'cellulose' and a fatty acid

$$C_{17}H_{32}O_3 = C_{16}H_{30}(OH) COOH$$

But investigations in this field are complicated by the resistance of the mixed tissues to proximate resolution; the true cuto-cellulose when obtained is more or less modified by the chemical treatments required for its separation,

According to Fremy, it is the cutose itself which is so resolved, but the author's experiments have always yielded a residue of cellulose. and the yields are small (Cross and Bevan, J. Soc Dyers, 1919, 35, 70).

When the textile fibres are isolated from compound structures this is accomplished for the most part by the mechanical processes of preparation, scutching, hackling, &c When, however, the tissue intervening between the fibres and the cortex or epidermis is of small extent, the separation is never complete. In flax, for instance, residues of the epidermal tissue remain associated with the fibre, and the relative difficulty of attacking these substances by chemical means is a factor of the laborious process of bleaching linen goods In isolating the so-called New Zealand 'flax' much greater difficulty This fibre consists of the fibrois experienced vascular and other fibre bundles of the swordshaped leaf of the Phormium tenax, and these are in such close and intimate contact with the epidermal tissues that their isolation is always very incomplete In those raw materials of the paper maker which consist of the stems and leaves of monocotyledons (straw and esparto), the epidermal adipocelluloses constitute a sensible proportion. They are resolved in this case by chemical means, which require to be much more drastic in consequence. The fibrous pormore diastic in consequence tions of these materials, on the other hand, are made up of a compound cellulose belonging to the next group which we shall have to consider, an important characteristic of which is the comparative ease with which they are attacked and resolved by alkalis Although, therefore, the connections of these cuticular celluloses with the fibres are for the most part only inducet or incidental, we see in the typical instances above cited that they have to be taken into account in relation to a great number of the treatments of cellulosic raw materials, both mechanical and chemical

Pectocelluloses. This, the second division of the compound celluloses, is characterised by the non-cellulose constituents belonging to the group of pectic substances or pectins. The pectins are carbohydrate-colloidal aggregates or supposed complexes of hexosanes and pentosanes, with a small proportion of acid groups combined as lactone or ester. Sensitive to acid hydrolysis and feriment actions, they occur naturally in the most varied torms. Thus in fruit juices they exist as colloidal ropy solutions. In the more permanent fibrous tissues they are insoluble in water (Tollens, Annalen, 286, 278–292, Cross, Ber 1895, 2609)

In composition they are more complicated than the celluloses, and they contain less carbon and more oxygen. In this and in many of their properties they resemble the oxycelluloses above described. Generally, they yield gelatinous hydrates, and under the action of hydrolytic agents they undergo a succession of changes resulting in the conversion of the comparatively mert members of the series pectose and pectin into highly acid derivatives, such as pectic and metapectic acids, bodies which, in addition to being acids, have properties indicating the presence of aldehydic groups

The typical pectocellulose is the flax fibre. The purified bast of a Russian flax was found by Kolb to contain C, 43.7; H, 5.9; O, 50 4.

On boiling with dilute alkaline solution about 20 p.c. of its substance is readily converted into

soluble derivatives, of which a considerable proportion is a body identical with Fremy's pectic acid (C 42 0 p c., H=48; i.e. C<sub>16</sub>H<sub>22</sub>O<sub>15</sub>) The fibrous residue from an exhaustive treatment with alkaline solutions, amounting in most flaxes to about 75 pc of the original weights, is approximately pure cellulose In this experimental account of its constitution we disregard such adventitious admixtures as cuticular tissue (adipocellulose) and wood or 'sprit' (lignocellulose), the influence of which may be calculated and eliminated from the result, but the presence of these in commercial flax introduces complications of very great moment in regard to the spinning of the fibre and the bleaching processes to which flax goods are subjected In regard to the latter, an important technical difficulty is experienced in washing flax yains after a 'chlorine' (hypochlorite) bleaching treatment 'Active chlorine' remains persistently in the goods. This is now elucidated, as due to the formation of chloroumine delivatives, from residues of chlorophyll and other nitrogeneous products containing amino- groups always present in cuticular tissues (Cross, Bevan, and Buggs, J Soc Chem Ind 27, 1908)

Lignocelluloses. As the name indicates, this group comprises the substance of the ground tissue of the woods. The simplest type of lignocellulose, chemically as it is seructurally, is the jute fibre, the lignified bast of an annual (Corchorus tibiacca) cultivated on an enormous scale in India, and the staple of an important textile industry centred in Dundee.

The elementary composition of the purified fibre is expressed by the following percentage numbers:—

The constitution of a lignocellulose is revealed by the action of chlorine, which combines with the non-cellulose or lignone component to form a quinone-chloride of constant composition,  $C_{19}H_{19}Cl_4O_9$ , with production of hydrochloric acid, also in constant proportion to the lignone, the estimation of the acid affords an indirect measure of the proportion of lignone or noncellulose constituents (Cross and Bevan, Cellulose, Heuser and Sieber) The chlorolignone reacts with sodium sulphite (solution) to form a sulphonated derivative of characteristic magenta-red colour, freely soluble as sodium salt, consequently, the chlorinated fibre is resolved by treatment with solution of sodium sulphite (2 p c Na<sub>2</sub>SO<sub>3</sub>), the lignone-chloride dissolving from the cellulose, The quantitative which is thus isolated constants of this reaction, which is specifically dia

0			P c of
			lignocellulose
Chlorine co	mbining with	lignone	8.0
••	as H	ICI .	. 80

And the lignocellulose may be statistically calculated to be composed of

The cellulose is separated actually as a hydrate of the composition  $3C_5H_{10}O_5,H_2O$ . It further differs from the normal cotton cellulose in being non-homogeneous. It is a mixture of two celluloses, the  $\alpha$ -cellulose (65 p.c.), approximating to the normal, and  $\beta$ -cellulose (15 p.c.); the latter being relatively sensitive to hydrolysis and yielding a large proportion (40–50 p.c. of its weight) of furfural on boiling with condensing acids

Constitution of lignone The characteristic groups of the lignone complex are those which combine with chlorine and which appear to be of diketo r hexene constitution. The reaction with bisulphites is also quantitative and the sulphonated derivatives are formed without resolution Certain decompositions yield products quantitatively related to original groups. thus acetic acid is a product of oxidations both acid and alkaline, and appears to result from hydrolysis of ketene groups By oxidation with CiO3 in presence of hydrolysing acids the lignone is entirely resolved to oxalic and carbonic acids, with liberation of acetic acid. From the formation of volatile pyrone derivatives in the first stages of destruction, distillation (150°-200°), and from the statistics of ultimate composition, the presence of a pyrone group in the lignone complex is inferred.

An integral expression of these quantitative relationships is given in the form of a general statistical constitutional formula for the lignone-cellulose complex

$$\begin{array}{c} \text{CO} \\ \text{CH} \\ \text{CH} \\ \text{CH} \\ \text{CH}_2 \\ \end{array} \begin{array}{c} \text{CH}_2\text{CO}_{12}\text{--HC} \\ \text{CH} \text{-CH} \text{-CH} \text{-OMe} \\ \text{CO} \\ \end{array} \\ \begin{array}{c} \text{CH} \\ \text{CH}_2 \\ \end{array} \begin{array}{c} \text{CH} \\ \text{CH} \text{-CH} \text{-CH} \text{-OH} \\ \text{CH} \\ \end{array} \begin{array}{c} \text{Cellulose} \\ \text{CO} \\ \end{array}$$

(Cross and Bevan, Researches in p 104) This has been critically examined by C Doré in relation to the study of the action of ozone on the typical lignocelluloses (J. Chem. Soc. 103 (1913), 685) of the results of which it affords consistent explanations

The wood substance of perennial woods (dicotyledons), with the same general characteristics, differs in the relation of lignone to cellulose, both in proportion and in mode of union. Whereas the jute fibre is attacked by solvent reagents similarly to the celluloses, the woods are extremely resistant. The following comparison of typical constants for beechwood is noteworthy—

The wood substance of the Conferæ, first investigated by Erdmann (Ann Suppl 5, 223), is a homogeneous complex—lignocellulose—of empirical composition,  $C_{30}H_{42}O_{21}$ , differing in minor respects from the woods of angiosperms chiefly in the lower proportion of 'furfuroid' and acetyl groups. A reaction of fundamental import and general for the entire group of

lignocellulose, is the basis of the 'bisulphite' process of preparing cellulose from woods, applied chiefly to the conferous woods, the insoluble residue of disintegration or cellulose constituting the most important staple of modern paper making. The lignone complex reacts quantitatively with the disulphites to form derivatives of the empirical composition C<sub>24</sub>H<sub>23</sub>(OCH<sub>3</sub>)<sub>2</sub>O<sub>3</sub> SO<sub>3</sub>H, the mechanism of the reaction being (1) a hydrolysis of 'acetal' groupings due to combination of H CO and bisulphite residues, (2) the  $SO_3H$  residues then migrating to unsaturated -CH = CH positions, the lignone complex being thus obtained as lignone sulphonates (Ca or Mg salts), which are gummy deliquescent solids

These reactions take place progressively in the range of temperatures 80°-150°, and industrially are carried out in digestors of special construction (silicate-lined) and enormous

capacity.

118

A third reaction characteristic of the lignone complex as such and taking place in definite quantitative proportions is its condensation with phloroglucinol in presence of HClAq There are two phases of the reaction (1) with formation of a crimson colouring matter. This takes place with a proportion of the phenol less than 1 p.c of its weight. The depth of colour is quantitatively related to the lignone, and is, therefore, an approximate measure of its proportion in a lignocellulose, as of lignocellulose (e g. 'mechanical' wood pulp) in admixture with cellulose (2) A further combination with the phenol (6-7 p c of its weight) to a product which is extremely resistant to hydrolysis (Cross, Bevan, and Briggs, Ber. 40, 3119, Cross and Bevan, J Soc Dyers, [v ] 32 (1916))

Characteristic colour reactions are those with aromatic bases; the anilines giving yellow to orange-colouring matters. Dimethyl-p-phenylenediamine give a deep-red colouration, which is the basis of the well-known quantitative method of estimating lignocelluloses in mixture

(C. Wurster)

Ferric ferricyanide in solution is reduced by the lignocelluloses, and the intermediate ferrosoferric blue cyanides in the highly hydrated colloidal form, are precipitated upon the fibre substance in intimate 'adsorption' combination. Jute fibre will take up from 30 to 50 p.c of its weight of the blue pigments thus formed, without any change of essential characteristics These phenomena have especial interest in relation to theories of dyeing and the colloidal state (Cross and Bevan, J. Soc Chem. Ind. 1893, 12, 104), and are of use in laboratory investigations of plant products (Sherman, J Amer. Chem Soc 1897, 291).

The lignocelluloses have many-sided affinities for colouring matters, due to specific reactivities of the constituent groups of the lignone complex. They are dyed directly by dyestuffs of the most varied constitutional types; and in this respect stand in marked contrast with the celluloses, which present a narrow and selective range of

direct finctorial capacity.

Other less characteristic reactions of the lignocelluloses may be briefly described.

Halogens.—Bromine reacts to form brominated lignone derivatives; but the attack is much feebler than with chlorine, and is complicated

by oxidations (Cross and Bevan, J. Soc. Dyers, vol. 32, 1916). Cellulose is isolated by repeated treatments with bromine water, followed by dilute alkalis. This is a useful quantitative method of cellulose estimation (Hugo Muller, Pflanzenfaser). Iodine is absorbed from its aqueous solutions (in KI) in definite proportions. Jute fibre digested at 18° with 20 times its weight of N/10 solution as ordinarily prepared, absorbs 12.9-13.3 p.c. iodine (Cross and Bevan, Cellulose, 138, 139).

Hydrolytic agents generally attack the lignocelluloses as a whole, that is, without resolving the lignonecellulose combination At elevated temperatures (100°-160°) dilute alkalıs (NaOH, Na<sub>2</sub>S) selectively attack the lignone groups, breaking them down to acid products-acetic acid, and the so-called lignic acids-which dissolve as sodium salts, and cellulose is obtained

as a residue.

Dilute acids at higher temperatures yield acetic acid as a product of hydrolysis (Cross and Bevan, Cellulose, 160, 161; W. E. Cross, Ber. 1910, 43, 1526), and a complex of products of condensation, including furfural

Oxy-hydrolytic agents attack the lignone complex owing to its unsaturated and oxidisable characteristics. By the action of nitric acid even in dilute form (5-10 pc. HNO<sub>3</sub>) and at low temperatures (70°-80°) the lignone is resolved into gaseous and soluble products, the B-cellulose components are also attacked, and a residue of a-cellulose is obtained, but more or less oxidised to oxycellulose

It is noteworthy that in presence of urea the action of nitric acid loses its specific character and resembles that of the simple hydrolysing acids (Cross and Bevan, Cellulose, 141, 145).

Chromic acid in presence of hydrolysing acids oxidises the lignone to oxalic and carbonic acids. Acetic acid appears as a product of hydrolysis (Cross and Bevan, J. Soc Dyers, vol. 32, 1916) The insoluble residue is an oxycellulose soluble in large proportion in dilute solution of sodium hydroxide.

Permanganates in sufficient proportion oxidise the lignone complex to products of low molecular weight, but the action may be regulated and graduated to produce valuable bleach-

ing effects

Hypochlorites are used in industrial bleaching operations (jute yarns and fabrics), but require most careful control to prevent chlorination of the fibre substance, the fixation of chlorine, even in minute proportion, leading to ultimate disintegration of the lignocellulose (Cross, Bull. Mulhouse, 1883)

Ultimate oxidations. By 'fusion' with the alkaline hydroxides at 250°-350° the lignocelluloses are oxidised to oxalic acid, the yields from the wood (sawdust) being large (80 p.c.). The process is of considerable industrial importance, being the main source of the oxalic acid of commerce

By chromic acid in presence of sulphuric acid the lignocelluloses are oxidised to gaseous products ( ${\rm CO}_2$  and some  ${\rm CO}$ ) and water. The reaction is the basis of a quantitative volumetric method of estimation.

Synthetical reactions. The ligno-Esters.celluloses react, as do the celluloses to forr... nitrates, acetatos, and henzoates; these, however, are mainly reactions with the cellulose of | Separate portion taken for each determination. the complex, the lignone groups containing no reactive OH groups: these remain in condensed combination in the resulting ester

The xanthogenic ester which results from the successive action of sodium hydroxide (17.5) p.c. NaOH solution) and carbon disulphide is a mixture or series of products, partly soluble, partly a highly hydrated and distended fibrous colloid which may be separated by filtration There is little resolution or separation of the lignone groups from the cellulose.

Destructive distillation. The highly complex changes which the lignocelluloses undergo when heated out of contact with the air, are only approximately accounted for in terms of the original substance. Typical of an enormously diversified series of volatile products are:

Methyl alcohol Acetone Acetic acid Furfural

Methyl furfural Methyl- and methoxyderivatives of Pyrogallol

which may be regarded as direct products of

resolution of the lignone complex.

Of great industrial importance are the products of the first group. The solid residue (about 30 pc) is wood charcoal, a highly condensed 'pseudo-carbon' of the approximate

elementary composition, C<sub>30</sub>H<sub>18</sub>O<sub>4</sub>.

Autoridation of liquocelluloses. Lignocelluloses in the form of ground wood or 'mechanical' wood pulp are largely used in modern printing Such papers are not only inferior in physical quality—tensile strength and elasticity -but in permanency; they change in colour (to yellow and brown) and in structure, becoming brittle. These are primary effects of oxidation; they are influenced by light, and by catalysts such as iron compounds usually present in papers as an incidental impurity, and resin acids added as sizing agents These effects and defects are generally recognised and lead to the specific exclusion of 'mechanical' pulps from papers intended for documents of permanent value (Report of Society of Aits Committee on Deterioration of Papers, J. S. A. 1898).

An important elucidation if these phenomena is suggested by the researches of the late W. J. Russell, described in the Royal Society papers on The Action of Wood on Photographic Plates in the Dark (Phil Trans (B), 1904, 197, 281, Proc. Roy. Soc. 78, 385, 80, 346) The action in question is a 'photographic' image reproducing the structural details of the wood sections, placed at some distance from ordinary sensitive plates, but with exclusion of light

On the evidence, the effects are due to an 'active emanation' from the wood substance, which appears to be a product having the characteristics of hydrogen peroxide. The general evidence also connects the phenomena with those of autoxidation, and these again with the constitution of the lignone groups of

the wood substance.

#### Assay of Fibrous Materials.

For the investigation of fibrous raw materials in the laboratory the following scheme, devised by the author (Ind. and Col. Exhibition Reports, 1887), has been generally adopted:-

Results calculated in percentage of dry substance.

1. Moisture .

Hygroscopic water, or water of condition, loss on drying at 100°.

2. Ash:

Total residue left on ignition.

3. Hydrolysis:

- (a) Loss of weight on boiling 5 minutes in 1 pc solution of caustic soda,
- (b) Loss of weight on continuing to boil one hour.

#### 4. Cellulose

Isolation and estimation as previously described (chlorination method).1

In the case of raw materials containing cutocelluloses the alkaline saponification is intensified by substituting alcoholic (2 p c NaOH) for the aqueous solution of sodium hydrate.

5. Mercerising:

Loss of weight on treating one hour with strong solution of caustic soda, 15-20 pc NaOH, in the cold.

6. Nitration.

Weight of nitrated product, obtained by treatment with mixture of equal volumes of nitric and sulphuric acids one hour in the cold.

7. Acid purification

Loss of weight after boiling with 20 p.c. acetic acid and washing with water and alcohol

8 Carbon percentage

Determined by combustion

1a Moisture. The mere operation of drying at 100° determines molecular changes in such compounds as the lignocelluloses, changes which affect the subsequent action of reagents. It is necessary, therefore, to weigh separate portions for the particular experiments in the air-dry condition, and calculate the dry contents from the data of the specimen weighed after drying at 100° The dried specimen is treated for 1b Fat, war, and resin These constituents are estimated as an aggregate extract obtained by boiling out with hydrocarbon solvents, or with ether-alcohol

The specimen weighed after extract-2 Ash ing may then be burned for the determination of ash The ash in isolated fibres is low, viz 1-2 p c; in fibre aggregates it is often high, thus in esparto and straw from 3-6 p.c., and should be taken into account in calculations of vields or loss of weight. In such cases, after weighing the product of any given reaction the specimen or a portion of it should be burnt and the ash determined. The ash-free product is calculated in terms of the original substance, also taken ash-free.

The ash constituents are: (1) those of the normal fibre; and (2) in certain cases adventitious mineral matter. These are easily distinguished and separately estimated.

3. Alkaline hydrolysis. This is the first stage

'After lengthened critical investigation and discussion (1895–1918) the method of chlorination is generally adopted as the standard process of estimating cellulose'—with variations in treatment in special cases (dense lignocelluloses—cutocelluloses) and reservation as to the definition of 'cellulose' to include furfural-yielding components For Bibliography, see W. H. Dore, J. Ind. & Eng. Chem. ii (1919), 556

towards the isolation of the cellulose. When the numbers obtained for the short period (a) and for the long digestion (b) show a marked difference, it is an obvious general indication of

low paper-making quality.

4. Cellulose Having isolated a white residue from a raw fibrous material, it may be weighed and then further investigated. An estimation of furfural will establish its position in the classification of the celluloses. For practical purposes it is sufficient to establish the degree of resistance of the cellulose to further alkaline hydrolysis, and to oxidation by alkaline cupric ovide (Barreswil's or Fehling's solution)

5 Mercerising The effect of the action of caustic soda as measured by loss of weight, and also changes in appearance and structure, may be usefully observed on the isolated celluloses, and in certain cases upon the raw fibrous The pectocelluloses are considerably materials gelatinised by the treatment, the fibres often undergoing agglomeration and drying to a harsh wiry condition The lignocelluloses are effected in the contrary direction The cutocelluloses are not attacked.

From all the above treatments the products should be treated with dilute acids by immersion in the cold, and copiously washed before drying The drying is accelerated by treatment with alcohol

6 Nitration, or conversion into nitric esters, affords useful information; but judgment must be exercised as to the applicability of the treatment to the raw material, to the partially purified products (alkaline hydrolysis), or the isolated cellulose It is a general measure of the proportion of reactive alcoholic OH groups, and also of resistance to oxidation

7 Acid purification removes basic mineral matter, often present in some quantity in raw materials. of the pectocellulose class. It may materials, of the pectocellulose class sometimes be required to attack and remove more resistant mineral constituents, such as silica or silicates In this case the material may be digested with a mixture of hydrofluoric and hydrochloric acids in vessels suitably resistant The treatment is to the action of these acids followed by copious washing

8 Carbon percentage. This is only necessary in certain investigations The value of the constant will be recognised from the fact that it varies considerably for the different groups of compound cellulose The most convenient method is that of combustion, with chromic

scid, after solution in sulphuric acid

For special purposes the above scheme is extended by operations on a larger scale, and under conditions which approximate to those industrially employed, as, for instance, in estimating the value of a raw material for papermaking purposes complementary investigation of structural characteristics, including measurements of length and diameter, of ultimate fibres (cellulose) is also required. processes and methods the special text-books must be consulted

The following is a general view of the

# CELLULOSE INDUSTRIES.

Celluloses, fibrous material, used as such: (1) Mechanical with incidental chemical treatments (bleaching, dyeing, mercerising finishing):

Textiles, fine fabrics:

Cotton, flax, hemp, ramie.

Coarse textiles:

Jute (flax and hemp).

Ropes, twines.

Hemp flax, manilla, aloe, and fibres of monocotyledons

Hat-making materials:

Straw, wood.

Paper, boards, and fibrous agglomerates: Cotton and linen rags and textile wastes (wood. straw. esparto pulps)

(2) Chemical industries. Cellulose derivatives, or celluloses, or products of resolution of compound celluloses.

Explosives:

Nitro celluloses.

Artificial fibres:

Nitro celluloses (acetates),

Aqueous solutions of cellulose derivatives.

Zinc chloride, cuprammonium. xanthogenic ester (viscose)

Films or sheets:

Nitrocellulose (acetates), xanthogenic ester.

Massive solids ·

Nitrocellulose (acetates), xanthogenic

Preparation of wood pulp, esparto, straw, and other celluloses for

Treatment of woods. esparto, straw, and textile waste materials.

(3) Products of decomposition:

Oxalic acid:

Fusion of wood wastes with alkaline hydroxides.

spirit, acetone,

Acetic acid, wood

creosote, charcoal: Products of destructive distillation of

## Supplementary Note. (Jan. 1, 1920)

The chemistry of 'cellulose' is obviously a section of the 'chemistry of colloids', the state of development of this extensive and complex subject is set forth in the Reports (I, 1918; II, 1919) of the British Association Committee Cellulose is in many respects the prototype of the organic colloids, as a primary natural product it is only known to us in its natural forms of organised structures, and it is an index of the necessary trend of progressive research in this field that the works of the histologist and chemist are convergent W. L Balls (Proc R. S (B) 1919, 90, 542) demonstrates daily growth rings in the cell wall of cotton by taking advantage of the xanthic ester reactions under limiting conditions, such as induce controlled rehydration of the cell substance without disruptive distortion

Robinson (Prov. Rep. R. S. Proc. Nov. 1919), in investigating the deformation of wood structures under stress, finds positive evidence of assocrated deliquification in the chemical sense.

Cross and Revan (J Soc. Dyers, 1918, 34,

215, 247) have investigated two cases of profound structural change in cotton under mechanical stresses, associated with fundamental changes of chemical constitution.

Of these effects the immediate factor of change may be a particular form of energy, in respect of which the effects of heat, electricity, light, and radio-active 'matter,' have been shown to be definitive (ibid.; and S J Lewis, 34, 167; W Harrison, 1919, 35, 243-250)

It is clear that for exact characterisation of cellulose, as a colloid, it must be investigated as such, and not in terms of products of proximate This postulates physical methods, resolutions of which the most obvious is the measurement of volume and volume changes (Cross and Bevan, Berl Ber 1909, 42, 2198), with temperatures and under reaction Such investigations have already suggested that the cellulose may be made up of reactive unit groups of small dimensions-of cyclic configurationand having the reactive continuity of liquid Research and progress by way of such problems and hypotheses, many of which arise in the technical routine of the cellulose industries, are the leading characteristics of the present-day movement towards a more comprehensive science of the subject

CELTITE v. EXPLOSIVES.

CELTIUM Ct At wt ' An extremely rare element intermediate in characters between luterium and scandium, occurring in gadolinite and first isolated by Urbain Forms a white oxide, and an anhydrous chloride more volatile then lutecium chloride, but less volatile than scandium chloride The hydroxide is a weaker base than lutecium hydroxide, but is stronger than scandium hydroxide Gives a characteristic arc spectrum (Urbain, Compt. rend. 1911, 152, 141)

CEMENT. In this article the word 'cement' is used to mean a calcareous compound employed in building, and does not refer to minor ad-

hesives of the class typified by glue

This material is so Portland cement. greatly more important than any other cement of its class, that it may appropriately be dealt with first The name is trivial, referring merely to the colour of the set product which somewhat resembles that of Portland stone 'he invention of Portland cement is attributed to Aspdin of Leeds, who calcined a mixture of chalk and clay, and found that the product, when ground and mixed with water, would set; but development from this elementary stage to the status of a valuable industry was the work of many minds, which, operating mostly empirically, arrived at a procedure competent to ensure a commercially useful product, although by methods of which the rationale was only dimly understood At the present time, a better state of knowledge exists, and except in a few minor points, such as the adjustment of the setting time, which still cannot always be completely controlled, the manufacture is performed with precision and the product is of uniform and excellent quality Nevertheless, the chemistry, both of the formation of Portland cement from its raw materials and of the changes which it undergoes on setting, is incomplete, many of the reactions supposed to occur remaining obscure and hypothetical

Composition —Portland cement consists of a mixture of compounds of lime and silica and of lime and alumina These are the essential constituents, but it commonly contains in addition loose compounds of lime with ferric oxide, magnesia, and small quantities of mert insoluble silica or silicates, alkalis and sulphates Except when perfectly calcined and absolutely fresh, it also contains a little water and carbonic anhy-The ultimate dride absorbed from the air composition of Portland cement varies with the nature of the raw materials from which it

has been made. The following is a typical analysis of cement made from chalk and clay in the Thames and Medway district :--

	Per cent,
	. 220
	0.7
	6 5
	3 3
	63 0
	10
	1.5
	0 5
	10
	0 5
	100 0

All the constituents may depart a good deal from these proportions The silica may vary from 18 to  $2\overline{7}$  p c, the alumina from 5 to 10 p c, the ferric oxide from ml to 7 pc, the lime from 58 to 67 pc, the magnesia up to 3 pc, the sulphuric anhydride up to 275 pc, the alkalis to 2 p.c, and the water and carbonic anhydride according to the length of time the cement has been made and the extent to which it has been exposed

The limits laid down by the British Standard specification are as follows The proportion of lime to silica and alumina shall be not greater than the maximum nor less than the minimum ratio (calculated in chemical equivalents) re-CaO presented by  $\frac{\text{CaO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3} = 2.85$  or 2.0 respectively. The percentage of insoluble residue shall not exceed 15 pc, that of magnesia shall not exceed 3 p c , and the total sulphur content calculated as sulphuric anhydride (SO<sub>3</sub>) shall not exceed 2.75 pc The total loss on ignition shall not exceed 3 p.c.

Although the ultimate composition of Portland cement is easily and accurately ascertained by the ordinary methods of chemical analysis, its proximate composition, that is, the nature and quantity of the chemical compounds or physical mixtures which constitute it, are not known with exactness and cannot be determined with precision by existing methods of inquiry The view most in favour and best supported by experimental evidence, is that the essential constituent is tricalcium silicate 3CaO SiO2, and that the body next in importance is a calcium aluminate, to which the formula 2CaO Al<sub>2</sub>O<sub>3</sub>, or alternatively

3CaO Al<sub>2</sub>O<sub>3</sub>,

is assigned. Dicalcium silicate 2CaO  ${\rm SiO_2}$  is also present. The oxide of iron occurs as a calcium ferrite, the magnesia possibly as such, the sulphuric anhydride and carbonic anhydride probably as calcium sulphate and carbonate, and the alkalis perhaps as double compounds with lime and silica or alumina As far as is known, the substances of primary importance are the tricalcium silicate and aluminate only, the minor bodies being little more than makeweights with the exception of calcium sulphate, which is of moment, because of its influence on the setting time of the cementitious constituents proper. The best proof that these smaller constituents are not essential is afforded by the fact that Portland cement of the highest quality can be prepared containing only silica, alumina, and lime in proper proportions.

It was formerly held that the calcium aluminate and silicate did not exist separately but as solid solutions, which are recognisable as distinct minerals in Portland cement clinker. The mineral termed alite is a solid solution of tri-(or di-) calcium aluminate in tricalcium silicate, whilst the solid solution of dicalcium aluminate in dicalcium silicate is called celite. As both are solid solutions and not definite compounds, their composition is not constant, but varies within the limits of solubility of the solute in each case Celite appears to be almost mert, and to take little part in the setting of the cement, but alite is decomposed by water, and both the calcium silicate and calcium aluminate are hydrated according to the following equations, in which, for simplicity, the two substances are dealt with separately

(1) 2(3CaO SlO<sub>2</sub>)+9H<sub>2</sub>O=2(CaOSlO<sub>2</sub>)5H<sub>2</sub>O+4Ca(OH<sub>2</sub>). Tricalcium silicate Hydrated monocalcium silicate.

(2)  $3CaO Al_2O_3 + 12H_2O = 3CaO Al_2O_312H_3O$ Hydrated tricalcium Tricalcium aluminate aluminate.

It will be seen that in the process of hydration of the tricalcium silicate, two-thirds of the lime are liberated and appear as calcium hydroxide, and in consequence this substance forms a large proportion of Portland cement when set. although—accepting the tricalcium silicate view—uncombined lime is absent from Portland cement as it comes from the kiln

The belief that tricalcium silicate is the essential constituent of Portland cement has been disputed on the ground that there is no conclusive proof of the existence of this body as a definite chemical individual. The alternative theory is that the essential constituent is dicalcium silicate 2CaO SiO2, associated as a solid solution with lime, which may be present in amount equal to that occurring in the tricalcium compound. On this assumption, the equations written above would still stand with the modification that this part of the lime is hydrated directly on setting, instead of being both liberated and hydrated by the action of water. Whichever view may be nearer the truth, it is certain that set Portland cement contains large quantities of calcium hydroxide, a fact which has an important practical bearing in the use of the material, as will be shown when dealing with puzzuolana.

Since the time when this idea was put forward the older view has been rehabilitated by the preparation of tricalcium silicate as a definite compound, and that it and tricalcium aluminate are the two substances to be considered as the essential constituents of cement It follows that the equations originally put forward by Le Chatelier may be taken as representing the process which cement undergoes on setting:-

 $3\text{CaOSiO}_2 + \text{Aq} = \text{CaOSiO}_2 2\frac{1}{2}\text{H}_2\text{O} + 2\text{Ca(OH)}_2$ and

 $3{\rm CaOAl_2O_3} + {\rm Ca(OH)_2} + {\rm Aq} = 4{\rm CeOAl_2O_3l2H_2O}$ 

It will be seen that the hydration of the tricalcium silicate provides ample calcium hydroxide for the production of tetracalcium aluminate, and as stated above the existence of this calcium hydroxide in set Portland cement is of importance when siliceous materials such as puzzolana are used conjointly with cement.

Insoluble silicious matter

Water, alkalis, and loss

Manufacture.—As would be expected from what has been said concerning the composition of Portland cement, the raw materials from which it can be prepared are of the most varied description Chalk, limestone, or any other approximately pure form of calcium carbonate on the one side, and clay, shale, or any typical argillaceous material on the other, can be mixed and burned together to produce Portland cement, provided that the product has a composition falling within the limits already laid down follows naturally that substances which contain both calcium carbonate and clayey matter, such as calcareous shales and argillaceous limestones, can be similarly used. On this account and because of the low price of the manufactured article and the consequent high proportion which freight bears to the total cost at the point of consumption, the manufacture of Portland cement is not confined to a particular spot, but is successfully undertaken wherever deposits of suitable raw materials occur, provided the cost of fuel is not extravagantly high But although it is perfectly practicable to manufacture Portland cement from a wide range of raw materials, yet certain of these possess qualities which give them a substantial advantage The large deposits of chalk in the Thames and Mcdway district, together with the clay in the form of river mud adjacent thereto, make this region one of the centres of the industry in this country In like manner, the existence of huge quantities of argillaceous limestone in Pennsylvania has led to the establishment of many large works in that State In the former case, the chalk and clay, being soft materials, can be readily handled and intimately mixed, and in the latter the mingling of the calcareous and argillaceous ingredients has already been accomplished, and a correct composition can be attained by the addition of a small amount of pure lime-

Whatever may be the raw materials, the first step in the manufacture of Portland cement is to secure their comminution and intimate admixture. It must be understood that as the process of burning cement involves the sintering but not the fusion of the materials, these two conditions are of primary importance. The raw materials are commonly ground so that they leave a residue of less than 10 p c on a 180×180-mesh sieve, and intimacy of contact is secured by mixing the materials together at as carly a stage of the process of comminution as is practicable, and in addition grinding them together

The procedure is as follows In the case of soft, wet raw materials, such as chalk and clay, the two substances in proportions determined from their analysis are weighed into a wash mill, which is a large tank in which a vertical spindle having radial aims from which depend harrows is caused to revolve Enough water is added to allow the materials, when well beaten up, to form a thick cream or slurry, which is mobile The slurry enough to flow and to be pumped passes through screens to retain stones and grit, and is ground either between millstones or in more modern practice in a tube mill, which is a cylinder made of steel lined with a hard material such as quartzite blocks and partly filled with flint pebbles The cylinder is set horizontally and revolved, the slurry being fed in through a trunnion and passing out at the other end. During its passage through the cylinder, it is ground by the pebbles which are continually raised up the periphery of the cylinder and continually drop back through the liquid mass, pounding its particles on the lining of the cylinder and between the pebbles themselves. After being thus ground, the slurry flows into large reservoirs, called dosage tanks, where it is sampled and

 $<sup>^{1}</sup>$  Corresponding with calcium carbonate (CaCO  $_{3})$  98 36 p.c

analysed and, if necessary, its composition is corrected by the addition of more chalk or clay In the early days of the industry, the slurry was prepared with so large a proportion of water as to be a thin cream from which the water was allowed to settle in large tanks, the supernatant water being drawn off and the deposited solids dug out when they had arrived at the consistency of mud, and this method is still occasionally practised Usually, however, the quantity of water used is the least that will allow the slurry to flow (35 to 50 p c of the weight of the slurry, according to the nature of the raw materials), adequate mixture being thus obtained and the delay and cost of double handling The next step is to dry and burn the slurry to clinker The modern method combines these operations, the slurry being pumped into the upper end of a rotatory kiln (see below), where it is dried and burned as it travels down the kiln. Before the invention of the rotatory kiln, drying was effected either by the heat of coke ovens used for manufacturing the coke needed in the subsequent burning or by the waste heat of chamber kilns (see below), the mass thus dried cracking into rough cakes suitable for loading into the kiln Where the kiln was of a type which provided no surplus heat, the slurry was dued independently, crushed, and moistened with a little fresh slurry, moulded into bricks, redried and burnt. The choice among these various procedures depends on the kind of kiln for which the slurry is destined

When dry raw materials such as limestone and shale are used, they are crushed in a stone breaker or between rollers, according to their hardness, any moisture such as quarry water or damp from exposure to weather being removed by passing through rotating cylinders, heated by flue gases, or by an independent fire or in towers through which hot air is blown, and are ground together in the calculated proportions grinding is performed by ball mills, consisting of a drum lined with perforated steel plates and partly filled with steel balls, followed by a tube mill, such as has been described above, or in mills of the Huntingdon class, in which rollers depending from spindles attached to a vertical axle are driven outwards by centrifugal force as the spindle is rotated and bear against a steel grinding ring between which and the rollers the material is ground It will be understood that many different forms of comminuting apparatus can be and are used in cement works, according to the nature of the material. Discussion of their relative merits would be out of place in an article of this kind. The dry raw materials are fed as powder (often slightly damped to prevent dust) direct into a rotatory kiln or are moistened sufficiently to allow them to be moulded into bricks, dried and burnt in one of the kinds of fixed kıln.

Although wet raw materials are naturally ground wet, and dry raw materials are ground dry, yet occasionally dry raw materials are ground wet, it being maintained by some that any extra expenditure of heat to drive off the water added is compensated for by the more intimate admixture of the raw materials and the ease with which the slurry may be conveyed by being pumped or allowed to flow in contrast to

dry raw materials which require elevators, worm conveyors and similar mechanism.

The raw materials finely ground, intimately mixed and in correct proportion (containing in most cases about 75 pc of calcium carbonate calculated on the dry substance, the balance being the clayey constituents) are burnt to cement clinkers in various types of kiln.

The earliest was the bottle kiln, a domeshaped brick structure lined with fire bricks, having a short chimney and a grate lumps of dried slurry were loaded into this, mixed with coke, and the charge fired and allowed to burn out, the products of combustion escaping at the top of the kiln An improvement on this is the chamber kiln shown in Fig 1 a cup-shaped structure, lined with fire brick, in which the dired slurry and coke are placed in layers, communicating with a wide flue, which forms a floor on to which wet slurry can be run, the far end of the flue being connected with a The hot gases from the kiln chimney stack proper pass over the slurry and dry it, so that a charge is ready when the previous one is burnt. An ordinary chamber kiln will produce about 30 tons of clinker per run, which, including

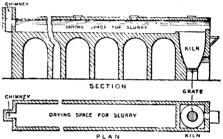

FIG. 1 —CHAMBER KILN.

loading and discharging, usually takes a week, and it will burn 40-50 p c of coke, reckoned on the weight of clinker produced. The coke is generally bought from gas works, though formerly coke ovens were in use at the cement works themselves, the products other than coke As the coke and raw materials being wasted are mixed in the kiln, the ash of the coke appears in the finished cement, raising the proportion of silica appreciably, on this account it is customary to use raw materials containing a higher percentage of calcium carbonate in a kiln of this kind than in one in which the whole of the ash is not retained, so as to compensate for the added silicious matter, but even with this precaution the product is irregular, the ash attaching itself chiefly to the outside of the clinker and not penetrating to the centre of the lumps. It is impracticable to buin the material uniformly. Parts will be almost fused, parts merely lightly calcined and decarbonated, barely sintered and not truly clinkered, while yet other parts will have attacked the silicious liming of the kiln, forming with it a sort of slag. Hence it is necessary to pick the charge when it is drawn, rejecting the underburnt and the slagged material, and on the perfection of this picking the quality of the finished cement largely depends.

The shaft kiln is another type of fixed kiln

n which the fuel is mixed with the raw material. I'here are various forms of shaft kiln, but the runciple is the same in all cases, the raw material and fuel proceeding vertically down a shaft to a soint where combustion occurs, and passing from his down a continuation of the shaft to a trawing hole from which the clinker can be exercted. Loading and drawing proceed reguarly, the kiln working continuously instead of ntermittently, as does the chamber kiln. The working is regenerative in the sense that the products of combustion from the burning zone assign through the unburnt raw material, which is thereby heated and the air for combustion flows.

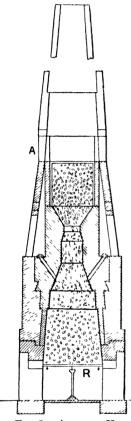

Fig. 2.—Aalborg Kiln.'

clinker in the lower part of the kiln, and thus is heated before taking part in the Combustion The Schneider and the Aalborg kiln are examples of this type, the latter is shown in Fig 2 Another wellknown shaft kıln with the modification that the upper and lower parts of the shaft are not in the same vertical line, is the Dietsch kıln (Fig 3) In this, the heated raw material is received on a stage between the upper and lower part of the shaft and passes thence the burning zone In the illustration, two such kılns are shown, built back to back There are various modifications of the shaft kiln differing in details of design. some working with forced draught

through the hot

From their regenerative
mode of working, they are
economical of

fuel, but require a good deal of moderately skilled labour and give a product mixed with the ash of the fuel and requiring picking

The Hoffmann or ring kiln (Fig 4), largely used for brick making, is also used in the manufacture of cement. The materials are moulded into rough bricks, and these are stacked in chambers arranged round a chimney which serves them all. Fuel is distributed between the blocks, and the working of the kiln is systematic, continuous, and regenerative Passage from one chamber to another and to the chimney can be controlled, and thus burning can be carried on in one chamber while the air for combestion flows in through hot clinker in chambers in which burning has been finished and the

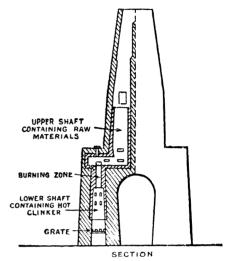

FIG. 3 -DIETSCH KILN.

the chambers, and yields a product lacking uniformity

In modern practice, these various kinds of fixed kiln have been displaced by the rotatory kiln, which, though originating in this country, was brought to a working success in the

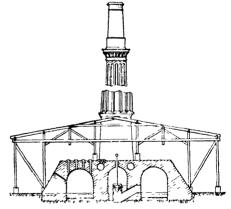

FIG. 4.—HOFFMAN KILN.

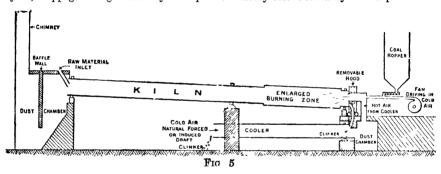

United States, and began to be adopted here and on the Continent about 1898. This kiln is a steel cylinder lined with fire brick, set at a small angle with the horizontal, and capable of being slowly rotated round its axis. At the upper end the raw material is fed in, and at the lower is a burner sufficiently powerful to reach a clinkering temperature (about 1400° C.). As the cylinder rotates, the raw material travels

down the cylinder on account of the inclination, and on its journey is gradually raised in temperature until it reaches the lower end, where it is clinkered and drops out. The process is continuous, systematic, and to a considerable extent regenerative. The labour required is small and the output large per unit of plant. A large proportion of the fuel ash passes through the kiln without attaching itself to the raw material, and such portion as remains is incorporated with the raw materials and forms part of the finished product instead of being largely confined to the surface of the clinker, as is the case with the product from fixed kilns. When burning is carried out properly, the whole of the product is uniformly clinkered and needs no picking, but may need quenching.

The earlier rotatory kilns were some 60 feet

The earlier rotatory kilns were some 60 feet long and 6 feet external diameter. At the present time, an ordinary size is  $200 \times 8\frac{1}{2}$  feet and larger have been made and used. The output of a single kiln of this size is as much as 1000 tons a week, according to its size, as compared with 30 to 70 tons a week for a fixed kiln. A rotatory kiln is iun as nearly as possible day and night, including Sundays, throughout the year, stoppages being made only for repairs

or to patch the coating of clinker which forms on the fire-brick lining of the kiln (Fig. 5). kiln was formerly of uniform diameter, but modern designs are of larger diameter at the burning end, so as to provide a wider portion at the place where combustion is at its height. The earliest form of 10tatory kiln which approached success, was fired with producer gas, but many difficulties arose in the use of this fuel, and although the idea has merits and has been revived, it has not reached fruition. Oil burners, like a large blast lamp, having the oil sprayed in by steam or compressed air, are used with complete success wherever oil is cheap enough, but as the cost is too high in most countries, powdered coal is the standard fuel. Coal, preferably bituminous, and containing a moderate amount (10 pc) of ash when well dried and very finely powdered, can be used to form a sort of blowpipe flame much as if it were a fluid, the powder being driven into the kiln by a blast of air and issuing from a jet much as gas might do, and burning there in a supply of secondary air supplied to the space around the jet and preferably pre-heated. In actual working, these conditions are realised in the following way. Small coal is dried in a rotatory drier heated by an independent fire cr

It is powdered very finely by the kiln gases so as to leave not more than 5 pc residue on a sieve having 180×180 meshes per square inch This powdered fuel is fed from a hopper into a pipe through which air is driven by an air compressor or a fan, and issues from the mouth of this pipe, which passes through a shield or screen covering the lower end of the kiln, as a jet of dry finely powdered combustible matter carried by a blast of air, insufficient for its combustion and serving chiefly as a means for its propulsion in the form of a jet This jet is set into the mouth of the kiln and pointing towards the far end. Air for the combustion is drawn in by the draught of the chimney stack, with which the upper end of the kiln communicates, and on its way passes through a rotating cylinder down which is proceeding the red-hot clinker issuing from the kiln, absorbing a portion of that heat, and carrying it to the place of combustion. By these means a powerful jet of flame is produced, the temperature of which is ample for clinkering

Either dry or wet raw materials can be burned in a rotatory kiln. Dry materials are fed in by a screw, the mass being usually slightly damped by a small proportion of water in the trough in which the screw works, so that the fine dusty particles are not carried away by the

draught of the kiln Wet raw materials are simply allowed to flow in from a trough in which the height of the slurry is maintained constant by a device such as a pump more than capable of the maximum flow, the surplus being returned by The water, about 40 pc of the a by-pass weight of the slurry, is evaporated by the hot gases coming from the lower end of the kiln and the dried slurry forms itself into small nut-like masses as it rolls round the inside of the cylinder. These travel slowly downwards in a spiral path, and their temperature rises until the calcium carbonate is decomposed, the clay is dehydrated, and union begins between the acid and basic oxides, the silica, alumina, and ferric oxide acting in the first and the lime, magnesia and alkalis in the second sense, until finally the material becomes slightly plastic, and full combination is effected at a point near the lower end of the kiln, where the temperature is highest white hot clinker passes into a cooler, such as the rotating inclined cylinder already mentioned in connection with the heating of the air necessary for combustion, where it is often sprinkled with water for the double purpose of completing its cooling and of hydrating any lime which may not have been perfectly combined in the kıln.

With dry raw materials the course of operations is the same, save that only the small quantity of water used to prevent dust has to be evaporated.

On account of the fact that cement clinker is a basic material and that fire brick is an acid substance, using those words in the ordinary metallurgical sense, interaction may occur between these at a clinkering temperature, and a slag may be produced. Any overheating will cause the rapid formation of this slag, with the result that the clinker will be spoiled and the lining destroyed. But if the burning is properly conducted, the action is not uncontrollable, and further can be prevented by the device of heating down the slightly plastic clinker on to the firebrick lining, so that it adheres and itself forms the true lining, to which, of course, the rest of the The coating clinker is chemically indifferent breaks away from time to time, and needs to be patched by beating down fresh clinker on the fire brick thus left bare Linings of less acid substances such as bauxite, and basic linings such as magnesia bricks, have been tried, but all present some practical defect which makes them less suitable than fire brick used in the way described

Good well-burnt clinker, whether made in a fixed or rotatory kiln, is a hard rock-like mass of dark colour, varying from brown to almost The pieces of clinker from fixed kilns are chiefly rough lumps of similar size to that of the blocks of raw material, and need a preliminary crushing in a stone breaker before they can be ground. The product from a rotatory kiln is in the form of small rounded masses, varying in size from a pea to a walnut times a number of these will stick together, making a mass a foot or more in diameter, but the bulk of the product is small enough to be

ground without previous crushing

Grinding is effected in machines similar to those used for preparing the raw materials Ball and tube mills and mills of the Griffin and Huntingdon class are in most general use, millstones, such as were used for grinding coin, having been superseded on account of their small output and heavy upkeep The clinker is ground to cement having a residue of not more than 14 pe on a 180×180-mesh sieve, and is conveyed mechanically to warehouses where it is stored and bagged or filled into casks. In a modern works, the whole operation from the reception of the raw materials to the filling of the bags is conducted almost wholly mechanically, manual labour being eliminated as completely as possible, an object easily attained with rotatory kilns, which do not require to be loaded and unloaded by hand

Testing Portland cement. The quality of Portland cement and its suitability for building purposes is ascertained by various mechanical tests and by its chemical analysis The analysis shows whether the constituents fall within the recognised limits stated above, and detects the presence of such adulterants as blast furnace slag or Kentish rag (a silicious limestone), which differ widely from cement in composition or contain some characteristic constituent such as calcium sulphide, which is almost or wholly absent from Portland cement. But as it is im-

Portland cement, the ordinary analytical figures will not indicate whether the raw materials have been sufficiently intimately mixed and sufficiently thoroughly burnt to form those cementitious substances constituting sound and serviceable Portland cement. This question can, however, be satisfactorily settled by physical and mechanical tests:

Codes of testing are in common use in all countries, and the following are the principal requirements of the British Standard Specification .

The fineness to which the cement has been ground is a useful indication of quality, masmuch as the coarser parts hydrate so slowly as to be of little or no cementitious value

The residue on a sieve  $180 \times 180 = 32,400$ meshes per square inch, shall not exceed 14 p c. The residue on a sieve  $76 \times 76 = 5776$  meshes

per square inch, shall not exceed 1 p c

The specific gravity of cement is a useful criterion, and shall not be less than 3 10 below the normal value, say 3 10 to 3 15, according to the degree of aeration to which it has been subjected, it may generally be inferred that the cement has been underburnt

The mechanical strength of cement is determined by ascertaining the tensile strain of briquettes of 1 square inch section made of neat cement, and also of cement mixed with three times its weight of standard sand

The breaking strength of the neat briquettes days after gauging shall not be less than 450 lbs. per square inch, and of the sand

briquettes 200 lbs per square inch The breaking strength of the briquettes at 28 days after gauging shall show an increase on the breaking strength at 7 days, and shall be not less than the number of lbs per square inch of section arrived at from the following formulæ for neat and sand briquettes respectively -

Breaking strength at 7 days

40,000 lbs Breaking strength at 7 days Breaking strength at 7 days

10,000 lbs + Breaking strength at 7 days

The setting time of cement is useful in aiding choice of a cement for a given class of work. Three distinct graduations of time of setting are arranged for, designated as 'quick,' 'medium' and 'slow,' ranging from 10 minutes to 7 hours.

Finally, the soundness of cement, that is, its constancy of volume when set and consequent freedom from tendency to expand in the work of which it forms part, and thus to subject the work to internal stresses sometimes so great as to cause its destruction, can be determined by observing the alteration of volume and condition of test pieces made of the cement and kept under conditions designed to develop and accelerate any latent tendency of the kind. The test is carried out by means of the Le Chatelier apparatus, which consists of a small split cylinder of spring brass or other suitable metal forming a mould 30 mm. diameter and 30 mm. high. On either side of the split is attached an indicator 150 mm. long with pointed end. The mould is filled with neat cement gauged in the usual manner and placed under cold water for practicable to make a proximate analysis of 24 hours. It is then boiled in water for 6 hours;

any alteration in the distance between the points is an indication of the constancy of volume of the coment. The expansion should not exceed 10 mm, when the sample has been aerated for 24 hours, or 5 mm, after the sample has been aerated for 7 days

The specifications in use on the Continent and in America are similar to the British Standard specification as regards their aim, which is to ensure that the cement shall be mechanically strong and chemically stable. The tests themselves are also generally similar, the chief differences concerning the use of compressive as well as tensile tests and variations in the mode of determining the soundness of the cement

Other cements of the Portland class. Roughly it may be said that all cements made by burning a mixture of calcarcous and argillaceous materials are of the Portland cement class, although they may not be true Portland cement Roman cement is an example. It was manufactured before the invention of Portland cement by calcining the nodules of indurated chalk and clay called septaria, found in the Isle of Wight, and dredged upon the Kent and Essex costs. On burning, without any preparation, these nodules give a cement having a composition of which the following analysis is an example—

Silica (SiO <sub>2</sub> )			P	er cent 19 62
Insoluble residue	•			5 86

Water $(H_2O)$				0.25
Alkalıs and loss	•	•	•	1 46
			_	100.00

Roman cement has been almost wholly replaced by Portland cement. It is reddish in colour and very quick-setting, this property making it useful for work which has to be exposed to water immediately after it is laid.

Various marls contain chalk and clay in about the proportion necessary to constitute Portland cement. These are burnt without preparation and form what is known as 'natural cement'. Cement of this soit is, of course, irregular in composition and is apt to be unsound. If well slaked before use, it is a serviceable material of its class. Magnesian limestones containing argillaceous matter, are largely used in the United States for making natural cement. The following is an example of their composition:—

_				Pe	er cent.

Hydraulic limes are cements of the Portland class, and are made by burning limestones containing sufficient clayey matter to yield the calcium silicates and aluminates necessary in hydraulic cement. There are two types, with many gradations between them. The first is Chaux do Teil, made by burning a limestone containing silica so finely divided and so evenly distributed that it unites almost completely with the lime without the aid of any considerable quantity of fluxing constituents, such as alumina and oxide of iron. Its composition is shown below

In a labla and las	Per cent.

	100 00

The second instance is afforded by the hydraulic lime prepared from blue has limestone occurring in the Rugby district, near Lyme Regis and by Aberthaw. In this material, the proportion of alumina is much higher relatively to the silica than in the case of the Chaux de Teil. An example of its composition is appended.

As it is not designed in the case of hydraulic limes to cause complete union of the acid and basic oxides, they invariably contain free lime which needs to be slaked. This is done systematically by the manufacturer of lime of the Chaux de Teil class, but is not generally practised in this country, the operation being performed by the user. In either case, perfect slaking is necessary because any negligence in this respect will lead to expansion in the work of which the lime forms part, and the slaking must be accomplished in such a way that, whilst the free lime is slaked, the cementitious compounds romain untouched.

There is, however, a material chalk and clav made in Germany and known as Eisen-Portland cement, which consists of Portland cement (often made from blast furnace slag) to which some 25 p c of slag has been added after the manufacture of the Portland cement itself. The slag added has a puzzuolanic function similar to that of other silicious materials which are sometimes added to Portland cement But apart from these uses of slag, various patented products, of which Passow cement and Collos cement are examples prepared by treating liquid blast furnace slag in such a way that it becomes definitely hydraulic and will set and resist the action of water as does Portland cement, are Processes for making these manufactured cements generally consist in suddenly cooling the liquid slag and in adding to it, at the moment of cooling, small quantities of some extraneous material such as salts of magnesium or the alkalis. The cause of the action of the mode of cooling and of the addition is obscure, but the fact remains that in this manner blast-furnace slag, which untreated is relatively mert, is conveited into a true hydraulic cement

Puzzuolanic cements. Except for limes which, being made from a silicious limestone, happened to possess hydraulic properties, the earliest kind of hydraulic cement was made from ordinary lime mixed with a puzzuolana, that is, a silicious material sufficiently active to combine with the lime and form a cementitious silicate Natural puzzuolanas are volcanic in origin, the deposits known as Roman and Neapolitan puzzuolana, santorin earth, and trass being examples.

Analyses are given below of Roman and Neapolitan puzzuolanas and of a similar material from Java

<u></u>	Neapo- litan puzzu- olana	Roman puzzu- olana	Java trass

Granulated blast-furnace slag, broken brick and burnt clay are artificial puzzuolanas sometimes used to produce hydraulic coments when added to ordinary lime. The quantity to be added can be calculated on the assumption that the liberated lime combines in about the same proportion with the active silica in these as it does with the silica in Portland cement, it being understood that the silicious material is sufficiently finely ground to unite with the lime. In practice, puzzuolanic materials are usually coarsely ground, and only a fraction of the active silica enters into combination, the balance of the puzzuolana acting merely as an aggregate

From what has been said concerning the constitution of Portland cement and the forma-

tion of slaked lime by its hydration in setting, it will be seen that there is a considerable quantity of calcium hydroxide unprovided for by any acid oxide. It follows that this will act in the same way as ordinary slaked lime in combining with any active silicious substance, and hence that puzzuolanas can be employed as additions to Portland cement which are useful in increasing its content of cementitious matter.

Use of Portland cement. The original object of manufacturing Portland cement and similar substances was to obtain a material which would both set and would resist the action of water But it was soon found that the great mechanical strength of Portland cement made its use advantageous, even when it had not to be exposed to water, and at the present day it is the structural cement par excellence, and on account of the great decrease in cost due to modern method of manufacture, it tends to displace all other building cements, including common lime Its largest application is to form concrete by cementing together any cheap meit stony material which may be locally available and by the use of this substance, huge works of all kinds are constructed at a cost much inferior to that of the same work in masonry It has been found that Portland cement, when made into mortar or concrete, will adhere strongly to non and steel if the latter is clean and not too smooth, and on this observation the preparation of the material known as reinforced concrete is based. It is made by constructing a skeleton of mild steel rods, often tied together by steel wire and filled in with Portland cement concrete, the steel being so disposed as to take the tensile stresses in the coimposite structure It fortunately happens that the coefficients of expansion by heat of ordinary mild steel and of concrete are nearly identical, and thus internal stresses, such as might occur where two diverse materials are bonded together and exposed to fluctuations of temperature, are of very moderate magnitude and do not appreciably influence the mechanical stability of the product Although on the whole a permanent material, Portland cement may be injured or destroyed under various conditions incidental to its use Set cement is the product of the action of water, but it is not indifferent to the further action of water The products of the hydration of Portland coment and its congeners are calcium hydroxide, which is soluble in, and hydrated calcium silicates and aluminates which are decomposable by water. Therefore when water has free access to set cement and can flow through the concrete or mortar of which it forms part, the cement is dissolved and destroyed. In practice good concrete is made so nearly impermeable that, except under heavy pressure, no such flow occurs, but if the concrete is loose in texture and the flow of water correspondingly easy, destruction is only a matter of time. When the water contains salts of magnesium or calcium sulphate, which act on the lime in the one case and on the calcium aluminate in the other, forming part of the set cement, the rate of destruction is much Thus it comes about that in all increased under-water work, and more particularly in sea water, the concrete to be permanent must be impervious. There are minor and local causes

of destruction such as contact with waters containing dissolved gases, eg CO<sub>2</sub> and SO<sub>2</sub>, competent to act on the calcareous constituents of cement, but in general the failure of a concrete structure, when due to chemical action and not to mechanical weakness, can be traced to the flow of water, and usually saline water, through the failure.

CEMENTATION v. IRON.
CEMENT COPPER v. COPPER.
CEMENT STEEL v. IRON.

**CEMENTITE**, an iron carbide, Fe<sub>3</sub>C, containing 6 9 p.c. carbon, is an important constituent of cast iron and steel (Abel and Deering, Proc. Inst. Mech. Engineers, 1885, 30., Moissan, Compt. rend. 122, 421). In steels containing 1.5 p.c. or more of carbon, free cementite is found crystallised in large pseudo-hexagonal plates (Groth, Chem. Krystallographie, 1906, 1), and in practically all steels it exists with pure iron (ferite), in the cutectic mixture called pearlite (Ledebur, Stahl u. Eisen, 1898, 742).

It is very brittle and harder than hardened steel or glass (H=6) (Muller, Stahl u Eisen, 1898, 292), and its presence is the cause of the hardness of 'white' or 'chilled' cast iron (Howe, Metallographist, 1901, 177) It is recognised under the microscope by its hardness and resistance to etching.

As cohemite, it is present in meteorites (Weinschenk, Ann Museum, Wien, 1889, 4, 94)

CEPHAELINE v IPECACUANHA. CERADIA v OLEO-RESINS.

CERARGYRITE or Hornsilver. Native silver haloids, Ag(Cl, Br, I), occurring as small holohedral-cubic crystals and as compact masses with a horny appearance and texture material is soft  $(H = 2\frac{1}{2})$ , tough, and sectile, and cuts like horn. On exposure to light, it quickly The name 'hornsilber' was used by C. Gesner in 1565, and the Greek form cerargyrite was first used by F S Beudant in 1832 After the recognition of the bromide and chlorobromide in 1841 and 1842, the name cerargyrite came to be applied more especially to the But as the different members of the group so closely resemble one another that they can often only be distinguished by analysis, it is more expedient to include them as sub-species

under the name cerargyrite (see Prior and

Spencer, Mineralog Mag. 1902, xiii, 174), viz.

Chlorargyrite, AgCl

Bromargyrite, AgBr. Embolite, Ag(Cl,Br) Iodembolite, Ag(Cl,Br,I) Grey or colourless, sp gr 5.556. Greenish-grey. Greenish-grey. Greenish-yellow to orange-yellow

Isomorphous mixtures are the rule, and of those sub-species embolite  $(q\ v\ )$ , with chlorine and bromine in indefinite proportions, is the most abundant. Large quantities of these minerals have been mined as silver ores in Mexico, Chañarcillo in Chile, and Broken Hill in New South Wales. They occur in the upper oxidise I zones of veins of silver ore, and have no doubt been formed by the action of salt waters percolating from above.

Silver include forms a distinct mineral (v. Iodyratte) crystallising in the hexagonal system, but at a temperature of 146° it passes over into a cubic modification. L. J. S.

CERASIN v. Gums. CERASINE, -ORANGE, -RED, v. Azo-COLOURING MATTERS.

CEREALS. The cereals are the fruits or seeds of various species of Gramineæ In all parts of the world they constitute the most important food of mankind, and are utilised not only for bread corn and the feeding of stock, but also for the fabrication of a number of fermented drinks and industrial products like starch

The most widely distributed cereals are wheat and barley, which grow in almost all climates, oats are more confined to nothern latitudes, maize, and still more so rice, do not ripen, as a rule, north of 45°, while the millets, sorghum, and durra are truly tropical or subtropical in their habits.

In view of their importance as food, a very large number of analyses have been made of the various cereals grown under all conditions, and of the products manufactured from them, the most complete sources of information on this point are Konig, Chemie der menschlichen Nahr- und Genussm. 1903, and the various publications of the U.S. Dep. of Agiic, Div of Chemistry, particularly Bull. 13 (1899), 9, 45, and 50

While each cereal grain possesses its own characteristic composition, subject to variations determined by climate, season, variety, &c, they have still a general similarity and possess many features in common The predominant constituent is always starch, which, together with certain closely allied carbohydrates-the amylans—and a little sugar, forms from 50 to 80 p c of the whole grain Various proteins are also present in inverse ratio to the carbohydrates. they fall as low as 6 p c in rice, and rise to 20 p c. in some varieties of wheat A small quantity of fat or oil is also found, most abundantly in maize and oats, where the average percentage is about 5-6 The proportion of fibre and of ash values very greatly according to whether the grain of commerce consists of the naked fruit alone, as in wheat, rve, and maize, or whether, as in barley and oats, the flowering glumes remain adherent and can only be removed by subsequent manufacturing processes The ash of the cereal grains shows certain marked characteristics it is always very rich in phosphoric acid, up to nearly one-half of the ash when the grain is naked; potash and magnesia predominate among the bases, lime and soda being present in but small amounts, while still less chlorine or sulphure acid (derived from organic sulphur compounds) are to be found; silica is almost absent from the naked grains, but may constitute 5-20 pc of the ash of these grains possessing an adherent husk.

The structure of all cereal grains shows the following features in common: in addition to the chaffy membranes of the flower, which may or may not be adherent, the grain proper possesses several fibrous coats or skins. Within these skins at the end of the grain formerly attached to the plant, lies the embryo or germ, constituting about 3 p.c of the whole, but the greater part of the seed is occupied by the starchy endosperm, the outer membrane of the embryo which abuts against the endosperm brung known as the scutellum. The endosperm

CEREALS.

consists of a series of thin-walled cells tightly Vilmorin, Bull Soc Nat. Agr France, 1901, 61, packed with starch grains enclosed within a thin network of protein, but immediately below the skin there exists a row of differently shaped cells known as the aleurone layer, especially rich in protein. It will now be convenient to consider the cereals separately.

Wheat. The average composition of wheat from various sources is given in Table 1, ex tracted from the sources above quoted A number of other analyses may also be found in (6) date of cutting, &c

131

The composition of wheat is subject to considerable variation, and as the value of the wheat for bread-making is intimately connected with the amount of nitrogen it contains, the effect of external conditions upon this constituent has been extensively studied As factors bringing about variation, we may enumerate (1) variety, (2) climate, (3) season, (4) soil, (5) manuing,

(1) High nitrogen content in wheat is usually associated with a horny translucent grain, hardness, and strength (ie capacity to make a large well-piled loaf). These qualities are most markedly seen in the wheats from Manitoba, Kansas, Hungary, and South Russia, where the high nitrogen content is mainly due to environment but partly to the varieties grown England, where the climate tends to produce a soft, starchy wheat, it is found that variety is the chief factor in determining the proportion of nitiogen In the typical English wheats, the variations in the percentage of nitrogen are small, 16 to 25 pc, according to the season, but certain wheats, like Rough Chaff, Red Lammas and Golden Drop, always show higher percentages of nitrogen than others like Rivett, Square Head's Master, and Stand Up, when grown alongside on the same soil and in the same Moreover, a few varieties have been found, notably Fife, a wheat of Galician origin but widely disseminated in Canada and the United States, which retains in England something of the high nitrogen content and strength characteristic of North-Western America, and nearly always shows a nitrogen content of well over 2 pc (see Hall, J. Board Agric 1904, 11, 321, Humphries and Biffen, J. Agric Sci 1907, 2, 1, papers read at the Winnipeg meeting of the British Association, Jour. Board Agric. 17, 1910) Moreover, Biffen (J. Agric Sci. 3, 1909, 86) has shown that high and low nitrogen content are Mendelian characters which segregate and are inherited without blending

new varieties thus raised, e.g. Cortain Burgoyne's Fife and Yeoman, combining the high introgen content and strength of Fife with

the cropping powers of English wheats, are now grown on a commercial scale

(2) Climate is more potent than any other factor in causing variations in the composition Leclerc and Leavett (US Dep of of wheat Agric Div of Chem Bull. 128, 1910) grew the same varieties of wheat in three localities with widely differing climates, and in the next year grew on seed from each locality at all three places, with the following results as regards protein content -

_		Protein	Protein in product grown in			
<b>Y</b> ear		in seed	Kansas	Calı- forma	Texas	
$ \begin{array}{r}     \hline                                $	Kansas Kansas California Texas	16 22 19 13 10 38 12 18	19 13 22 23 22 23 22 81	10 38 11 00 11 33 11 37	12·18 16 97 18 22 18 21	

Thus the seed of Kansas origin and containing 1913 pc. of protein, when grown in Califorms in 1907 yielded grain only containing 11 00 p c of protein, whereas in the same year seed from the same original stock but grown in California in 1906 and only containing 10:38 p.c. protein, when moved back to Kansas, yielded grain containing 22 23 p c. of protein In these cases, the influence of environment is enormous, and in the main the strong high nitrogenous horny wheats of the American North-West, Hungary and Russia, owe these qualities to their environment They are spring sown when the severe winter is over; they receive considerable rainfall during their early growing months, followed by great heat with progressive dryness of the atmosphere, the cycle of growth being completed in four months or less. The soft low-nitrogenous wheats are generally winter sown with an equably distributed rainfall, as in Western Europe, though, as the experience of California, Oregon, Australia, and India shows, great heat and dryness at the ripening stage will not ensure a high nitrogen content. While climates like Kansas impart a high nitrogen content to all varieties, some varieties commonly grown there, like Fife, possess a high nitrogen content congenitally and retain it in climates like the English, where other wheats with a high nitrogen content in Kansas at once deteriorate

(3) Season has a much greater effect than manuring in altering the composition of wheat, change of season being, in this respect, comparable to change of climate and environment. The variations of English seasons, however, are

never sufficient to induce 'strength' comparable to that found in the wheats of the American North-West, &c

The following table shows the variation in the composition of wheat grown on the experimental plots at Rothamsted in 1852, a wet cool year, and 1863, a dry and hot year

(4) Taken by itself, soil has not a very large effect upon the character of the wheat grown; in fact, in practice it is difficult to disengage the variations due to soil from those depending on the changed environment generally, soil being, as it were, a factor in climate

(5) The composition of wheat shows some variation with the character of the manuring, but the variations are not large. The following results were obtained with the wheat grown on the Rothamsted Experimental plots in 1893, the fortieth season in which the plots had been

The wheats from these plots have also been ground and the flours resulting baked separately, whereupon they show extreme differences in quality and in the character of the loaf they yield (see Hall,  $l\,c$ )

(6) It will be seen from the table of composition that spring wheat possesses a higher nitrogen content than winter wheat, and it has been supposed that the difference can be correlated with the shorter period of growth of the former. Direct experiment, however, with the same variety of wheat sown at monthly intervals, did not support this view (Humphreys, l.c.). In the climates producing high nitrogen content

and strength, the wheats must be necessarily spring sown,  $\iota$  e spring sowing and high nitrogen content are both results due to the same environment and are not casually related

Similarly, the farmer's idea that early cutting gives rise to strength is not confirmed by experiment, though wheat cut green may appear somewhat horny Again, premature ripening is associated with climates producing strength, though it is not the cause of strength

(7) Various investigations have been made into the change of composition of the grain of wheat during its development (Pierre, Mem Soc Linnéene de Normandie, xv 1869, 1, 220; Déherain, Ann Agron 8, 1882, 23; 20, 1894, 561; Adorjan, J fur Landw. 1902, 50, 193; Teller, Arkansas Expt Sta. Bull. 52, 1899).

Hall and Brenchley (J Agric. Sci 1909, 3,195) obtained the results on wheat grown at Rothamsted, shown in table on opposite page.

It will be seen that the immature grain is richer in nitrogen and ash; it also contains more ready-formed sugar, and possesses a slightly higher diastatic power. Other determinations show that in the early stages about three quarters, but at ripeness practically the whole, of the nitrogen is in the protein form. The figures, however, do not support the idea that in the later stages of filling the grain, only starch

enters, the material entering the grain is of almost uniform composition throughout. In the final ripening piocess, desiccation is the most pionounced change setting in

Carbohydrates of Wheat—The carbohydrates present in wheat grain have been examined by Stone (US Dep. of Agric, Office of Expt Stations, Bull 34, 1896), who found sucrose and reducing sugars, amylans and pentosans, in addition to starch, which is the principal constituent of the endosperm. It has also been shown by Whymper (Int. Cong. App. Chem. London, 1909) that the larger granules of the starch contained in the endosperm are more readily attacked by the diastase secreted during germination.

The sugars are chiefly present in the germ, and among them Schulze and Frankfurter identified raffinose (Bei 27, 1893, 64)

Proteins—The proteins contained in wheat, and particularly in flour, have been the subject of considerable investigation, references to Ritthausen and the other earlier workers will be found in Osborne's papers (Amer Chem J 1893, 15, 392; 1894, 16, 524; Amer J Phys 1905, 13, 35; 1906, 17, 223; Carnegie Inst Washington, 1907, Pub 84), from which the following summary has been extracted—

'The proteins of the wheat keinel are gliadin, insoluble in neutral aqueous solutions, but distinguished from all the others by its ready solubility in neutral 70 pc alcohol, glutenin, a protein having a similar elementary percentage composition to gliadin, soluble in very dilute acid and alkaline solutions, but insoluble in dilute alcohol or neutral aqueous solutions, and yielding a wholly different proportion of decomposition products when boiled with strong acids; leucosin, an albumin-like protein, freely soluble in pure water, and coagulated by heating its solution to 50°-60°; a globulin similar in composition and properties to many globulins found in other seeds, and one or more proteoses which are present in very small quantity It has also been shown that the proteins obtained from the embryo of the wheat are the globulin, albumin, and proteose above mentioned, and that these form nearly all of the protein substance of this part of the seed It thus appears that these three proteins are contained chiefly in the embryo, and that gliadin and glutenin form nearly the whole of the proteins of the endosperm, or over 80 pc of the total protein matter of the seed. It is possible that a part of the albumin, globulin, and perhaps minute quantities of the proteose, are contained also in the endosperm, for these proteins are always found in flour from which, in the milling process, the embryo is very nearly completely separated.

Gluten contains the greater part of the protein matter of the seed, together with a little starch, fat, lecithin, and phytocholesterin, and possibly some carbohydrate substance or substances of as yet unknown character non-protein substances are probably not united with one another in the gluten, but are mechanically mixed. The quantity of staich that remains in the gluten depends on the thoroughness of the washing, while the other substances owe their presence largely to their insolubility ın water The chief constituents of the gluten are the two proteids, gliadin and glutenin, the relative proportions of which vary with the variety of wheat from which the flour is made. The character of the gluten and the commercial value of the flour depend, to a large extent, on the proportion of gliadin to glutenin

In the most gluten, these proteins are present combined with about twice their weight of water, which is gradually lost on exposure to dry air or at an elevated temperature.

dry air or at an elevated temperature

'The gladin and glutenin are present as such in the seed, and are not, as was formerly supposed, derived from other protein substances through the action of an enzyme. This is shown by the fact that they may be obtained directly from the flour by the same treatment as that which yields them from the gluten, and under conditions which preclude the action of an enzyme.

'The characteristics of the different wheat constituents, the products which they yield on hydrolysis, and related questions are also considered, and the nutritive value of wheat gluten and other proteins is discussed on the basis of the kind and amount of the cleavage products which they yield on hydrolysis.

134 CEREALS.

'The amount of glutaminic acid which the gluten proteins yield is far greater than that yielded by any of the other food proteins, with the exception of gliadin from rye and hordein from barley The proteins of the legumes and nuts which are used as food yield from 15 to 20 p c of glutaminic acid, so that the mean amount of this amino- acid from the wheat protein is nearly twice as large. The same also is true of ammonia

'The proportion of arginine from wheat gluten is relatively small compared with that from most other seed proteins, many of which

yield from 10 to 16 p c of this base 'The proportion of lysine is likewise small, especially compared with that obtained from the leguminous seeds. The amount of histidine, however, does not differ very greatly from that of the other seed proteins What significance these differences have in respect to the nutritive value of these different proteins must be determined by future investigation, for it has only very recently been discovered that such differences exist

Fat —Wheat contains about 15 p.c of fat, the highest proportions being found in the wheats from the ('anadian North-West It is mostly present in the germ, in which it may

amount to 15 pc. This oil easily turns rancid, and is characterised by a high iodine number

Ash —Analyses of the ash of wheat may be found in Wolff, Aschenanalysen, Berlin, 1871 and 1880, Lawes and Gilbert, Chem. Soc. Trans. 1884, 45, 305

The table given below, from unpublished Rothamsted records, shows the variations induced by manuring in 1896, the forty-fourth season in which the wheat had been grown on the same plots with the same manures.

Mill products of Wheat -An account of the various products obtained during the conversion of wheat into flour, with analyses, is contained in Part 9, Bull 13 (1898) US Dep of Agric Div of Chem See also Maurizio, Geticide Mehl

u Brot Berlin, 1903. For milling offals, see Cranfield, J. Agric Sci. 1914, vi. 102 Baking qualities of Wheat Flour—The earliest attempt to determine the quality of flour in a baker's sense, i e the power of the flour to produce a large firm loaf, consisted in estimating the weight of gluten that could be kneaded out of a given weight of flour. While this test proved to be of value in comparing flours from similar wheats or from wheats grown in the same locality, so many exceptions occurred that

no absolute value could be attached to the test

Estimates based on the total nitiogen in the flour proved to be subject to the same errors Measurements were then made of the gliadin, the wheat protein soluble in 70 pc alcohol; Fleurent further suggested that the ratio of the gliadin to the glutenin in the gluten determined its quality, but these methods in turn broke down under cuticism (see Hall, lc) T. B. Wood (Jour. Agric. Sci. 1908, 2, 139, 267) regards baking quality as dependent on two factors . the size of the loaf is determined by the amount of sugar contained in the flour, together with that produced in the dough by diastatic action. This determines the evolution of carbon dioxide, under the action of the yeast, both as to rate and total amount Then the quality of the gluten, which determines how the

dough will stretch into a sponge and retain the carbon dioxide, depends on its physical character, which will vary enormously according to the state of equilibrium between the colloid gluten and the salts in the water with which it Under certain conditions the is in contact gluten loses all consistency, its physical character being entirely conditioned by the surrounding liquid.

In practice millers now add malt extract to certain flours in the dough-making process, in order to increase the evolution of carbon dioxide. Soluble phosphates are also introduced whereby the elasticity and gas-retaining power of the gluten is increased. The quantities necessary depend upon the origin of the wheat, and must be determined empirically for each flour mixture (see Wood, The Story of a Loaf of Bread: Cambridge University Press, 1913).

CEREALS. Nutritive Value of Wheat.—The nutritive calculated by Chamberlam (U.S. Dep. of Agric value of various samples of wheat has been Div. of Chem. Bull 120, 1909) as follows:—

		1	Digestible o	onstituents			Production	Albu-
Variety	Water	Protein	Fat	Carbo- hydrates	Crude fibro	Ash	calories per 100 lbs.	minoid ratio
North-West spring Soft winter Durum	10 11 10·55 9 77	11 78 9 96 13 02	1 41 1 20 1 72	73 04 75 24 70 77	1 17 1 17 1 33	1.85 2 00 2 02	94,717 94,760 94,457	6 6 7 9 5 8

from the total constituents of the wheat, and in the last column but one the value of the wheat for the production of energy or increased weight is expressed as calories developable from 100 lbs. of the grain, after allowance has been made for the non-digestible portions and the work consumed in the process of digestion. The last column gives the ratio of the non-nitiogenous constituents [digestible carbohydrates and fibre+digestible fat  $\times 2.25$ ] to the digestible proteins.

The question of the digestibility and food value of the different fractions of the wheat grain produced in commercial milling—the comparison between 'white' and 'brown,' 'standard' or 'whole meal' bread, has received greatly increased attention during the war, which forced war bread 'upon nearly all civilised nations Before the war wheat was milled to yield less than 70 pc of white flour and 30 pc or over of offals, during the war the extraction was raised to 80 p.c and eventually to 90 p c The general result of the experience goes to show that the digestibility of the included fractions is higher than had been expected from previous experiments, and that only a comparatively small fraction of the population suffers from digestive

The analyses give the digestible as distinct | troubles in consequence of cating bread from flour containing a marked proportion of husk While the old conclusion that white bread is the most concentrated and digestible of all breads is confirmed, the utilisation of the wheat grain for human food increases up to the 90 pc. extraction, both as regards available energy and protein. See Report of the Food (Wai) Committee of the Royal Society, 1918 The older literature is summarised in Hamill, Local Government Board Reports on Public Health and Medical Subjects, No 55, 1911

Wheat Straw -The composition of wheat straw is more variable than that of the grain: the more complete the ripening process the more thoroughly will the carbohydrates, proteins, and valuable ash constituents of the straw be transferred to the grain. The variations in the composition of the straw in response to different conditions of soil and manufing, are minimised in the grain, which the plant endeavours to make of as constant a composition as possible The following table (Konig) gives a few typical analyses of straw, which are followed by a table of the mean composition of the ash of straw from wheat grown on the Rothamsted plots, to illustrate the variation with manufing

Methods of Analysis. - In the analysis of wheat. the ordinary methods employed for feeding stuffs are followed, the only special determinations required being those of gluten and gliadin

For the determination of gluten, 20 grams of dry flour, or of the ground wheat from which the husk has been sifted, are weighed out on to a piece of bolting silk, about 8 inches square, moistened with water and kneaded up into a paste silk is then gathered together over the dough and kneaded in several changes of water or under a tap until no more starchy liquid flows away, being finally kneaded in the air until it ceases to lose water. The gluten will then generally form an elastic coherent mass which can be removed from the silk without loss, weighed in its wet condition, spiead on a tared sheet of glass or porcelain basin, dried at 100° to a constant The ratio between weight, and weighed again wet and dry gluten is regarded as of some importance

For gliadin, 5 grams of flour are put in a flask with 250 c c. of 70 p.c. alcohol, and shaken in a machine for 6 hours. The mixture is then rapidly filtered, and 100 c c of the solution are placed in a Kjeldahl flask The alcohol is distilled off and the nitrogen in the residue is determined in the usual way Nitrogen  $\times 5$  68= gliadin.

Barley generally shows a smaller Barley. protein content than wheat, this difference is not only characteristic of the two species, but barleys are likely to have been unconsciously selected for low protein content, this being the quality most desired by the brewer, who has always been the chief purchaser of barley The adherent glume and pale further cause an increase in the crude fibre and ash, as compared with wheat

The following analyses of barley are derived, 1-6 from the author, 7 from Konig (lc), and 8 and 9 from Wiley (lc):—

The composition of barley is affected by climate, environment, manuring, &c, in the same way as the composition of wheat, barley being somewhat more susceptible to change The commercial value of barley varies also to a much greater degree, not only are there two distinct grades-barley for malting and barley for feeding purposes, the price of the former being nearly 50 p.c. higher than that of the latter, though the two kinds grade off into one another-but special prices are paid for bailey of exceptional quality

(I) Variety The number of barley varieties is small compared with that of wheat. The tworowed varieties fall into two types, wide and narrow eared, and are most prized for brewing purposes The four-rowed and six-rowed types are not so much used for brewing comparative analytical data are lacking

(2) The following data, drawn from the Rothamsted records, show the effect of season and manuring upon the character of the barleyin 1893, a summer of extreme heat and dryness, and 1894, a wet and cool season .-

Plot	Manuring	Yield of grain		Weight p	er bushel	Grain to	100 straw	Nitrogen per cent in grain		
1100	Manuing	1893	1894	1893	1894	1893	1894	1893	1894	
10 40 1A 2A 3A 4A	Unmanured Minerals, no N N only N, $P_2O_5$ , no $K_2O$ N, $K_2O$ , no $P_2O_5$ N, $K_2O$ , $P_2O_5$	Bush 8 3 9 9 11 6 18 1 16 8 30 8	Bush 10 0 13 1 10 4 34·9 17 8 41 4	1b. 55 6 56 1 55 1 54 0 55 8 56 3	1b 51 1 52 1 50 4 51 9 51 5 54 1	71 9 74 3 85 3 101 0 85 9 102 2	70 3 79 2 67 5 77 0 73 8 77 7	1 899 2 011 2 188 2 129 2 171 2 081	1 409 1 467 1 646 1 600 1 614 1 440	

The results, as shown in the table at top of next page, also obtained at Rothamsted, show the effect of nitrogenous manuring

These results confirm the general opinion that barley for malting purposes should not be grown on land that is in high condition, either as a result of its previous treatment or through

the recent application of nitiogenous ferti-

- 1 Containing starch, 57 9 p c.

Composition of Barley -(a) Carbohydrates Barley contains soluble sugars, which may amount to 4 p c of the dry grain; sucrose is the chief constituent, but dextrose is also found, and O'Sullivan has shown the presence of raffinose The main carbohydrate present is starch, of which H T Brown and his colleagues found 55.5 pc in the dry material of 10 baileys examined (Trans Guinness Research Lab 1903, I, 91) The same investigators (l c. 1906, 2, 312) proceeded to the determination of certain water soluble polysaccharides, called by O'Sullivan amylans, which yield on acid hydrolysis a racemic acid, glucose, arabinose and xylose

They further showed that the sum of the sugars, starch, and amylans, with a little ash and soluble protein, made up the whole of the barley grain that goes into solution when the barley is extracted with boiling water and hydrolysed with malt extract. They obtained from 95 to 10 p c of amylans on the dry weight of various samples of barley examined.

137

In the 'grains' not rendered soluble by diastase, there are considerable quantities of furfuroids' to be found, besides cellulose and

(b) Osborne and Ritthausen have examined the proteins of barley, and Osborne (J Amei Chem Soc 1895, 17, 539) obtained 4.5 p.c. of an insoluble protein, 4 p c of hordern soluble in dilute alcohol, 03 p c of leucosin, and 195 p c of edestin and proteose soluble in water has also been shown that a small proportion of the nitrogen of barley is not combined as protein

(c) The ether extract of barley is found to contain neutral fats, free fatty acids, and lecithin.

(d) The following analyses show the composition of the ash of barley from the Rothamsted plots in 1871 —

BARLEY-SEASON 1871.

Maize. Maize or Indian corn is a cereal grain characterised by a high proportion of carbohydrates and oil but comparatively low protein and ash. Its composition does not vary to the same degree as that of wheat or barley. The average analyses (shown on top of page 138)

are derived from Wiley (US Dep of Agric. Div of Chem Bull 50, 1898) and Konig (l c.).

The only variation in composition worthy of note is that in 'sweet corn,' varieties of which are grown in America to yield immature cobs for boiling as a vegetable, the grains contain a

higher proportion of sugar than is normal, especially in the immature state, and also a greater amount of oil.

Marze oil is expressed in considerable quantities from the germ, which is removed in preparing meal from the grain. It is a light amber-coloured tasteless oil used for salad oil, as a lubricant, and for soap making

Carbohydrates —Less than 1 pc of sugar is present in maize, the greater part being suciose with a small amount of reducing sugar. Starch is the principal carbohydrate, but a little dextrin or other gum-like body has been found, also furfuroids and pentosans up to about 5 pc

Proteins—Osboine has isolated from maize, myosin, vitellin and another unnamed globulin, small quantities of two albumins, and zein, the characteristic protein which exists in both a soluble and insoluble form. It is noteworthy that zein, on hydrolysis, yields no lysin and no tryptophan, and certain defects in the nutrition of animals fed on maize alone have been set down to the lack of these groups in the zein molecule

Ash—The following table from Wolff's Aschenanalysen gives the average composition of the ash of maize —

	c. ash n dry K <sub>2</sub> O	Na <sub>2</sub> ()	CaO	MgO	Fe <sub>2</sub> O <sub>3</sub>	$P_{2}O_{\mathbf{\delta}}$	$so_3$	SiO <sub>2</sub>

German .	1 72   25 73		2 03	17 35	1 51	43 80		4 99

Maze Products—Maize is ground into a meal, 'corn flour,' the germ and the more flinty portions of the grain being removed, and the composition of the meal is set out in the table below, in which is also given the composition of maize 'stover,' i e the stalk, leaves, &c, without the cob

A large number of commercial products are derived from maize, especially starch and glucose; and the manufacturing processes give use to various by-products—maize germ meal, gluten feed, &c, used for feeding cattle, but their composition depends entirely upon the method by which they are prepared.

As might be expected, the composition of oats varies with variety, climate, season, and manufing, in much the same way as wheat does. Of these variations, those due to the variety of

oat are of most importance, particularly in the

Trans. H & Ag Soc. 1901, v. 13, 292 and 293.
 U S. Dep. of Agric. Office of Expt. Sta. Bull. 28, 1899.

CERITE. 139

manufacture of oatmeal. The proportion of husk to kernel is of most significance, and the individual Scotch analyses, of which the mean is given in the table above, show variations in the fibre of from 6 to 14 p.c., and in oil, the other variable constituent, of from 4 to over 8 p.c.

Wilson (Trans. H. and Ag. Soc. 1903, v. 15, 183) gives figures relating to the amount and composition of the oatineal obtained from several varieties of oats grown on the same experimental area in Aberdeen, as follows:—

Chamberlam (l  $\epsilon$ ) has calculated the feeding value of the cereal grains of American origin as follows —

	Produc- tion value, cala per gram	Starch cquiva- lent	Albumi- noid ratio
Wheat .	2 08	88 1	6.5
Barley	1 99	84.2	80
Oats	1 70	72.0	58
Maize	2 23	94.2	12 3
Emmer .	1.64	69.4	60
Einkoin	1 60	67.8	5.2
Rye	2 08	88 2	6.9
Panicum miliaceum	1.84	78 1	115
$And ropogon\ sorghum$	2 06	87.2	10 5

The production value represents the number of calories of energy available from the gram of food, after deduction has been made for the energy in the excreta and the energy consumed in digestion processes. The starch equivalent gives the effect of 100 lbs. of these foods in the production of fat or external work in terms of lbs of pure starch required to produce the same effect.

A. D. H

CEREBRIN v ENZYMES
CEREBROSE (Galactose) v CARBOHYDRATES
CEREDINE. Trade name for a preparation
of dry powdered yeast.

CERESIN. Ceresin occurs in commerce in the form of thin round masses several inches in diameter, harder than wax, of a dazzling white appearance, inodorous, and transparent at the edges. The fracture is somewhat similar to that of wax, but ceresin does not become plastic in warm water The melting-point is between 75° and 80°. It is not attacked by acids, either in the cold or when heated, nor by alkalis, which do not saponify a trace of it. It is entirely volatilised at a high temperature without alteration Ceresin is apparently a paraffin, it does not appear to be obtained from coal tar, but from Galician 'earth-wax,' i c ozokente. It is used Galician 'carth-wax,' i c ozokerite as a substitute for beeswax (J. Soc. Chem. Ind. 11, 372

CERFLUORITE v. YTTROCERITE. CERIN and CERYL CEROTATE v CORK; WAXES

CERISE. A trade name for a variety of amiline red and acid magenta

CERITE. A hydrous silicate of cerium metals. Rammelsberg's analysis (1859) showed the presence of 64 55 p.c. Ce<sub>2</sub>O<sub>3</sub> with 7·28 p.c. (La,Di)<sub>2</sub>O<sub>3</sub> and approximated to the formula 2Ce<sub>2</sub>O<sub>3</sub> 3SiO<sub>2</sub>:3H<sub>2</sub>O. Later analyses showed a predominance of lanthanum and didymium, suggesting the name lanthanocerite. Crystals are orthorhombic, but of rare occurrence. The mmeral is usually found as reddish granular masses much resembling in appearance certain

1 Type analyses from various data.

140 CERITE.

varieties of corundum, from which, however, it is readily distinguished by its lower hardness (H 5½; sp.gr. 49) It occurs as a bed in gneiss at Bastnas in Sweden, and was the material in which the element cerium was first detected L. J. S.

CERIUM. Symbol Ce. At. wt 140.25 (H Robinson, Proc. Roy. Soc. 1884, 37, 150; Brauner and Baték, Zeitsch. anorg. Chem 1903, 34, 103, 207) The most abundant of the rareearth elements. The metal has been prepared by (1) the electrolysis of the fused chloride with or without an admixture of barium or calcium chloride or alkali chloride, (2) the electrolysis of a mixture of cerium dioxide and cerium fluoride (Borders and Stockem, D R. P. 172529; Muthmann and Weiss, Annalen, 1902, 320, 231; 1904, 331, 1, 1907, 355, 116). By the latter process, the yield corresponds with 57 p.c. of a current of 750 amperes and 7.5 volts with current densities of 9-10 amperes and 3 amperes per sq cm. at cathode and anode respectively.

Metallic cerium has the colour and lustre of non; its hardness is comparable with that of silver or tin, mp 635° (Hirsch), 623° (Muthmann and Weiss); sp gr. of fused product of electrolysis 692 at 25°, sp.heat 005112 (20°-100°), hardness (as determined by the scleroscope), 25 9 and 9 5 for rolled and freshly cut surfaces respectively; ultimate strength (as determined in an Olsen machine, with test bars of 0 212 in diameter), 12,900 lb. per square inch; and no elongation with a constant load at 350 lb. Cerium is paramagnetic, magnetic susceptibility, (K)+182 2 10-6 (Monatsh. 1899, 20, 369) In dry air the metal is moderately stable, but becomes superficially tarnished with yellow dioxide. The temperature of ignition in oxygen is about 150°-180° (Annalen; 1903, 325, 261) The metal is malleable and ductile. it has a fairly high latent heat of fusion and thermal conductivity. The heat of oxidation of the metal is 1740 cals per gram, or 60,900 cals per gram. equiv. (CeO<sub>2</sub>=243,600); the wire burns even more brightly than magnesium, and combines readily with the halogens. Cerium is very slightly attacked by cold water, a slow evolution of hydrogen occurs in boiling water, and the metal is tarnished black, it is readily dissolved by dilute acids, but concentrated nitric acid produces a brown deposit consisting mainly of dioxide By heating the metal to 345° in hydrogen, cerum hydride is produced, without luminescence. At 1000° it combines with nitrogen to form the nitride, and direct combination also occurs when the metal is heated in sulphur vapour (Hirsch, Met and Chem Eng. 1911, 9, 540) Alloys have been prepared by melting cerium with other metals under molten sodium and potassium chlorides, the combination with aluminium, magnesium, bismuth, silicon, or zinc is attended by a generation of heat; liquid and solid cerium amalgams have also been obtained. Cerium silicide (CeSi2) is formed by the reduction of cerium oxide with graphite and silicon. This compound is brittle and when added to cerium in such proportion that the mixture contains about 15 pc. of silicon, forms a good pyrophoric alloy. The magnesium-cerium alloys are excellent for thermal reduction processes since—the combination of the two metals being endothermic-

more heat is developed by the oxidation of the alloy than by that of the two metals in admixture (Hirsch).

When scratched or rubbed with a steel edge, cerium emits brilliant sparks, and this property has been utilised in the preparation of gas lighters. For a description of pyrophoric cerium alloys, see Engineering and Mining Journal, 1917, p. 212, Vogel, Zeitsch. anorg. Chem. 1917, 99, 25.

Separation and purification of ceria.—Of all the rare earth oxides, ceria is most readily isolated in a pure state, and the following methods have been employed in separating this oxide from lanthana, prascodymia and neo-

dymia:-

(1) Treatment of the hydroxides suspended in aqueous caustic alkalis with chlorine, ceric hydroxide iemains undissolved, while the other hydroxides are converted into soluble chlorides and hypochlorites (Mosander, J pr Chem. 1842, 30, 276. Mengel, Zeitsch anorg. Chem. 1899,

19, 67)

(2) The mixed oxides dissolved in hot nitric acid and the solution evaporated down with ammonium nitrate until ceric ammonium nitrate separates. The double salt is crystallised from nitric acid until the oxide left on ignition has a light-yellow colour (Auer von Welsbach, Monatsh. 1881, 5, 508, Schottlander, Ber. 1892, 25, 378); or the mixed oxides are treated with four times their weight of concentrated nitric acid and gradually heated to 60°. The solution, after decantation from any insoluble matter, is evaporated to a syrupy consistency, mixed with water from 10 to 30 times the weight of the oxides taken, and 1 gram of ammonium sulphate added for each litre of The fiquid is boiled for a few minutes, solution when a pale greenish-yellow precipitate of basic ceric nitrate and sulphate is formed, which is separated and washed with a solution of a mixture of ammonium nitrate and sulphate (Wyrouboff and Verneuil, Sterba)

(3) The solution of mixed nitrates neutralised with ammonia and boiled with magnesium or sodium acetate and hydrogen peroxide whereby cerium is completely precipitated as a basic acetate (Meyer and Koss, Ber. 1902, 35, 672).

- (4) The mixed ammonium double nitrates boiled with aqueous ammonium persulphate, calcium carbonate being gradually added to keep the solution neutral. The precipitate contains all the cerium as ceric nitrate and sulphate mixed with calcium sulphate (Witt and Theel, Ber. 1900, 33, 1315, cf. Meyer and Marckwald, ibid 3003)
- (5) The joint action of potassium permanganate and a basic substance (mercuric oxide, zinc oxide, magnesia, sodium carbonate, &c) in neutral solution. The precipitate contains all the cerium as ceric hydroxide (Stolba, Ber. bohm Ges Wiss. 1878, Drossbach, Ber. 1896, 29, 2452, D. R. P 143106; Meyer, Zeitsch. anorg. Chem. 1903, 37, 878).

The last of the foregoing methods is generally applicable to the mixed oxides of the rare earths, and permits of the complete separation of cerium in one operation. These processes require to be repeated before the cerium is completely freed from the last traces of lanthanum; thorium also is removed completely, only with

CERIUM. 141

some difficulty. The solution of nitrate, mixed with an excess of ammonium carbonate, is treated with ammonia when the greater portion of the thorium is precipitated. To remove the remainder, anhydrous cerium sulphate is prepared and added to ice-cold water, when the pure hydrated salt separates (Wyrouboff and Verneurl, Compt. rend 1897, 124, 1230; 125, 950; 128, 1331; Urbain, Ann Chim Phys. 1900, [7] 19, 184; Sterba, *ibid* 1904, [8] 2, 193; Brauner, Zeitsch. anorg. Chem. 1903, 34, 103; Meyer, *ibid*. 37, 378; Orloff, Chem. Zeit. 1906, 30, 733, 1907, 31, 562; Neish, J. Amer. Chem. Soc. 1909, 31, 517).

Only a small proportion of the cerium oxide extracted from monazite is used in the mantle industry, the greater amount is employed in the manufacture of sparking alloys for eigar lighters, &c. A further quantity is used (in the form of fluoride) for impregnating arc-light carbons; in weighting silk, in the dyeing and photographic industries, and to a slight

extent in medicine.

Cerium forms several series of compounds derived from the oxides Ce<sub>2</sub>O<sub>3</sub>, Ce<sub>4</sub>O<sub>7</sub>(?), CeO<sub>2</sub>, and CeO<sub>3</sub>.

#### CEROUS COMPOUNDS.

Cerium hydride CeH<sub>3</sub>(?). Cerium combines readily with hydrogen at 250°-270°, yielding a brownish-black amorphous hydride which not improbably consists to some extent of CeH4. This product is stable in dry air at the ordinary temperature, but on heating it is converted explosively into cerium oxide and nitride (Matignon, Compt. rend 1900, 131, 891; Muthmann and Kraft, Annalen, 1903, 325, 281

Cerous fluoride 2CeF<sub>3</sub>,H<sub>2</sub>O (John, Bull Soc chim 1874, [2] 21, 533), known also in the anhydrous condition, and employed in the electrolytic production of the metal (v. supra, and cf. Brauner, Ber 1881, 1944, 1882, 109, 115,

Monatsh. 1882, 3 1)

Cerous chloride CeCl<sub>3</sub>,7H<sub>2</sub>O or 2CeCl<sub>3</sub>,15H<sub>2</sub>O (J. Amer. Chem. Soc. 1894, 16, 649; Ber. 1902, 35, 2622)

The anhydrous chloride, a fusible deliquescent crystalline mass, is obtained by the following

- (1) Heating the dry oxalate or cerium dioxide in hydrogen chloride (Robinson, Proc. Roy. Soc 1884, 37, 150).
- (2) Decomposing cerium carbide with chlorine or hydrogen chloride
- (3) Reducing anhydrous cerous sulphate to sulphide by heating in hydrogen sulphide and decomposing the latter with hydrogen chloride (Ber. 1899, 32, 3413) Cerous sulphide and hydrogen bromide yield cerous bromide.

(4) The anhydrous sulphate, when heated in a current of chlorine and sulphur chloride is converted directly into cerous vapour,

chloride.

The dry chloride is readily soluble in alcohol and ebullioscepic determinations of the molecular weight in this solvent gave numbers corresponding with CeCl<sub>s</sub> (Muthmann, Ber. 1898, 31, 1829).

It forms double salts with the chlorides of mercury, gold and platinum, and of certain organic bases.

Cerous bromide CeBr<sub>2</sub>, and lodide CeI<sub>2</sub> are

also known, as are the bromate Ce(BrO<sub>2</sub>)<sub>3</sub>,9H<sub>2</sub>O,

and sodute Ce(IO<sub>3</sub>)<sub>3</sub>,2H<sub>2</sub>O.

Cerous hydroxide Ce(OH)<sub>3</sub>, a white precipitate obtained from soluble cerous salts with ammonia or caustic soda, is stable only in absence of oxygen. Exposed to air it becomes slowly oxidised to yellow ceric hydroxide, passing through an intermediate reddish-violet stage xCe(OH)<sub>3</sub> yCe(OH)<sub>4</sub> (J. Amer. Chem. Soc. 1894, 18, 649).

Cerous oxide has not been isolated with certainty, since the ignition of decomposable cerous salts (nitrate, sulphate, oxalate, &c.) leads to the production of cerium dioxide. The reduction of the latter oxide with hydrogen at high temperatures gives rise to an unstable darkblue oxide approximating in composition to Ce<sub>4</sub>O<sub>7</sub>

Cerous sulphide Ce<sub>2</sub>S<sub>3</sub> (v. supra), a reddish purple substance (Ann. Chim. Phys. 1904, [8] 2, 193), is moderately stable in air and slowly

decomposed by boiling water.

Cerium nitride CeN, obtained by heating cerium in nitrogen (Annalen, 1903, 325, 261), or by passing ammonia over heated cerium carbide (Compt. rend. 1900, 131, 865), is decomposed by water, yielding cerium dioxide, ammonia and hydrogen. An explosive cerium azide is precipitated by adding sodium azide to aqueous cerous nitrate (Curtius and Darapsky, J. pr. Chem 1900, [2] 61, 408).

Cerous nitrate Ce(NO<sub>3</sub>)<sub>3</sub>,6H<sub>2</sub>O, prepared by (1) dissolving cerium dioxide in nitric acid in the presence of a reducing agent; (2) decomposing cerous oxalate with strong nitric acid. Deliquescent triclinic crystals. When heated strongly, pure cerous nitrate leaves a residue of pale-yellow cerium dioxide, but when praseodymium nitrate is present, the residual oxide is brown (J. Amer. Chem. Soc. 1909, 31, 517).

Cerous sulphate  $(e_2(SO_4)_3)$ . The anhydrous sulphate is produced by dehydrating the hydrated salt at 400° Above 500° it decomposes, leaving a residue of dioxide A saturated solution of the sulphate at 0° deposits the dodecahydrate Ce<sub>2</sub>(SO<sub>4</sub>)<sub>2</sub>,12H<sub>2</sub>O (asbestos-like needles) Above 5° this hydrate is labile, and at higher temperatures the solution of the sulphate deposits hydrates containing 12, 9, 8, 5, and 4 molecular proportions of water. With the sulphates of ammonium, sodium, and potassium cerous sulphate forms double sulphates isomorphous with the corresponding salts of lanthanum, neodymium, and praseodymium. In moderately strong sulphuric acid, cerous sulphate gives rise to the acid sulphate Cc(HSO<sub>4</sub>)<sub>3</sub> (Brauner and Picek, Zeitsch. anorg. Chem. 1904, 38, 322). This acid salt has been recommended as an oxidising catalyst in the production of aniline black, 03 gram of cerous oxide in this form sufficing to develop the black from 6 kilos of aniline hydrochloride.

Cerous carbonate Ce<sub>2</sub>(CO<sub>3</sub>)<sub>3</sub>,5H<sub>2</sub>O, prismatic crystals, precipitated from solutions of cerous salts by ammonium carbonate, forms soluble crystalline double carbonates with the alkali and ammonium carbonates.

Cerous cobalticy anide  $Ce_2(COC_6N_6)_2, 9H_3O$ . The most soluble of the rare-earth cobaltieyanides in 10 p.c. hydrochloric acid (1000 pts. of saturated solution contain 10.75 parts of the 142 CERIUM.

Cerous oxalate Ce<sub>2</sub>(C<sub>2</sub>O<sub>4</sub>)<sub>3</sub>,10H<sub>2</sub>O, crystalline white precipitate (Power and Shedden, J. Soc. Chem. Ind. 1900, 19, 636), has been used medicinally as a sedative in sickness, particularly that of pregnancy, also in chronic diarrheea, hysteria, epilepsy, and migraine

Cerous phenoxide has been recommended as a non-irritant disinfectant (J Soc. Chem. Ind.

1909, 1221; D. R. P. 214782).

Cerous acetylacetonate Ce(CH<sub>2</sub> CO CH CO CH<sub>3</sub>)<sub>3</sub>,3H<sub>3</sub>O, obtained by the interaction of cerous ammonium nitrate, acetylacetone, and ammonia (Urbain, Ann. Chim. Phys 1900, [7] 19, 184; Biltz, Annalen, 1904, 331, 334)

Cerous dimethyl phosphate Ce2(Me2PO4), H2O white, hexagonal plates, solubility 796 at 25° and about 65 at 95° (Morgan and James, J. Amer. Chem Soc 1914, 36, 10).

For other cerous salts of organic acids, v Biltz, Annalen, 1904, 331, 334; Wolff, Zeitsch anorg Chem 1905, 45, 89; Morgan and Cahen, Chem Soc Trans 1907, 91, 477; Pharm J. 1907, 78, 428; Rimbach and Kilian, Annalen, 1909; 368, 110; Pratt and James, J. Amer Chem. Soc. 1911, 33, 1330, Katz and James, ibid. 1913, 35, 872; Erdmann and Wirth, Annalen, 1908, 361, 190; Rimbach and Schubert, Zeitsch physikal. Chem 1909, 67, 183, Jantsch and Grunkraut, Zeitsch, anorg Chem 1913, 79, 305

For complex cerum salts, v. Wyrouboff and Verneuil, Ann. Chim Phys. 1906, [8] 9, 289, Barbieri, Atti R. Accad. 1908, [5] 17, 1, 540

#### CERIC COMPOUNDS.

Cerium carbide CeC<sub>2</sub>; microscopic crystals, sp gr 5 23, prepared by melting together in the electric furnace cerium dioxide (192 parts) and sugar carbon (48 parts), using a current of 300 amperes and 60 volts (Moissan, Compt. rend. 1896, 122, 357, 1897, 124, 1233)

$$\begin{array}{c} 2\text{CeO}_{2} + \text{C} = \text{Ce}_{2}\text{O}_{3} + \text{CO} \\ \text{Ce}_{2}\text{O}_{3} + 9\text{C} = 2\text{CeC}_{3} + 3\text{CO} \\ \text{CeC}_{3} = \text{CeC}_{3} + \text{C} \end{array}$$

When decomposed with water, the carbide yields 75.5 p.c acetylene, 20.5 p.c. methane, and 4 p.c.

ethylene

Cerium silicide CoS12; small crystals with a steely lustre, produced by heating cerium dioxide with crystalline silicon, stable in air and decomposed by acids (Sterba, Compt. rend. 1902, 135, 170)

Ceric oxide (syn. Cerium dioxide) CeO<sub>2</sub>; a white or light-yellow powder, sp gr 6 405; also in isotropic crystals, sp gr 6 76-7 905. The in isotropic crystals, sp gr 6 76-7 905. amorphous oxide is prepared by (1) the oxidation of the metal in oxygen; (2) the ignition of cerous salts (nitrate, sulphate, carbonate, oxalate) or ceric compounds (hydroxide, nitrate, sulphate) The colour of ceric oxide is pure white when prepared at low temperatures, but becomes pale yellow with decrease in volume on ignition (Spencer) It darkens when heated, but becomes nearly colourless or at most pale yellow when cooled The colour of ordinary ceria is probably due to traces of praseodymium The ignited oxide is insoluble in hydrochloric or nitric acid or in dilute sulphuric acid. The crystalline form, obtained by heating the amorphous variety with sodium chloride, borax or potassium hydrogen sulphate, is quite

unaffected by acids or alkalis. The dioxide is reduced with difficulty by aluminium and magnesium, when the corresponding cerium alloys are produced. For further references to cerium dioxide, v. Compt. rend. 1895, 120, 663; 1897, 124, 618, 1233, 1300; 125, 950; 1901, 133, 221; Ber 1900, 33, 3003, 3506; Ann Chim. Phys. 1904, [8] 2, 193; Zeitsch. anorg. Chem 1903, 34, 103, 207; 37, 378); Hofmann and Höschell, Ber. 1914, 47, 238; Jiede and Birbrauer, Zeitsch anorg Chem 1914, 87, 160; Bekk, Ber. 1913, 46, 2574, Reimer, J. Amer. Chem. Soc. 1915, 37, 1636).

Ceric hydroxide Ce(OH), a yellowish precipitate obtained from soluble ceric salts by means of ammonia or the caustic alkalis. Cerous hydroxide is slowly oxidised to ceric hydroxide by atmospheric oxygen and more rapidly by

mild oxidising agents.

Although ceric hydroxide is more stable than the lower hydroxide, the ceric salts are less stable than the cerous compounds. Ceric chloride itself has not been isolated, but its additive compounds, R2CeCl6, with the salts of organic bases (pyridine, quinoline, triethylamine, &c.) are stable in alcoholic solution.

Colloidal ceric hydroxide is obtained by dialysing an aqueous solution of ceric ammonium nitrate The hydrosol is readily coagulated and dues to a gummy mass, soluble in hot water (Biltz, Ber. 1902, 35, 4431, 1904, 37, 1095).

Ceric sulphate  $Ce(SO_4)_2$  The anhydrous salt is produced by heating the dioxide with strong sulphuric acid With the diluted acid oxygen is evolved, and the resulting solution deposits, on concentration, ceri-cerous hydrogen sulphate  $2\text{Ce}(SO_4)_2, \text{Ce}_2(SO_4)_3, \text{H}_2SO_4, 24\text{H}_2O$ (Brauner. Zeitsch. anorg Chem. 1904, 39, 261), and then yellow hydrated ceric sulphate, Cc(SO<sub>4</sub>)<sub>2</sub>,4H<sub>2</sub>O. The former of these compounds corresponds with the intermediate oxide  $Ce_4O_7$  (=2 $CeO_2$ ,  $Ce_2O_3$ ).

Ceric sulphate forms a series of double sulphates (e.g.  $Ce(SO_4)_2$ ,  $2K_2SO_4$ ,  $2H_2O$ ) with the

alkalı sulphates.

Basic ceric sulphates, 4CeO<sub>2</sub>,3SO<sub>3</sub>,12H<sub>2</sub>O, and 2CeO<sub>2</sub>,3SO<sub>3</sub>,4H<sub>2</sub>O have been described by Hauser and Wirth (Zeitsch anorg Chem. 1908),

and CeO<sub>2</sub>SO<sub>3</sub>,2H<sub>2</sub>O, and 3CeO<sub>2</sub>,4SO<sub>3</sub> by J. F. Spencer (Chem. Soc. Trans 1915, 107, 1265).

Ceric nitrate Ce(NO<sub>3</sub>)<sub>3</sub>·OH,3H<sub>2</sub>O. This basic salt separates from a solution of ceric hydroxide in nitric acid. The normal ceric nitrate has not been isolated, but the double nitrates R<sub>2</sub><sup>I</sup>Cc(NO<sub>3</sub>)<sub>6</sub>, where R<sup>I</sup> is ammonium or an alkali metal, are well-defined crystalline substances, having a bright-red colour; they are very hygroscopic and readily soluble in alcohol or The double nitrates R<sup>II</sup>Ce(NO<sub>3</sub>)<sub>6</sub>,8H<sub>2</sub>O, where R=Mg,Zn,N1,Co,Mn, form a well-defined These cerium double nitrates are quite analogous to the corresponding double nitrates of thorum.

For other ceric salts, v. Barbieri, Atti R. Accad. Lincei, 1907, [5] 16, 644; Ber. 1910, 43, 2214. For double ceric fluorides, v. Brauner, Ber. 1881, 1944; Monatsh. 1882, 3, 1; Chem. Soc. Trans. 1882, 41, 68; Rimbach and Kilian, Annalen, 1909, 368, 101; Pozzi-Escot, Compt. rend. 1913, 156, 1074; Browning and Flora, Amer, J. Sci. 1903 [iv.] 15, 177).

For ceric acetylacetonate, Ce(CHAc<sub>2</sub>)<sub>4</sub>, ese Job and Goissedlt, Compt. rend. 1913, 157, 50.

Cerium peroxide and its derivatives. The addition of ammonia and hydrogen peroxide to a solution of a cerous salt determines the precipitation of reddish-brown hydrated cerium peroxide Ce(O<sub>2</sub>H)(OH)<sub>3</sub>. When cerous nitrate or chloride is added to concentrated aqueous potassium carbonate, the solution takes up atmospheric oxygen and assumes a deep-red The liquid slowly deposits crystalline dark-red potassium per-ceric carbonate  $4K_2CO_3$ ,  $Ce(CO_3)_3O_3$ ,  $12H_2O$  In the presence of glucose, this alkaline solution acts catalytically When shaken in the air, oxygen is taken up and the per-ceric compound produced On standing, this substance is reduced by the glucose to cerous salt, and the colour disappears peated shaking leads to renewed production of per-ceric compound, so that oxidation and reduction proceed alternately to an indefinite extent (Pissarjewski, J. Russ. Phys. Chem Soc 1900, 32, 609, Zeitsch, anorg. Chem 1902, 31, 359, Wyrouboff and Verneun, Comp. 121, 1898, 127, 863, Job, Compt. rend. 1898, 126, 246, 1899, 128, 178, 1089, 1902, 134, 1052; 1903, 136, 45, Engler, Zeitsch. anorg. Chem. 1903, 36, 2642, 1904, 37, 49, 3268).

Applications of Cerium.—Metallic cerium (in the form of 'mischmetal,' v. ('ERIUM METALS), has been used in the reduction of the refractory oxides of columbium, tantalum, molybdenum, &c.

The oxidising action of cerium compounds has led to their use in photography (Lumière, Compt. rend 1893, 116, 574), and as oxidising catalysts in organic preparations (Atti R. Accad. Lincei, 1907 [5] 16, i 395), and as an ingredient of 'driers.' The oxides have been suggested for use in colouring glass (Chem. Ind. 1904, 27). Cerium salts have been employed as mordants in dyeing In the preparation of leather, hide powder decomposes cerum salts, fixing the element in the form of hydrated oxide. hide partially reduces ceric sulphate or ceric ammonium nitrate, absorbing oxygen yielding a good quality of leather which has a yellow tint and resists the action of water (Garelli, Atti R. Accad Lincei, 1907, [5] 16, 1 **532).** 

In addition to cerous oxalate, other salts (e.g. hypophosphate, and double ammonium eitrate, tartrate and lactate) have been utilised medicinally in the treatment of sea-sickness and nervous disorders. Incandescent gas mantles contain about 1 p.c. of ceria and 99 p.c. of thoria (Meyer and Anschütz, Ber. 1907, 40, 2639).

(For the detection and estimation of cerium, v. Analysis.)

7. ANALYSIS.)

For a bibliography of cerium, see Hirsch,
J. Soc Chem. Ind. 1912, 477.

CERIUM METALS AND EARTHS. (The

Rare Earths.) The so-called rare earths include a scries of basic oxides, very similar in physical and chemical properties, which are generally found associated in certain rare minerals of complex composition (silicates, phosphates, titanates, columbates, tantalates, zirconates).

The metals contained in these oxides may be divided roughly into two groups, named after the minerals cerule and ytterbite, in which the rare earths were first discovered.

The cerite metals (cerium group) are cerium, lanthanum, neodymium, praseodymium and samarium.

The ytterbite metals (yttrium group) include dysprosium, holmium, erbium, europium, qadolinium, lulecium, celtium, scandium, terbium, thulium, ytterbium (neoytterbium), and yttrium of the latter section, europium, gadolinium, and terbium form an intermediate series (the terbium group) connecting the cerium metals with the remaining rate earths of the yttrium group proper. Closely associated with these elements is the metal thorium, and zirconium is generally included in the category of the metals of the rare earths.

Historical Summary. In 1794 ytterbrte, obtained from Ytterby near Stockholm, was shown by Gadolin, its discoverer, to contain a new oxide, to which Ekeberg subsequently gave the name yttria. From the Swedish mineral cerite, Klaproth, in 1803, isolated another new oxide which is called ceria by Berzelius and Hisinger, who also examined it Thoria was isolated by Berzelius in 1828 from the cilicate

thorite, found at Brevig in Norway. In 1839 Mosander isolated the oxides lanthana and didymia (Annalen, 1839, 32, 235; 1842, 44, 125) from cerite, and also effected a further separation from ytterbite of the earths erbia and terbia (Phil Mag. 1843, 23, 251, J pr Chem. 1843, 30, 288). In 1878 Marignae separated from crude crbia a less basic coloui less component which he called ytterbia (Compt. rend 1878, 87, 578), and this fractionation was speedily followed by Nilson's discovery of scandia, the least basic of the ytterbite earths, and its identification as the oxide of the hypothetical ekaboron, predicted by Mendeléeff. In the same year Cleve effected a further separation of the old 'erbia' and found two new earths, namely thulia and holmia (Compt rend 1879, 89, 478, 708). The doubt expressed by Mangnac as to the homogeneity of didymia was shared by Delafontaine, on the ground of spectroscopic evidence (Compt. rend. 1878, 87, 634), and substantiated by Lecoq de Boisbaudian (Compt. rend. 1879, 88, 323), who isolated from this earth the less basic oxide samaria. The didymia left after the removal of the last-mentioned oxide was still regarded as a mixture by Brauner (Monatsh 1882, 3, 486; Chem. Soc Trans. 1882, 43, 278), and in 1885 Auer von Welsbach, by fractional crystallisation of the double didymium nitrates of ammonium and potassium, succeeded in separating this earth into two components, which he named neodymia and praseodymia (Monatsh. 1885, 6, 477). Lecoq de Boisbaudran now showed that Cleve's holmia was a mixture containing a new constituent dysprosia (Compt. rend. 1886, 102, 1003), the simple nature of which was afterwards confirmed by Urbain (Compt. rend. 1904, 139, 736, and 1905, 141, 521).

Gadoinna, which had been recognised by Marignac in samarskile (Compt rend. 1880, 90, 899), was isolated in a more definite form by Lecoq de Boisbaudran (Compt. rend. 1889, 108, 165; 1890, 111, 409, 472), and by Bettendorf (Annalen, 1890, 256, 159, 1891, 263, 164; 1892, 270, 376), and further purified by Demarçay and by Urbain and Lacombe (v. GADOLINIUM). Further researches by Demarçay on Cleve's samaria led to the isolation of europia (Compt.

rend. 1896, 122, 728), an earth provisionally symbolised as Z, and afterwards shown to be identical with oxides indicated by the symbols  $Z_e$  and  $Z_t$  (Lecoq de Bosbaudran, Compt. rend. 1892, 114, 575, 1893, 116, 611, 674) and  $S_\delta$  (Crookes, Compt. rend. 1885, 100, 1380, 1495; Proc. Roy. Soc 1885, 38, 414).

Terbia, which occurs only in small amount in ytterbite, has been isolated in a purified state by Urbain (v Terbium), and Marignac's ytterbia (i.c) has been fractionated by Auer von Welsbach (Monatsh. 1906, 27, 935), and separated into two components, neoytterbia and lutecia, by Urbain (Compt rend. 1907, 145, 759) In 1911 Urbain discovered that the lutecium from gadolinite is accompanied by a small quantity of a rare earth metal which he called celtium (Urbain, Compt. rend 1911, 152, 141).

Occurrence (v. Das Vorkommen des seltenen Erden, Schilling, 1904, Phipson, Chem. News, 1896, 73, 145) The following is a short description of the most important sources of the rare

(For details concerning the various minerals, see under their respective headings)

### 1. Minerals containing thiefly Cerium Earths.

Cerite (ochroite, cererite, cerinstein), a hydrated silicate containing 60-70 p c of cerium and its allies, together with smaller amounts of iron, calcium, and the yttrium earths, found in the Bastnas mine at Ryddarhyttan in Sweden.

Orthite (allanite, bodenite, cerine, muromontite, pyrorthite, tautolite, uralorthite, wasite). a double silicate of aluminium and the cerium metals (16-25 pc), together with smaller quantities of thorium, iron, calcium, and the yttrium metals, found in Greenland, Scandinavia (Arendal, Hitteroe, Stockholm), United States (New York, North Carolina, Pennsylvania, Virginia, Texas), Ural Mountains (Miask), and in several localities in Germany

Monazite (cryptolite, edwarsite, eremite, mengite, turnerite), an orthophosphate of the cerium metals (Ce, La, Nd, Pr)III PO<sub>4</sub>, containing 40-70 pc of these elements together with varying amounts of thorium (0-18 pc), it occurs in the plutonic and older volcanic rocks, and in the alluvial sands of the rivers and coasts of Brazil, North and South Carolina, and Travancore, in the Federated Malay States, Ceylon and Nigeria, &c

Eschenite A complex, columbate-titanate, containing approximately equal proportions (13-23 pc) of thorum and the cerum metals, together with a small proportion of the yttrium group, found at Hitteroe (Norway) and Miask (Ural Mountains)

#### 2. Minerals containing chiefly Yttrium Earths.

Ytterbite (gadolinite), a basic silicate contaming yttrium earths (40-48 p.c.) and cerium earths (5-10 pc), together with glucinum and iron; found in Colorado, Germany (Harz Mountains and Silesia), Scandinavia (Fahlun, Hitteröe, Ytterby), and Texas.

Yttrialite, a silicate of the yttrium metals (43-47 pc), thorium (10-12 p.c.), and cerium metals (5-8 p c.), found in Texas.

Xenotime, a phosphate of the yttrium metals

(54-64 p.c.), corresponding with monazite; it contains also smaller amounts of the cerium metals and thorium; found in Brazil, North Carolina, Georgia, Norway, Sweden and Switzer-

The following minerals contain the yttrium earths and smaller quantities of thoria and the cerium earths united with varying proportions of the more acidic oxides of columbium, tantalum, titanium, tungsten, tin, uranium, silicon, and zirconium

Fergusonite (bragite, kochelite), found in Ceylon, Greenland, Arendal, Ytterby, Massa-chusetts, North Carolina, and Texas.

Yttrotantalite, found in Norway, Sweden, and the Ural Mountains.

Samarskite (nohlite, vietinghofite, ytteroilmenite), found in Canada, Connecticut, North Carolina, and Ural Mountains (Miask)

Polycrase, found in Canada, Scandinavia, and North and South Carolina

Euxenite (loranskite), found in North Carolina, Norway Hitteroe, Brevig), Swaziland

Many other rare complex minerals (fluorides. zircono-silicates, titanates, columbates, tantalates, uranates, &c) contain considerable amounts of the rare earths, which are also not infrequently found in small quantities in commoner minerals (e q limestones, apatites, scheelites, &c ) Traces of the rare earth metals have been detected in mineral waters, in the ashes of plants, in urine, and in bone ash.

Extraction of the Rare Earths -The finely powdered mineral, made into a paste with concentrated sulphuric acid, is heated till the mass becomes dry and hard. The product is extracted with water, the solution treated with hydrogen sulphide to remove copper, bismuth, molybdenum, &c., and the metals of the rare earths precipitated as oxalates by the addition of oxalic acid. The oxalates are decomposed at 400°, the residual oxides dissolved in dilute sulphuric acid, and the solution saturated with sodium or potassium sulphate, when the double sulphates of the cerium metals are precipitated, whilst those of the yttrium metals remain

The complex minerals containing columbium. tantalum, titanium, &c., may be decomposed by hydrofluoric acid, when the foregoing elements form soluble fluorides, whilst the fluorides of the rare earth metals are precipitated. Or these minerals may be broken up by heating with strong sulphuric acid or potassium hydrogen sulphate and the rare earths precipitated by ammonia from the solution of their sulphates. These hydrated oxides are freed from the coprecipitated columbium, tantalum, and titanium hydroxides by prolonged boiling with nitric acid, when the latter hydroxides separate in an insoluble form. The rare earths are precipitated as oxalates from their solution in nitric acid, the oxalates ignited, and the resulting oxides subjected again to the nitric acid treatment until a complete separation is effected. Or the minerals may be heated in the vapour of disulphur dichloride S<sub>2</sub>Cl<sub>2</sub>, or carbonyl chloride COCl<sub>2</sub>, when the chlorides of columbium, tantalum, titanium, &c., are volatilised, and the rare earth metals are converted into non-volvtile chlorides (Hicks, J. Amer. Chem. Soc. 1911, 33, 1492; Barlot and Chauvenet, Compt. rend. 1913, 157, 1153).

The methods of separating and purifying the rare earths, which will be further described under the appropriate headings (v. CERIUM, YTTRIUM; TERBIUM; THORIUM, &c.) may be divided into the following two classes.—

1. Separations based on differences of

basicity.

a. The fractional precipitation of the earths with bases of varying strengths: ammonia, caustic alkalıs, magnesium hydroxide, organic bases.

b. The fractional decomposition by heat of the solid nitrates and other salts.

2. Separations based on differences of solu-

bility.

Considerable ingenuity has been shown in separating the metals of the rare earths by taking advantage of the slight differences of solubility exhibited by their salts with acids of widely different types. The following series does not exhaust the list of compounds which have been utilised in these intricate separa-Sulphates, double sulphates, nitrates, double nitrates, chromates, bromates, formates, oxalates, succinates, ethyl-sulphates, acetylacctonates, dimethyl phosphates, glycollates, and sulphanilates (if. James, J. Amer. Chem. Soc. 1912, 34, 757).

The progress of these separations is controlled by chemical and physical methods.

I The chemical control consists in determining the equivalent of any fraction either by a gravimetric analysis of its sulphate (Kruss, Zeitsch. anorg. Chem 1893, 3, 44, Wild, ibid 1904, 38, 191; Brill, ibid 1908, 47, 464, Jones, *ibid.* 1903, 36, 92; Brauner and Pavhček, Chem. Soc. Trans 1902, 81, 1243), or by a volumetric analysis of its oxalate (Feit and Przibylla, Zeitsch. anorg Chem. 1905, 43, 202).

2. The physical methods consist in observing the magnetic susceptibility of the fractions and their spectroscope characters. The rare earths differ considerably in magnetic susceptibility, and determinations of its amount are readily made by the magnetic balance of Curie and Chereveau (Urbain, Compt rend 1908, 146, 406, 922, 1908, 147, 1286, 1909, 149, 37, 1910, 150, 913; 1911, 152, 141, 1914, 159, 323).

The most convenient spectroscopic con-

trols are (1.) the absorption spectra, exhibited by solutions of the salts of many rare earths (e g neodymium, praseodymium, samarium, terbium, erbium, thulium, dyspiosium and europium), (11.) the arc spectra, in which all the rare earths give characteristic lines both in the visible and ultra-violet regions of the spectrum. Carbon electrodes are employed, the lower one containing a hollow in which is placed the salt under examination. The arc spectra are photographed and the lines identified by comparison with the photograph of an iron spectrum taken under similar conditions The method is extremely sensitive, although not equally so for different elements (cf. Spectrum analysis and v. Exner and Hascheck, Die Wellenlangen der Bogenspektra, 1904; and Hagenbach and Konen, Atlas der Emissionspektren der meisten Elemente, 1905). Other emission spectra (the flame, spark, and cathode luminescence spectra) have been found to give useful indications in certain cases

(Crookes, Phil. Trans. 1883, 174, [3] 891; Proc Roy. Soc. 1885, 38, 414; 1886, 40, 77, 236, 502. Chem. News, 1886, 54, 39, 54, 63, 76, 155; 55, 83, 95; 56, 59, 62, 72, 81; Chem Soc. Trans 1889, 55, 255; Proc Roy Soc. 1899, 65, 237; Lecoq de Bosbaudran, Compt. rend 1885, 100, 1437; 101, 552, 588; 1886, 102, 153, 899; 1536, 103, 113, 627; 1887, 105, 258, 301, 343, 784; 1890, 110, 24, 67; Bettendorf, Annalen, 1892, 270 376; Baur and Marc, Ber. 1901, 34, 2460).

PHYSICAL AND CHEMICAL PROPERTIES OF THE RARE EARTHS AND THEIR MORE IMPOR-TANT COMPOUNDS.

Hydrides. The rare earth metals combine directly at 220°-270° with hydrogen to form brittle amorphous solids ranging in colour from bluish-black (Ce and La), indigo blue (Nd), to green (Pr), and readily dissociated at higher temperatures (Muthmann, Kraft and Beck, Annalen, 1902, 325, 261; 1904, 331, 581).

Oxides and hydroxides. The metals of the rare earths were formerly supposed to be diads (cf. Wyrouboff, Bull Soc chim. 1889, [3] 2, 745, 1899, [3] 21, 118; Compt rend 1899, 128, 1573), but they are now regarded as tervalent elements forming oxides of the type R<sub>2</sub>O<sub>3</sub>, although cerium, neodymium, praseodymium, and terbium are capable of yielding higher The more stable oxides of thorium and zircomum are of the form RO2 The present view of the valency of the metals of the rare earths is supported by the following facts:-

(1) The isomorphism of bismuth nitrate and certain nitiates of the raie earth series (Bodman,

Ber 1898, 31, 1237)

(ii) The cryoscopic and ebullioscopic determination of the molecular weights of the chlorides and acetylacetonates (Ber 1898, 31, 1829; Compt rend 1901, 133, 289, Annalen, 1904, 331, 334); these salts are thus found to have the general formula RX<sub>3</sub>

(III ) The electrical conductivity of the chlorides and sulphates in aqueous solution (Zeitsch physikal Chem. 1899, 30, 193; Amer. Chem J 1898, 20, 606).

(iv ) The specific heats of cerium, lanthanum and didymium (Annalen, 1873, 168, 45; Ber 1881, 2821; Bull Soc chim 1882, [2] 38, 139)

The rare earth oxides vary considerably in basic power, lanthana, praseodymia, neodymia, and ceria, Ce,O3, being the strongest; whilst neoytterbia, lutecia, scandia, and cerium dioxide are among the weakest bases of the series. In general, the oxides (R2O3) of the cerium metals are stronger bases than those of the yttrium

The hydroxides are thrown out of solution as gelatinous precipitates by ammonia, ammonium sulphide, and the caustic alkalis, even in the presence of ammonium salts; but this precipitation is prevented by citric or tartaric acid (except in the case of scandium). Unlike thorium and zirconium, the metals of the cerium, terbium, and yttrium groups are not precipitated as hydrated peroxides from neutral solutions by hydrogen peroxide, but their peroxides separate from alkaline solutions (Brauner, Ber. 1881, 14, 1944; Cleve, Bull. Soc. Chim. 1885, [2] 43, 53). These peroxides are very unstable, evolving oxygen at even the ordinary

temperature; they are completely destroyed by acids (v. Cerium; cf. Melikoff and Pissarjewski, Zeitsch. anoig Chem. 1899, 21, 70). Chlorides. The chlorides of the rare earth

metals are deliquescent salts readily soluble in water or alcohol, and crystallising from the former solvent with 6 or 7 molecular proportions of water. The anhydrous chlorides, which are fusible at red heat, but very slightly volatile are obtained either by evaporating their solutions to drvness with ammonium chloride, by heating the corresponding oxides with carbon in a stream of chlorine, or preferably by heating the oxide or dry sulphate in a current of sulphur chloride or carbonyl chloride or carbon tetrachloride (Matignon and Bourion, Compt. rend 1901, 133, 289, 1902, 134, 657, 1308, 1904, 138, 631, 1905, 140, 1181, Muthmann and Stutzel, Ber. 1899, 32, 3413, Petterson, Zeitsch anorg Chem 1893, 4, 1, Chauveret, Compt rend 1911, 152, 87).

The chlorides of the rare earth metals combine additively with ammonia and organic bases (e.g. pyridine, cf. Compt. rend 1905, 140, 141, J. Amer. Chem. Soc. 1902, 24, 540, 1903, 25, 1128, Ber. 1902, 35, 2622), and exhibit a great tendency to form double salts with the less electropositive metals The platinichlorides of the cerium metals are isomorphous and crystallise in regular octahedra (Ber. 1876, 1722,

Annalen, 1878, 191, 331)

Fluorides. The rare earth metals, including thorum, are precipitated completely as gelatinous fluorides by soluble fluorides and by hydrofluoric and fluosilicie acids, in this respect differing from zirconium, which forms a soluble double fluoride.

Nitrides. The rare earth metals when heated combine directly with nitrogen to form nitrides of the type MN They are brittle amorphous solids, decomposed by moist air or by water, torming ammonia and the corresponding hydroxide.

Nitrates. The nitrates of the rare earths dissolve readily in water or alcohol, those of the cerium group crystallising with 6 molecular proportions of water, whilst the corresponding salts of the yttrium group contain 3-6 molecules of water. The cerium metals readily furnish stable crystallisable double nitrates with the univalent and bivalent metals (ammonium,

sodium, magnesium, &c)

Sulphates. The rare earths dissolve in dilute sulphuric acid, and the solutions deposit hydrated sulphates containing frequently 4, 8, or 12 molecules of water The octahydrated sulphates of praseodymium, neodymium, yttrium, gadolinium, and ytterbium are isomorphous (monoclinic); but the cerous salt  $Ce_2(SO_4)_3$ , 8H2O is rhombic. With excess of acid, the normal sulphates of the rare earths are converted into acid sulphates of considerable stability (Bull. Soc. chim 1889, [3] 2, 745, Compt. rend. 1902, 134, 657; Zeitsch anorg Chem. 1904, 38, 322, Chem. Soc. Trans, 1902, 81, 1243; James and Holden, J. Amer. Chem. Soc. 1913, 35, 559).

The sulphates of the rare earths have the characteristic property of combining with the alkalı sulphates; the double sulphates of the cerium group are only sparingly soluble in concentrated solutions of the alkali salts, whilst those of the yttrium group are readily soluble. The double sulphates of the terbium group occupy an intermediate position, being moderately soluble in solutions of alkali sulphates

Carbides of the raic earth metals may be prepared by heating the oxides with carbon in the electric turnace. They have the general formula MC<sub>2</sub> They are brittle, crystalline solids, transparent in thin layers and of a yellow colour. They are decomposed by water, forming a mixture of acetylene, hydrogen, ethane, and ethylene, and the hydroxide of the metal M(OH)3

Carbonates. Ammonium, sodium, and potassium carbonates precipitate the neutral of basic carbonates from solutions of the rare earths, but these precipitates are soluble in excess of the reagents, and from the solutions thus obtained, crystalline double carbonates are deposited on evaporation. The carbonates of the yttrium metals are generally more soluble than those of the cerium group in solutions of the alkali carbonates.

Oxalates. The rare earth oxalates are precipitated by oxalic acid or soluble oxalates in neutral or acid solutions, and the sparing solubility of these compounds in acids is a characteristic property which serves to separate the rare earths from other metallic bases (Ber. 1898, 31, 1718, 1899, 32, 409)

The oxalates of the rare earths proper dissolve only slightly in ammonium oxalate, differing in this respect from the oxalates of thorium and zinconium, the latter being also soluble in free oxalic acid (Chem Soc Trans. 1898, 73, 951) Aqueous ammonium acetate dissolves the oxalates of the yttirum group (Bull Soc. chim 1896, [3] 15, 338)

Formates. The formates of the cerum group are less soluble than those of the yttrium group These salts have proved useful in separating the elements of the terbium group.

Acetates. The acetates of the cerum group are very soluble and crystallise with difficulty; those of the yttrium group are less soluble Boiling with sodium acetate precipitates ziiconium and thorium from solutions of their soluble salts, but not the rare earths proper, excepting cerium from ceric salts (Bei 1902, 35, 672).

Acety lacetonates. Acetylacetone furnishes well-crystallised salts with the rare earths, and the fractionation of these compounds from alcohol has served in the separation of the yttrium group (Urbain, Compt. rend. 1897, 124, 618, Bull. Soc chim 1897, [3] 17, 98, Ann Chim Phys 1900, [7] 19, 184, Biltz, Annalen, 1904, 331, 60, Zeitsch anorg. Chem. 1904, 40, 218, Hantzsch and Desch, Annalen, 1902, 323, 26, Biltz, *ibid.* 1904, 331, 334, James, J. Amer Chem. Soc. 1911, 33, 1332; Morgan and Moss, Chem Soc Trans. 1914, 105, 189)

Dimethyl phosphates. A solution of the rare earths is made in dimethyl phosphoric acid, the temperature raised and the precipitate collected; additional fractions are obtained by evaporating the mother liquor. In the case of a material containing gadolinium with just sufficient terbium to colour the oxide orangebrown, the gadolinium collects in the most soluble fraction, and the terbium in the least soluble. Lanthanum, cerium, praseodymrum, and neodym'um are left in the mother liquor.

Samarium, europium, and gadolinium are much less soluble than these, but more soluble than terbium, dysprosium, and holmium, erbium thulium, yttrium, and ytterbium collect in the least soluble fractions (Morgan and James, J.

Amer. Chem. Soc 1914, 36, 10).

The Metals of the Rare Earths.—The oxides of the rare earths are very refractory substances, which have not been reduced directly; the metals are generally set free from the anhydrous chlorides. This reduction may be effected with sodium or potassium, but is preferably carried out electrolytically. The dry chlorides, mixed with a small proportion of alkali chloride, or barium chloride, are electrolysed in a copper crucible, fitted with earbon electrodes, the electrolysis being carried out with a current of 30-40 amperes and 12-15 volts. The mixed metal collects in a molten state round the cathode, which passes through the bottom of the The anode is movable, so that the resistance and therefore the temperature can be increased until all the separated metal melts together. A yield of 750 grams of metal can be obtained with a current of 120 amperes in 6 hours.

With the mixed chlorides, prepared from the waste exides of the thoria manufacture, the product is the so-called 'mischmetal' (Ce, 45 pc; La, Nd, Pr, 35 pc.; Sm, Ei, Gd, Y, 20 pc), which has been used, like aluminium in the Goldschmidt process ('thermite'), to effect the reduction of the refractory oxides of molybdenum, vanadium, columbium, and tantalum (Muthmann, Hofer, and Weiss, Annalen, 1902, 320, 331; 1904, 331, 1; 1905, 337, 370).

CERUSSITE. Native lead carbonate (PbCO<sub>3</sub>), of some importance as an ore of lead (Pb, 77 5 p.c), being known as white lead-ore. It crystallises in the orthorhombic system and 18 isomorphous with aragonite (CaCO<sub>3</sub>) and

witherite (BaCO<sub>3</sub>). Six-rayed stellate groups of twinned crystals are extremely characteristic. The crystals possess an adamantine lustre, are very heavy (sp gr 65), and effervesce with dilute acid, they are very brittle, breaking with a bright conchoidal fracture; hardness, 3-31. The mineral occurs in the upper oxidised zones of veins of lead ore, having been formed by the action of carbonated surface waters on galena Enormous deposits of cerussite intermixed with embolite (silver chloro-bromide) and iodyrite (silver iodide) have been extensively mined at Broken Hill in New South Wales, where little or none of the oxisided ore now remains mately mixed with hemimorphite (hydrated zinc silicate), it is abundant at Broken Hill in North-Western Rhodesia At both of these localities, many finely crystallised specimens have been

CERYL ALCOHOL v WAXES.

CETIACOL. Trade name for pyrocatechol methylcetyl ether

CETINE v. WAXES

CETOSAN. Trade name for a mixture of the higher alcohols of spermaceti, mainly cetyl and octodecyl alcohols, with vaseline. shaken with water, it forms a permanent creamy emulsion (Blatz, J. Soc. Chem. Ind. 1908, 865)

CETYL ALCOHOL, CETYLIC ACID and CETYL-ACETIC ACID (v SPERMACETI).

CETYLMALONIC ACID

 $\mathrm{CH_3(CH_2)_{15}CH(CO_2H)_2}$ 

Prepared from a-cyanstearic acid and potash (Hell and Sadomsky, Ber. 1891, 2781), or diethylmalonic ester, methyl iodide, and cetyl iodide (Guthzeit, Annalen, 206, 357), m p. 121 5°-122°

CEVADINE AND THE ALKALOIDS OF VERATRUM SPP. The sources principally concerned are the seeds of Schoenocaulon officinale (A Gray) [Asagræa officinalis (Lindley)], and the rhizomes of Veratrum viride (Ait.) (green hellebore) and Veratrum album (Linn.) (white hellebore), all of which belong to the N O. Liliaceae, and have nothing in common with the hellebores proper, which belong to the N O. Ranunculace The alkaloids present in these three drugs are as follows .--

Sabadilla sceds ('evadine (crystallised veratrine)

Cevine (sabadinine) Veratridine (amorphous vera-

Sabadiline (cevadiline)

Sabadine

White Hellebore Protoveratime Jervine

Pseudojervine Rubijervine

Protoveratudine

Veratralbine

Green Hellebore Cevadine

Veratridine Jervine

Pseudojervine Veratralbine

It should be noted that there has been considerable confusion in the nomenclature of these alkaloids. Commercially the name 'veratrine' is applied to an amorphous mixture of alkaloids obtained from sabadilla seeds. The name

verafrine is also frequently applied to veratridine, usually, however, with the prefix 'amorphous,' and to cevadine, with the prefix 'crystalline.' The name veratridine was also applied by Robbins (Pharm. J. 1877-1878, [m.] 8, 316) to a crystalline alkaloid contained in green hellebore, and which, in some respects, resembles protoveratrine It is not identical with Bosetti's veratridine isolated from sabadilla seed (Ber. 1883, 16, 1384).

# Alkaloids of Sabadilla Seeds.

[ Cevadine (crystallised veratrine) C32H49O2N 18 the chief alkaloid of sabadilla or cevadilla seeds

(Schoenocaulon officinale [A. Gray]).

Preparation. The finely-powdered seeds are extracted with alcohol, containing 1 p.c. of tartaric acid. The acid liquid is evaporated and diluted with water, to precipitate resin. To the clear solution soda is added in slight excess, and the mixture completely extracted by repeatedly shaking with other. The othereal solution is mixed with light petroleum and the filtrate allowed to evaporate spontaneously. Crystals of cevadine separate from the syrup, and are recrystallised from their solution in alcohol. The remaining syrup contains veratridine (amorphous veratime) and sabadilline (Wright and Luff, Chem. Soc. Trans. 1878, 33,

338). 'Commercial veratrine' is a macroscopically amorphous mixture of cevadine and veratridine (q.v), possibly with small quantities of other alkaloids It was deleted from the BP. 1914, but is retained in the USP. It is used externally, chiefly against lice. Sabadilla seeds contain about 0.7 pc. of total alkaloids, of which about one-seventh can be crystallised (cevadine)

Properties Rhombic prisms, containing 2C<sub>2</sub>H<sub>5</sub>OH when crystallised from alcohol. The alcohol is lost at 130°-140°, and the alkaloid then melts at 205° with decomposition Nearly insoluble in water, soluble in alcohol or ether Optically inactive (Freund and Schwarz, Ber 1899, 32, 800)

The aurichloride, mp 182° (decomp), and the mercurichloride, mp 172° (decomp), are characteristic crystalline compounds (Ahrens, Ber. 1890, 23, 2700) In carbon disulphide solution additive compounds with chloral and bromal are formed (Frankforter and Kritschevsky, J Amer Chem Soc. 1915, 37, 2567)

Cevadine is intensely poisonous; minute

quantities cause violent sneezing.

Reactions.—When warmed with concentrated hydrochloric acid cevadine produces a fine purplish-red colour, which is a somewhat delicate test for the alkaloid Concentrated sulphuric acid produces a carmine-red colouration, or, if the alkaloid is previously mixed with a little sugar, a blue colour.

Cevadine is a monacidic tertiary base. contains no methoxyl groups and no : NMe group; one HO group is present.

When anhydrous cevadine is distilled β-pico-

line is obtained with tiglic acid.

When heated with alcoholic potash, cevadine undergoes hydrolysis furnishing

C27H48O8N

Luff, Chem. Soc. Trans. 1878, 33, 338; 1879 35, 405; Bosetti, Arch. Pharm. 1883, [iii.] 21 81; Ahrens, Ber. 1890, 23, 2700; Freund an collaborators, ibid. 1899, 32, 801; 1904, 3 1964). Cevine crystallises with 31H2O from dilute alcohol, m.p. 195°-200° (anhydrous), an yields derivatives both with metals and acid It is less toxic than cevadine (Freund, l.c.).

According to Hess and Mohr (Ber. 1919 52 B, 1984) cevine is identical with sabadining which Meick (Arch Pharm. 1891, 229, 164 isolated from the mixed alkaloids of sabadill

seeds.

Veratridine (amorphous veratrine) C<sub>37</sub>H<sub>53</sub>O<sub>11</sub>] is found in sabadilla seeds, and is isolated from the amorphous alkaloids precipitated in th earlier stages of the preparation of cevadin (see above) by treating them with ether, whe they separate into insoluble matter (sabadilline The latter 1 and soluble matter (veratridine). purified by conversion into the sparingly solubl Veratridine is sternutatory, yellowish white, amorphous, soluble in 33 parts of water and melts at 180° On hydrolysis by alkalıs ı yields verine C<sub>2</sub>, H<sub>45</sub>O<sub>8</sub>N, which closely resemble cevine (see above) and veratric acid (3: dimethoxybenzoic acid)

Sabadilline (cevadilline) C<sub>34</sub>H<sub>58</sub>O<sub>8</sub>N 18 second amorphous alkaloid occurring in sabadilla seeds. It yields amorphous salts (W and L lc.)

Sabadine  $C_{29}H_{51}O_8N$ , crystals, mp. 238° 240°, also occurs in sabadilla seeds; the salt are crystalline (Merck, Arch. Pharm. 1891, 229 164)

Sabadıllıne and sabadıne resemble cevadını in action, but are less toxic

Cevadine and veratridine, the two principa alkaloids in 'commercial veratrine,' cannot be separated by crystallisation of the former from alcohol, or extraction of the latter by water but they may be estimated by hydrolysing with alcoholic sodium hydroxide, acidifying, and estimating the volatile tiglic acid (from the cevadine), and the non-volatile veratric acid (from the veratridine), the latter acid is extracted by ether (Wright and Luff, lc.).

#### Alkaloids of White Hellebore Rhizome.

Protoveratrine  $\rm C_{32}H_{51}O_{11}N$  is the character istically toxic alkaloid of white hellebore 'roots. It crystallises in thin four-sided tablets from alcohol, m p 245°-250°, 239°-241° (Bredemann) and dissolves in sulphuric acid with a greer colouration, which gradually passes into deep It is readily decomposed by acids yielding sobutyric acid as one product.

Protoveratrine is accompanied in white

hellebore rhizomes by

Jervine C26H37O3N, prismatic crystals, m.p. 238°-242°; toxic.

Pseudojervine C<sub>29</sub>H<sub>43</sub>O<sub>7</sub>N, six-sided tablets.

m.p. 300°-307°; not poisonous.

Rubijervine C<sub>26</sub>H<sub>48</sub>O<sub>2</sub>N, long prisms, m.p.

240°-246°, 234° (Bredemann); not poisonous. Protoveratridine C<sub>24</sub>H<sub>45</sub>O<sub>8</sub>N, four-sided plates

m p. 265°, not poisonous.

The chief papers relating to protoveratrine and its congeners are Wright and Luff (Chem. Soc. Trans. 1879, 35, 405), Salzberger (Inaug. Diss. Erlangen, 1890; Arch. Pharm. 1890, 228, and angelic and tiglic acids  $C_5H_5O_2$  (Wright and Pehkschen (Inaug. Diss. Dorpat, 1800; J. CHALK. 149

Pharm. Chim. 1890, [v.] 22, 265), and Bredemann (Apoth. Zeit. 1906, 21, 41, 53).

Alkaloids of Green Hellebore Rhizome.

The chief alkaloids occurring in this drug (Veratrum viride, U.S.P.) have been described already, viz. cevadine (see under Alkaloids of sabadilla seeds), jervine, and pseudojervine (see under Alkaloids of white hellebore rhizome). Veratridine (see under Alkaloids of sabadilla seeds) occurs only in traces in green hellebore. Robbins isolated from green hellebore rhizomes (Pharm. J. 1877-1878, [iii.] 8, 316) a crystalline alkaloid which he called veratridine, and which, like protoveratrine of white hellebore, gives a green colouration with sulphuric acid. The amorphous alkaloid veratralbine was also obtained by Wright and Luff from this source (Chem. Soc. Trans. 1879, 35, 421).

CEYLON MOSS v. ALGÆ CHAGRAL GUM v. GUMS.

CHAILLETIA TOXICARIA (Don) A plant found in Upper Guinea, Sierra Leone, and Senegambia, the seeds of which contain a poisonous resin used for killing rats and other animals (Power and Tutin, J. Amer. Chem. Soc. 1906, 28, 1170).

1906, 28, 1170). CHALCANTHITE. Native copper sulphate, CuSO<sub>4</sub>,7H<sub>2</sub>O, found as a bright-blue efflorescence, or rarely as distinct crystals, in many copper mines, being especially abundant in some of the Chilean mines. In solution it is always present in the waters issuing from copper-mines; these are allowed to flow over scrap iron, the copper being precipitated as cement-copper. About 100 tons of copper have been so saved annually from the waters of the Rio Tinto mine in Spain, and considerable amounts were formerly obtained from the mine waters in Co. Wicklow.

CHALCEDONY. A native form of silica occurring in reniform, botryoidal, or stalactitic masses lining and filling cavities in rocks. is usually greyish or creamy-yellow in colour, and has a characteristic waxy lustre with a certain degree of translucency. It possesses a minutely fibrous structure, the fibres being arranged perpendicularly to the concentric banding of the material. The optical character and orientation of the fibres is variable; and based on these differences French authors have distinguished several forms of silica under special names (quartzine, lutecite, lussatite, chalcedonite, and pseudochalcedonite). The physical characters of the mineral approach those of quartz, but with slightly lower values, sp.gr. 2.57-2.64; hardness  $6\frac{1}{2}-7$ ;  $n_{Na}$  1.5325, 1.5435. Analyses show, in addition to silica, the presence of variable amounts of impurities (iron oxides, alumina, &c.), and on the average about 1 p.c. of water. The water is probably present as adsorbed water held between the fibres; and its presence supports the idea that the mineral was deposited in a colloidal form as hydrated silica, and that it afterwards intominutely crystalline quartz Depending on the nature of the impurities present (and partly also on the state of aggregation of the material) the mineral may be of various colours, and on these differences are based several trivial varieties which are used as semiprecious stones. Carnelian owes its red colour

to ferric oxide, and sard its brown colour to hydrated ferric oxide; sard passes over into carnelian when ignited. The apple-green colour of chrysoprase is due to mckel silicate and the dark-green of plasma to an iron silicate. Heliotrope shows blood-red spots on a dark-green ground. Smoke-grey flint passes imperceptibly into more typical chalcedony In agate differently coloured layers are banded together in the same as those of agate (q,v) On the artificial colouring of chalcedony, v. AGATE.

L. J. S.

CHALCOCITE v COPPER-GLANCE

CHALCOPYRITE v. Copper-pyrites.

**CHALCOTRICHITE.** Native cuprous oxide (v. Cuprite).

CHALK. A white or greyish, loosely coherent kind of limestone rock, composed almost entirely of the calcareous remains of minute maiine organisms (foraminifera, coccoliths, &c) and fragments of shells. The purest kinds contain up to 99 p c of calcium carbonate in the form of the mineral calcite. Silica is always present in small amounts as the mineral opal, representing the remains of other minute marine organisms (radiolaria, &c ) and sponge spicules, and it is often segregated as the nodular masses of flint so commonly found embedded in chalk Minute grains of quartz, felspar, zircon, rutile, and other minerals are also often present With the admixture of clayey material there may be an insensible gradation from pure chalk to chalk-marl (v MARL). In phosphatic chalk, there is much calcium phosphate (up to 45 p c); in green qlauconitic chalk there is an admixture of grains of glauconite (a hydrated iron potassium silicate); and in red chalk there is some iron hydroxide Not only may there be considerable variations in the composition of chalk, but there may also be wide variations in the colour (snow-white, grey, &c), and texture of the material. It may be soft, incoherent, and porous, or quite hard and crystalline (as the chalk of the Yorkshire coast)

The following analyses of chalk are selected from those quoted by A J Jukes-Browne, The Cretaceous Rocks of Britain, Mem Geol Survey, 1903 (which see for details respecting the English chalk); I, Middle Chalk from Wye, Kent; II, Chalk Rock from Boxmoor, Hertfordshire; III, soft white Upper Chalk from

150 CHALK.

The uses of chalk are numerous. For example, as a writing material in form of white and coloured crayons; for the manufacture of quicklime, mortar, Portland cement, plaster, &c., and as a fertiliser. Whiting is prepared by grinding chalk and collecting the finer sediments from water; this is used for polishing, making putty, and many other purposes. Under the name of 'Paris white,' chalk is used in the manufacture of india-rubber goods, oilcloth, wall-paper, &c. The harder kinds are extensively used as a building stone

Large quantities of chalk are quarried in the counties of Kent, Surrey, Sussex, Cambridge, Lincoln, and Hampshire; Kent being by far the most important. The production of English chalk is not far short of five million tons per annum. A certain amount of this is exported to the United States, though there are extensive beds of chalk in Kansas, Arkansas, and Texas

CHALK, FRENCH. Steatite or soapstone CHALKONES  $(\chi \alpha \lambda \chi \delta s)$ , an ore, particularly copper), the name proposed by v. Kostanecki and Tambor (Ber 1899, 32, 1923) for benzalacetophenone and its derivatives, on account of the fact that by suitable transformations they can be made to furnish reddish-yellow dyestuffs

In order to show the relationships of the various chalkones with one another, the following scheme of notation is adopted —

$$4' \underbrace{\sum_{5'=6'}^{3'-2'}}_{5'-6'} 1' - \text{CO-CH} = \text{CH} - 1 \underbrace{\sum_{6=5}^{2-3}}_{6-5} 4$$

Benzalacetophenone is obtained by the action of sodium hydroxide on an alcoholic solution of benzaldehyde and acetophenone at ordinary temperature For this purpose 21 grams benzaldehyde and 24 grams acetophenone are dissolved in 200 grams alcohol and 20 grams of a 10 pc solution of sodium hydroxide added The mixture is then allowed to stand for 24 hours, and the precipitate collected and recrystallised from alcohol. Benzalacetophenone is a yellow crystalline solid which dissolves in concentrated sulphuric acid with an intense yellow colour By heating 10 grams benzaldehyde with 30 grams acetophenone (dissolved in 100 grams alcohol) for a quarter of an hour at water bath temperature with 25 grams of a 40 p c solution of sodium hydroxide, benzaldiacetophenone  $\mathrm{C_6H_5\ CH(CH_2\ CO\ C_8H_5)_2}$  is obtained This melts at 85° and crystallises in colourless prisms. Its solution in concentrated sulphuric acid is colourless, but gradually shows a blue fluorescence, and on standing for one or two days becomes faint yellow in colour, showing a strong green fluorescence. Similarly by using a mixture of 21 grams benzaldehyde with 36 grams acetophenone in 200 grams alcohol and warming with 50 grams of a 40 p c solution of sodium hydroxide for 12-24 hours at 40°-50°, dibenzaltriacetophenone is formed It is a white crystalline solid, which melts at 198°. It dissolves slowly in concentrated sulphuric acid, the solution after some time developing a red colour and a cinnabar-red fluorescence, which slowly disappears By carrying out the preparation at boiling waterbath temperature, an isomeride melting at 256° is obtained (v. Kostanecki and Rossbach, Ber. 1896, 29, 1488).

Of the various derivatives, the 2'-hydroxy-chalkones possess the greatest importance, on account of their relationship to the naturally occurring dyestuffs of the flavone and flavanol groups, e.g. chrysine, luteoline, apigenine fisctin, &c  $(q\ v)$  The 2'-hydroxychalkones are obtained by

The 2'-hydroxychalkones are obtained by the condensation of o-hydroxyacetophenones with aromatic aldehydes in the presence of sodium hydroxide

2'-Hydroxychalkone

crystallises in yellow needles, melts at 88°-89° dissolves in alkali hydroxides with an orange colour, and in concentrated sulphuric acid with a yellow colour (v. Kostanecki and Tambor, Ber. 1898, 31, 715). It is converted into flavone by the action of alkali hydroxides on the dibromo-addition product of its acetyl derivative (v. Kostanecki and Feuerstein, *ibid* 1758)

OH
$$CO CH : CH C_{6}H_{5}$$

$$CO CH : CH C_{6}H_{5}$$

$$CO C B_{1} H$$

$$CO C B_{1} H$$

Numerous hydroxychalkones are described in the papers of v Kostanecki and his pupils, for which consult Ber. 1898, et seq

CHALMERSITE. A sulphide of copper and iron, CuFe<sub>2</sub>S<sub>3</sub>, first found as small orthorhombic crystals with pyrrhotite in the Morro Velho gold mine, Minas Geraes, Brazil Later it was found in considerable quantity in the Ellamar district and on Knight Island in Prince of Wales Sound, Alaska, where it has been mined as an ore of copper Here the material is massive and intimately intergrown with copper-pyrites. It is pale yellow in colour with metalle lustre and is strongly magnetic, sp gr. 468; hardness 3½ L. J S

CHALYBITE. Native iron carbonate, FcCO<sub>3</sub>, forming rhombohedral crystals isomorphous with calcite (CaCO<sub>3</sub>), and of importance as an ore of iron. It is often known as siderite, but this name had earlier been applied to two other mineral species, and it is also used as a group name for meteoric irons. Sp gr. 3'9; hardness, 3½ Small, brilliant crystals of varying habit are common in many mineral veins, for example, those of Cornwall. Veins of massive sparry material showing cleavage surfaces (Spathic iron-ore) are mined in the Brendon Hills in Somersetshire, in Weardale, Co. Durham, the Siegen district in Westphalia, dep. Isère in France, &c. The fresh, unaltered material is creamy white in colour ('white ore'), but when slightly weathered it is brown ('brown ore'). The Cleveland ore is a pisolitic form of chalybite occurring as beds in the Lias strata;

and the important clay-iron-stone and black-band iron-stone of the Coal-measures consist of compact chalybite, intermixed with clay and carbonaceous matter. A nodular form with an internal radiated structure is known as sphærosiderite.

Analysis I is of pure selected crystals from near Camborne, Cornwall (A. Hutchinson, Min Mag 1903, xiii, 209); II-IV of ores, by A. Dick, in Iron Ores of Great Britain, Mem. Geol. Survey, 1856-1862, II yellowish-grey spathose ore from Weardale; III greenish-grey earthy oblitic ore from Cleveland (also K<sub>4</sub>O 0 27 in the portion soluble in HCl); IV clay-iron-stone from Shelton colliery, Hanley, Staffordshire.

CHAMOMILE FLOWERS. Anthemis nobilis An examination of the flowers of Anthemis nobilis (Linn) by Power and Browning (Chem Soc Trans 1914, 105, 1833) has shown that these contain in addition to numerous other substances an angenin glucoside C<sub>21</sub>H<sub>20</sub>O<sub>10</sub>·2H<sub>2</sub>O, faintly yellow microscopic crystals melting at 178°-180°. It dissolves in alkalis with a yellow colour and gives with aqueous ferric chloride a purplish-brown colouration. Dried at 125°-130°

it loses one molecule of water of crystallisation, but the second molecule cannot be eliminated without decomposing the substance. This is evident from the composition of the hexacetyl derivative  $\rm C_{21}H_{14}O_{10}(COCH_3)_6$ , colourless microscopic crystals, mp  $\rm 144^\circ\!-\!146^\circ$ , the molecule of water in question being eliminated in the process of acetylation

By digestion with 5 pc aqueous sulphuric acid for three hours, this glucoside yields apigenin and dextrose according to the equation:

$$C_{21}H_{20}O_{10}, H_{2}O = C_{13}H_{10}O_{5} + C_{6}H_{12}O_{6}$$

CHARTREUSE. A famous liqueur formerly prepared at the head-quarters of the Carthusian monks near Grenoble, but now, since the retreat of the monks from France in 1906, made at Tarragona in Spain

The recipe for the original liqueur or 'elixir vita' as it was called, was given by the Marquess d'Estrées to the Carthusian monks of Paris in 1602, but, owing to the difficulty of procuring the necessary alpino plants, they presented it to their brethren of the Grande Chartrouse in 1735

The elixii vitæ was valued as a stimulant for the less robust members of the frateinity, weakened by age or by the privations and hardships entailed by the severity of their religious exercises, and was also dispensed to the feeble poor of the district

After numerous disasters by fire, pillage, and confiscation of their property through religious and political persecutions, culminating in the loss of everything during the French Revolution, the monastery of La Grande Chartreuse was restored in 1816, although in a very impovershed condition

The secret of the manufacture of the 'elixir' had, however, been carefully preserved, and this was made the basis of other varieties of liqueur, by the sale of which the monks hoped to improve their finances. The result was the production of green, yellow, and white 'chartreuse,' the virtues of which were advertised far and wide by the military officers who had been quartered in the monastery about the middle of last century Extensive and modern plant was installed at Fourvoisie in 1863, and, in course of time, the sale of chartreuse increased the revenue of the monastery to a point it had never reached before.

After the passing of the French Religious Associations Act, in 1906, the monks of the Grande Chartreuse migrated across the border to Tarragona in Spain, carrying their secret formula with them

More than 200 ingredients are said to be used in the manufacture of genuine chartreuse, and its spirit basis is rectified grape spirit distilled from sound wine. The usual alcoholic strength of the three varieties of chartreuse is green, 55° of alcohol, or 96 p c of proof spirit; yellow, 42 5° alcohol, or 74 5 p c proof spirit; and white, 30° alcohol, or 52 5 p c of proof spirit

There are innumerable imutations of chartreuse, mostly prepared from plain spirit flavoured with essential oils and coloured by means of the various ingredients described under Cordials and Liqueurs. The formulæ given in the table on p 151 are amongst the best of those suggested for the preparation of imitation chartreuse.

Digest in the alcohol for 24 hours, distil until nearly all the spirit is over, and dilute to 100 litres. Colour green or yellow as described under Cordials and Liqueurs, add the sugar, allow to rest till clear, and filter (see Cordials and Liqueurs).

CHAULMOOGRA OIL GROUP. This group is remarkable on account of the considerable optical activity which these oils exhibit, owing to the presence of the strongly active chaulmoogric and hydnocarpic acids (discovered by Power and his collaborators, Chem Soc Trans. Hitherto, three oils belonging 1910, 97, 1285) to this class have been described, viz. Chaulmoogra oil, obtained from the seeds of Taraktogenos Kurzıı (King); Hydnocarpus oil, obtained from the seeds of Hydnocarpus Wightiana (Blume); and Lukrabo oil, the fat obtained from Hydnocarpus anthelminticus (Pierre). The saponification values of these oils lie between 204 and 213, and their iodine values between 90 The seeds of Taraktogenos contain a and 86 4 cyanogenetic glucoside Chaulmoogra is chiefly used in the treatment of leprosy and various skin diseases in Indo-China, Siam, and to some extent also in Europe A few years ago chaulmoogra oil was imported to the Continent as 'Cardamom oil' and used in margarine with disastrous results. Hydnocarpus oil, also known as kavatel oil, is occasionally sold as genuine chaulmoogra oil, but is inferior in its medicinal properties and contains a larger proportion of free fatty acids. The genuine oil from T. Kurzu is now official in the British Pharmacopæia, which describes it as a brownish-yellow soft fat, with a distinctive odour and acrid taste; sp gr. 0 940 at 45°; m.p 22°-30°; iodine value,

96-104; acid value, 21-27; and saponification value, 198-213. It is partially soluble in cold and almost completely soluble in hot 90 p c. alcohol. It is largely composed of the glycerides of acids of the chaulmoogric series, having the general formula  $C_nH_2-n_1O_2$ , and contains palmitin (Power, Amer. J. Pharm 1915, 87, 493) Gynocardia oil, sometimes confused with chaulmoogra oil, is optically inactive. For an account of the origin of the confusion in the nomenclature of the acids derived from chaulmoogra oil and the oils which have been considered as identical with it, see Pyman, Reports of Progress of Applied Chemistry, 1916, 1, 292.

CHAULMOOGRIC ACID  $C_{18}H_{32}O_2$ . An unsaturated acid found by Power and Gornall among the fatty acids contained in chaulmoogra oil from  $Taraktogenos\ Kurzii$  (King) Optically active  $[a]_p+56^\circ$ ; mp.  $68^\circ$ ; bp.  $247^\circ-248^\circ$  (corr)/20 mm Easily soluble in chloroform and ether Forms readily crystallisable salts with metallic bases, and esters with diphatic radicals (Chem Soc. Trans 1904, 838 and 851).

CHAY ROOT. Chay root or Chay-aver (from chaya = which fixes colours, and ver = root); also called Indian madder, is the root of Oldenlandia umbellata (Linn), Rubiacea. It bears the following Indian vernacular names: turbuli (Bengali); cheri-vello (Telugu); ché or chay, The plant is a small sayawer, imburel (Tamil) bush or herb found on sandy soils, chiefly near the sea-coast It occurs in North Burma and Ceylon, but is most abundant in certain tracts of the Madras Presidency, from Orissa south-It does not appear to be used in Bengal, but on the Malabar and Coromandel coasts, especially the latter, it is or was extensively cultivated, and employed in dycing a colour analogous to Turkey-red The chief market is Madras, where it was sold in small bundles at about 4d a lb The roots are usually about 10-12 ms long and 4 m thick, somewhat straight and stiff, tough and wiry, and with few or no lateral fibres When freshly gathered, they have an orange colour; but when dried and kept, they assume a yellowish-grey hue Boiling water gives merely a pale yellow extract, but if alkalı is added, a blood-red decoction is soon obtained The colouring principles seem to reside chiefly, if not entirely, in the bark of the root

The older literature connected with chay root is extremely meagre, and is for the most part contained in the following publications: Philosophy of Permanent Colours, 2282, 1813, Bancroft; Bulletin de la Société industrielle de Mulhouse, 5302, 1832, E Schwartz and D. Koechlin; L'Art de la Teinture des Laines, 475, 1849, Gonfreville. Quantities of the root were imported into Europe in 1774 and at later periods, and its dyeing properties were examined by the above-mentioned experts. It met with little practical application, however, as it was not found to possess any advantage over madder; indeed, it was considered to have but one-half or even a fourth of the colouring power of madder; further, it was found to contain certain undefined yellow substances of an acid character, which interfered somewhat with its dyeing power. Still, it was recognised as a good dyestuff, giving the usual madder colours, and equally fast to soap It is evident that the yellow substances referred to are not the same as those described in this article, as Schwartz states that they were present in larger quantity in 'nona' (Morinda citrifolia) than in chay root, whereas the yellow substances described later exist in much larger quantity in chay root than in morinda root. Very probably they refer to Rochleder's 'rubichloric acid,' as this is contained in morinda root in larger amount than in chay root. Schutzenberger, in his Traité des Matières colorantes, 2, 291, 1867, states that he found chay root to contain alizarin and chlorogenin (rubichloric acid) and that it was easy to exhaust the root by extraction with alcohol.

In many respects chay root resembles madder, as both contain ruberythric acid, alizarin, rubichloric acid, and cane sugar, but there are very marked differences in the nature of the other constituents of the two roots. Madder, as is well known, contains purpurin, purpurin- and purpuroxanthin-carboxylic acids, &c., and but traces of yellow crystalline substances, forming barium compounds soluble in water, which have not been fully investigated In chay root the former substances are entirely absent, but, on the other hand, although the root contains considerable quantities of yellow crystalline substances, they are quite distinct from those contained in madder

The phenolic constituents of this root have been studied by means of the sulphurous acid extraction method described in detail in connection with Madder, and also by a subsequent exhaustion of the residual-root with boiling lime-water. In this manner, chlororubine, alizarin, and a mixture of non-tinctorial yellow substances were isolated. These latter are present in chay root (probably as glucoside) in comparatively large amount (1 p c), and have been shown to consist principally, if not entirely, of the following substances.

Alizarin a-methylether crystallises from dilute methyl alcohol in long orange-yellow needles, melting at 178°-179°. It has the constitution—

This compound may be synthesised by the action of an ethereal solution of diazomethane on a nitrobenzene solution of monoacetylalizarin (Oosch and Perkin, Chem Soc. Proc 1914, 30), subsequently removing the acetyl group Owing to the fact that the so-called monoacetylalizarin is a mixture of the two monoacetylalizarins, both  $\alpha$ - and  $\beta$ -alizarin methylethers are thus simultaneously produced. Addition of alcoholic potast to a solution of the  $\beta$ -methylether as potassium salt, the  $\alpha$ -methylether thus remaining in solution

The methoxyl group present in this substance is much more readily hydrolysed than is usually the case, for prolonged digestion with boiling baryta water is sufficient for this purpose, a precipitate consisting of barnum alizarate thus separating. This property, therefore, accounts for the difficulty in obtaining either this compound or alizarin dimethylether by means of methyl iodide, for in this process of methylation a prolonged digestion in the presence of free alkali is necessary. On the other hand, whereas

alizarin is only converted with considerable difficulty into alizarin dimethylether, by the action of methyl sulphate, alizarin  $\alpha$ -methylether readily yields this substance when treated with this reagent in the usual manner.

Acetylalizarın a-methylether crystallises in

yellow needles, melting at 212°
Anthragallol dimethylether (A) forms yellow needles, and dissolves in alkaline solutions with a red colouration. It is distinguished from the isomeric compound described below, in that it yields an ammonium salt, crystallising in searlet prisms, which is sparingly soluble in cold alcohol. Heated with sulphuric acid to 180°, or with hydrochloric acid, it is converted into anthragallol, and when methylated by means of methyl sulphate, is readily converted into anthragallol trimethylether. By the action of 10 pc potassium hydroxide in a sealed tube at 180° for 5 hours, it is partially converted into methoxyalizarin:

and a similar reaction occurs when sulphuric acid at 100° is employed. The constitution assigned to this anthragallol dimethylether (A), is therefore as follows—

Anthragallol dimethylether (B) crystallises in yellow leaflets, melting at 230°-232°, and gives a red ammonium salt which is soluble in cold alcohol Heated with 10 pc potassium hydroxide solution to 180° for 5 hours, it is partially converted into a compound having the reactions of methoxypurpuroxanthm

and most probably possesses the following constitution.—

By methylation with methyl sulphate in the usual manner, this compound is readily converted into anthragallol trimethylether

Acetylanthragallol dimethylether (B) consists of long yellow needles, melting at 176°-178°

Hystazarine monomethylether obtained as long prange-yellow needles, melting at 232°, when heated with hydrochloric acid at 180°, is converted into hystazarine. Alkaline solutions dissolve it with a crimson colouration, and its ammonium and potassium salts, which crystallise in garnet-red needles, are insoluble in sold 1800 butylic alcohol. The constitution of hystazarine monomethylether is as follows:—

hystazarine dimethylether, which consists of yellow glistening needles, melting at 235°-236°.

pale - yellow Metahydroxyanthraquinone, needles, melting at 302°, is identical with the well-known artificial compound prepared from anthraquinone-\(\beta\)-monosulphonic acid by digestion with alkalı.

Dyeing Properties -Although chay root contains acid principles which tend to dissolve the mordants, its employment as a dyestuff presents no difficulty. The only precautions presents no difficulty necessary to be observed are to add 2 pc. of chalk to the dye-bath, and to raise the tempera-

ture gradually to the boiling-point

Dyeing experiments on ordinary stripeprinted calico, containing aluminia and iron mordants, have shown that the dyeing power of chay root is equivalent to the presence of a percentage of 0 33-0 35 alizarin Compared with ground madder root of good quality, it seems to have about half its dyeing power when the comparison is made before soaping, but after soaping it appears to be quite equal to madder The reds, pinks, and chocolates have a distinctly bluer shade than those given by madder, and the blacs are much fuller and brighter and very similar to those obtained from alizarin last feature alone ought to have secured a ready market for chay root among the European dyers, previous to the introduction of artificial alizarin, and it is somewhat strange that its marked suitability for lilacs should have escaped the observation of those who formerly made dyeing experiments with this root

On oil-prepared calico, mordanted with alumina, chay root gives an excellent blue shade of Turkey-red, withstanding the operation of clearing with soap and stannous chloride better even than a madder-dyed red, and quite equal to one obtained by means of artificial alizarin Good brown, red, orange, and purple colours are readily obtained on wool, and also on silk, suitably mordanted with chromium, aluminium, tin, and iron, according to the ordinary method usual with dyers. On wool, the colours not being submitted to any soaping operation, chay root appears to possess about

half the dyeing power of madder Boiled with dilute sulphuric acid, chay root yields a 'garancine' of a very dark-green colour and possessing about three times the dyeing

power of the original root

Literature.—A. G Perkin and J. J Hummel, Chem Soc. Trans 1893, 63, 1160, ibid 1895, 817; A.G. Perkin, ibid 1907, 91, 2066, J. J. Hummel and A G. Perkin, J Soc Chem Ind. 1894, 13, 346

CHEDDITE. An explosive consisting of a mixture of ammonium perchlorate, dinitroto-luene and castor oil (" Explosives)

CHEESE. A solid preparation of the chief constituents of milk, which, by the action of certain enzymes, are made digestible and palatable.

The action of enzymes is to a large extent influenced by the reaction or hydrogen ion concentration of the curd, which in turn is brought about by the extent to which the lactic organisms are controlled or encouraged in the process of manufacture

Cheeses may be made from the milk of

By means of methyl sulphate, it yields | various animals, but they are usually prepared from cows' milk, which is either used in its natural condition, or may be first divided into cream and separated milk, from both of which products cheeses are also made

In the case of cream and cottage cheeses, the lactic acid produced by the lactic ferments may be used for coagulating purposes; but in the majority of cheeses, rennet is used to precipitate the cascin The caseinogen of the milk is converted into casein by the rennet ferment, and this, in the presence of the lime salts of the milk, is followed by the separation of insoluble calcium caseinate or curd, which carries with it nearly all the fat, some of the other constituents of the milk, and the enzymes of the rennet and milk. This curd differs from that produced by acids, which throw out caseinogen from the combinations with lime in which it occurs in milk

The condition of the rennet curd, used for making different cheeses, is controlled by the acidity of the milk and by the temperature of renneting If milk is curdled with rennet without the previous development of acidity, a soft curd results, this curd will not shrink so much as a curd produced from an acid milk. Too much acidity, on the other hand, results in a hard curd, which will shrink to a much greater

extent, giving a hard 'acid' curd

Temperature also exerts an important influence in cheese making; the action of the rennet is hastened up to about 100°F, and ceases at about 130°F. The temperature employed, the degree of acidity, and the quantity of rennet used, will vary with different cheeses and also with the nature of the milk, the ash constituents probably exerting a considerable influence The acidity is often controlled by the addition of 'starters,' i.e. pure cultures of suitable lactic ferments or of mixed cultures in milk or whey, to the milk The average temperature used is about 84°F., at which the coagulation takes some 40 to 60 minutes some cheeses, e g Leicester, Dutch cheeses, &c, annatto is added as colouring matter at least 10 minutes before the rennet. Salt is also added in the case of hard pressed cheese, when the curd has been ground prior to being put in the mould for pressing into shape, in the case of soft cheese, about the time it is fit to take out of the mould.

With hard-pressed cheeses such as Cheddar. Cheshire, Derby, Leicester, Gloucester, Ementhaler, Gruyère, and Edam, the curd is cut up by means of curd knives, it is then stirred and heated to acquire the correct stage of dryness, consistency, and acidity, after which the whey is drawn off and the curd allowed to remain till a certain degree of acidity has developed. This is determined by means of a hot iron against which the curd is pressed, the length of the threads which are drawn out on pulling away the curd being taken as an index of the acidity produced; the percentage of acidity at the various stages of manufacture may accurately be determined by means of the acidimeter. The curd is then ground in a mill, and afterwards pressed in a mould into a shape which varies with the different cheeses. After being pressed for 2 or 3 days, the cheese is ripened in a curing room, the humidity and temperature of which should be under control;

CHEESE. 155

a temperature of about 55° to 65°F. being most generally desirable.

To another group of cheeses, in which the process of manufacture varies considerably from the above, belong the moulded cheeses, in the making of which the pressing process is omitted, or in the case of Wensleydale greatly reduced; the resulting cheese being softer and admitting of the growth of blue veins of mould (Penicillium glaucum) in the cracks left between the pieces of curd which extend throughout the cheese. To this group belong Stilton, Roquefort, Gorgonzola, Wensleydale, &c

In the case of the small 'soft' cheeses of the Camembert type, considerable variations are made in the process of manufacture, the resulting cheese being quickly ripened by moulds, or rather by the enzymes produced by moulds, which grow on the outside of the cheeses. Penuellium candidum and Oidium Lactis play an important part in the ripening of Camembert.

Indole is present in Limburger and Camembert cheeses and in Handkase Limburger cheese also contains phenol Cheddar, Swiss, 'Gammalost,' Wick, and Roquefort cheeses do not contain indole or phenol. Scatole is absent in all cases The amount of indole in Limburger cheese increases during the ripening process until it reaches as much as 1 part in 52,800 parts of cheese (Nelson, J. Biol. Chem. 1916, 24, 533) All cheeses contain p-hydroxyphenylethylamine, which is produced by the action of micro-organisms on tyrosine; the amine is a normal constituent of cheese, and is produced before actual decomposition of the latter takes place The organisms which produce the substance are probably identical with the Baccasei-a-Freudenreich (Ehrlich and Lange, Biochem Zeitsch. 1914, 63, 156).

Tryptophane has also been found in ripe Stilton cheese

The chemical analysis of cheese includes the determinations of the water, fat, total nitrogen, ash, and salt. The products of ripening are also sometimes determined, and the fat may be examined for adulteration with animal fats

To determine the water, ash, and salt, 2 or 3 grams of well-sampled cheese, cut into small pieces, are weighed into a flat-bottomed dish and placed on the water-bath at 100°C, the dish being inclined so that the fat runs off the drying curd. Weighings are made every hour, and the water is found to have all been driven off in about 5 or 6 hours

The melted fat is then poured off and the residue well macerated in hot amyl alcohol; the residue may then be burnt and the ash weighed, the salt being afterwards dissolved out with water and the solution titrated with N/10 silver

The water may be determined more rapidly by heating from 8 to 12 grams of the cheese with petroleum in a distilling flask connected with a condenser. In from 30 to 45 minutes the whole of the water will have been expelled and may be measured in a graduated tube (Analyst, 1913, 146)

According to Evans, Hastings, and Hart (J. Agric. Research, 1914, 2, 167), the organisms present in Cheddar cheese in such numbers as to indicate that they must have some function in the ripening process, are included in the four

groups: B lactis acidi, B. casei, Streptococcus, and Micrococcus; each of these groups may be divided into a number of varieties according to their fermentative powers' The B. cases group is apparently responsible for the pungent taste which develops late in the ripening period The action of two or more organisms growing together is not the sum of their individual When growing actions when growing alone together, they may attack substances that neither can attack alone, or they may produce a larger quantity of acid than the sum of the quantities that either can produce alone. volatile acids formed in cheese result from the action of Streptococci and Micrococci on the citric acid, lactose, or protein present the varieties of Streptococcus b forms comparatively large quantities of alcohols and esters which contribate to the flavour of the cheese. The B. cases group of organisms form propionic acid, acetic acid, and lactic acid. Certain members of the B casei group form llactic acid, and others form d-lactic acid, a mixture of these organisms produces racemic lactic acid The racemic lactic acid found in cheese during the curing process may also be produced to a small extent by enzymic acid, but it is more probably due to the combined action of B lactis acidi and the organisms of the B. casei group (J Soc Chem Ind 1915, 34, 97)

To obtain a typical Cheddar cheese from pasteurised milk, the pasteurising temperature should not exceed 88° (190°F) when the milk is heated rapidly, or 77° (170°F) when the time of heating is from 15 to 30 minutes Heating to at least 77° (170°) is needed to reduce the number of organisms; at 93° (200°F) practically all the organisms are destroyed Cheeses pre-pared from 'heated' milk contained. water, 33.61-36.22; fat, 32.36-34.53; insoluble nitrogen (probably unaltered casein), 2:49-2:91 pc (Benson, J. Board Agric 1915, 21, 878)

Ether may be used to extract the fat, and the dried curd and fat afterwards weighed, but a better method is to take a fresh portion of 3 or 4 grams of the cheese and grind with twice its weight of anhydrous copper sulphate in a small mortar, afterwards extracting with ether in a Soxhlet extractor

Modifications of the Werner-Schmid or Gottlieb-Rose methods also give good results.

The total nitrogen is determined by the Kjeldahl method in about I gram of cheese

According to Richmond, the products of ripening may be determined in the following manner: 10 grams of the cheese are placed in a small mortar and ground up with 25 cc of boiling water, the liquid is then decanted through a filter into a 250 c c flask, the process being repeated with nine further similar measures of boiling distilled water The total filtrates are then cooled, made up to the 250 cc. mark, and well mixed The products of ripening are determined by the evaporation in a dish of an aliquot part (50 c.c); this, after drying till constant at 100°C, is burnt, the weight of the dish and ash being subtracted from the weight of the dish and dry residue. The difference between 100 and the sum of the water, fat, ash, and products of ripening, may be taken as unaltered casein.

The primary products of ripening may be

156 CHEESE.

determined in another 50 c.c. of the filtrate by the Ritthausen method as follows: 5 c.c. of copper sulphate solution are added and the solution neutralised with caustic soda solution; the precipitate which forms is collected in a weighed Gooch crucible, it is then washed well and dried in a water-oven, the fat is then extracted with ether, and the residue dried till constant. The crucible and its contents are then ignited and weighed, the difference giving the weight of the primary products of ripening, i.e. soluble proteins, &c

To examine the fat, about 50 grams are dried till the fat runs out: the remaining fat is then extracted from the residue with ether, the ether evaporated and the fat examined, as in the case of butter fat. The soluble and insoluble acids and the Reichert-Wollny figure being generally determined, the addition of animal fats can be thus detected. The removal of fat from milk used in making cheese can be assumed if the fat is less than 45 pc of the dried cheese or less than six times the total nitrogen.

The ripening process in cheese, whereby it usually acquires a more agreeable flavour, is essentially a fermentation of slow character, which is brought about by micro-organisms which are generally present in the milk or in the air of the dairy. They can only be controlled, to a limited extent, by the process of making, temperature, &c It is not possible to destroy undesirable organisms by sterilisation, for heated milk will not make typical cheese as far as is at present known, though heating to 150°F is now practised for soft cheeses. Cleanliness, from the moment the milk leaves the cow, is of the utmost importance

The organisms which (ause most trouble to the cheese maker are those which produce gas, which, when it develops in the curd, produces what is known as heaving or blown cheeses These organisms, to which Bacillus coli communis belongs, often come from manure. Their munis belongs, often come from manure. absence can be demonstrated by what is known as a fermentation test, which consists in placing about 10 c.c of the milk in a sterile test-tube and keeping it at blood heat for about 18 hours, after which time no signs of bubbles of gas should be seen in the tube

Bitterness in cheese is sometimes caused by bacteria, as is the case when the milk is infected with Micrococcus casei amari or Tyrothrix geniculatus. An interesting example of a bitter cheese organism is that of Torula amara, which, after causing much trouble and loss in Canada, was eventually traced to the leaves of the sugar maple, from which source it infected the clean chaurns which were stood under the trees after be ng cleaned.

produced by two groups of bacteria acting upon caseinogen and certain amino acids

Black spots in cheese may be caused by moulds or by particles of iron which get into the milk and are afterwards changed to sulphide by the sulphuretted hydrogen produced in ripening Other organisms which produce colours (moulds, &c), may get into the milk or may be derived from the air or utensils of the dairy at later stages of the manufacture.

The cheese magget is the larva of the fly Piophila case: There are four species of cheese mites. (1) Carpoglyphus anonymus (the Cheddar mite); (2) Tyroglyphus siro; (3) Tyroglyphus longior; (4) Aleurobius farinæ (2, 3, and 4 are Stilton and Cheddar mites) (N. B. Eales, 1917)

It must be remembered that micro-organisms and the enzymes they produce play a most important part in ripening; how far this process is also dependent on the proteolytic enzymes of the rennet and to the natural enzymes of the milk is not yet fully ascertained. As above mentioned, pure cultures of lactic acid organisms are sometimes added to milk to be used for hard-cheese making, and Camembert is often infected with the appropriate mould. Gorgonzola is also sometimes infected with mould to make the desired blue veins. As a general rule, however, the dairy and district where a particular kind of cheese is made contain the organisms which are necessary for the successful manufacture of the cheese in question.

The natural rind on Gorgonzola cheese amounts to from 2 to 4 p.c. of the weight, but ng cleaned.

In artificially coated cheese it may amount to Discolouration of Stilton cheese may be from 16 to 27 p.c. of the whole weight. This artificial coating consists of a mixture of barytes | stitute for butter has led manufacturers, and tallow coloured on the outer side with oxide of iron The importation of coated cheese into France is prohibited (Hinks, Analyst, 1911, 36, 61).

Oleomargarine and Lard Cheese. The success attending the sale of margarine as a sub- seed oil.

especially in America, to introduce foreign fats of animal or vegetable origin in the production of cheese as a means of utilising skim-milk; the cream which has been abstracted being re placed by lard, oleomargarine, and by cotton-

Analyses of Oleomargarine and Lard Cheeses (Bell).

In flavour and character these samples closely resembled milk-fat cheese. Comparison of the results of the analysis of the two samples with those yielded by genuine cheeses in the former table conclusively proves the admixture with foreign fat. The low percentage of soluble acids indicates that more than one-half of the fat has not been derived from milk. J. G.

CHEIRININE. See under CHEIROLINE

CHEIROLINE C<sub>5</sub>H<sub>9</sub>O<sub>2</sub>NS<sub>2</sub>, colourless prisms, m.p. 47°-48°, optically mactive, occurs in wallflower seeds (Cheiranthus Cheiri [Linn.]), 1.6-1.7 pc, and in Erysimum species has the constitution CH<sub>3</sub> SO<sub>2</sub> CH<sub>2</sub> CH<sub>2</sub> CH<sub>2</sub> NCS and has been synthesised (Schneider, Annalen, 1910, 375, 207). It is present as a sinigrin-like glucoside, which is hydrolysed by myrosin from white mustard seeds. Wallflower seeds contain an enzyme capable of liberating mustard oil from (myrosin-free) black mustard seeds (Schneider and Lohmann, Ber. 1912, 45, 2954). Cherroline has no basic properties, and is said to be antipyretic (Wagner, Chem. Zeit. 1908, 32, 76). From wallflower leaves or seeds Reeb has obtained cheirinine C1.4H35O17N3, which resembles quinine in physiological action (Arch. expt. Path. Pharm. 1898, 41, 302; 1899, 43, 130) and a glucoside cheiranthin

CHELERYTHRINE (121H17O4N occurs in various Papaveraceous plants, e.g. Chelidonium majus (Linn.), Glaucium flavum (Crantz.), Sanguinaria canadensis (Linn) (Probst, Annalen, 1839, 29, 120, 250), Bocconia spp. Forms colourless rhombohedra with \$\frac{1}{2}H\_2O \text{ or } 1C\_2H\_5OH, m p 203°, [α]<sub>D</sub>=0°. Salts intensely yellow and well crystallised. The free base is colourless. It contains a carbonyl group, and if this is altered the basic properties are lost. Perhaps it forms oxonium salts (Karrer, Ber 1917, 50, 212). Contains two methoxyl groups, and may be a methyl ether of sanguinarine (q.v.). Narcotic (Konig and Tietz, Arch. Pharm. 1893, 231, 145, 161; Murrill and Schlotterbeck, Ber. 1900, 33, 2802; Fischer, Arch. Pharm. 1901, 239, 409, 426, 438)

CHELIDONINE C20H19O5N, H2O occurs with protopine, chelerythrine, sanguinarine, and  $\alpha$ -,  $\beta$ -, and  $\gamma$ -homochelidonines in the root of the common celandine (Chelidonium majus [Linn.]), and with one or more of the same alkaloids in Stylophorum diphyllum (Nutt.) (Selle, Arch. Pharm. 1890, 228, 96), Adlumia-cirrhosa (Rafin.)

(see under Adlumine), and possibly in Sanguinaria canadensis (Linn.) (Konig and Tietz, Arch. Pharm. 1893, 231, 145, 161) It crystallises in monoclinic tablets, m p.  $135^{\circ}-136^{\circ}$ ,  $[a]_{0}+115^{\circ}$ Yields a benzoyl derivative, m p. 217°, and when heated with zinc-dust furnishes ammonia and a substance with a phenanthrene-like odour (Schlotterbeck and Watkins, Pharm. Arch. 1903, 6, 141). Salts crystallise well (Wintgen, *ibid*. 1901, 239, 438). It is slightly toxic, resembling morphine in its action

CHEMICAL AFFINITY. There has been much fruitless speculation about chemical affinity, about the nature of the force which impels two different substances to react with one another During the last half-century, however, the efforts of physical chemists have been devoted rather to the practical investigation of the way in which chemical affinity manifests itself, and of the extent to which the operation of this force is modified by altering the external conditions Quantitative methods have been devised for studying the influence of concentration, of temperature and pressure, and of foreign substances, on the course and products of a reaction The object of this article is to give an outline of the methods employed and the results obtained in this study of the operation The three chief divisions of chemical affinity into which the discussion of the subject naturally falls are (1) velocity of chemical reactions; (2) chemical equilibrium; (3) catalysis.

Velocity of chemical reactions. It is well known that different chemical reactions proceed to completion at very different rates. One change may be so rapid as to be practically instantaneous, whilst in another case the reacting substances may appear almost indifferent to each other. The rate of chemical change depends, however, to a marked extent on the temperature, so that the velocity of a reaction which takes place with extreme rapidity is moderated on lowering the temperature, and becomes amenable to experimental investigation. Suppose now that for such a reaction as that represented by the equation A+B=C+D, a range of temperature has been found over which the change proceeds at a measurable rate; the question next arises, How is the velocity of the change, at a given temperature, dependent on the quantities of the reacting substances A and B? In dealing with this question, we shall assume that the reaction system is homogeneous, and that the change proceeds completely from left to right, i.e. until

either A or B has disappeared

The reaction system being homogeneous, it is permissible to regard matters from the molecular-kinetic point of view, and to conceive the interaction of the substances A and B as taking place only in so far as the molecules of A come in contact with the molecules of B The velocity of the reaction, therefore—that is, the rate at which A and B disappear—will be proportional to the frequency of the collisions between a molecule of A and a molecule of B, even although only a certain proportion of the collisions is followed by chemical interaction Now, on kinetic grounds, the frequency of the collisions between molecules of A and B is proportional to the product of their concentrations, hence the velocity of reaction between A and B is proportional to the product of their concentrations (or their 'active masses,' as it is sometimes put) This proposition is nothing else than the law of mass action, applied to the chemical change under consideration.

The foregoing proposition may be formulated m more definite shape If a is the concentration of the substance A, and b is the concentration of the substance B at the beginning of the reaction, then the initial velocity of the change,  $V_0$ , is given by the equation  $V_0 = k_1$  ab, where  $k_1$  is a proportionality factor, the numerical value of which is independent of the concentrations of the reacting substances, and varies only with temperature and other external conditions If, now, the reaction is allowed to proceed for an interval of time t, and if x represents the extent to which the concentrations of A and B have been diminished by the progress of the change, then the velocity at time t, Vt, is given by the equation  $V_1 = k_1 (a-x)(b-x)$  It is obvious that  $V_t$  must be less than  $V_0$ , and that the velocity of the reaction must diminish continuously from the start onwards . Vt, therefore, represents the velocity of the reaction only for an infinitely short space of time This velocity is defined by the rate at which x is, at that moment, increasing with the time, and if, using the language of the differential calculus, we indicate by dx the extent to which x increases in the infinitely short space of time dt, we may

write 
$$V_{\bullet} = \frac{dx}{dt} = k_1 (a-x)(b-x)$$
.

The applicability of the law of mass action, as expressed in the foregoing formula, is best appreciated by reference to a particular case, such as the inversion of sucrose. Although this change, which may be represented by the equation  $C_{12}H_{12}O_{11}+H_2O=2C_6H_{12}O_6$ , takes place with appreciable velocity only in the presence of a catalytic agent such as hydrochloric acid, yet the latter is found unaltered when the reaction is over, and the inversion of sucrose may be regarded as a particular case of the reaction A+B=C+D. The fact that the inversion is carried out in aqueous solution permits, however, a simplification of the formula  $\frac{dx}{dt}=k_1$  (a-x)(b-x); the water taking part in the reaction is a small fraction of the total water present, so that x may be neglected in comparison

with b, and we may write  $\frac{dx}{dt} = k(a-x)$ , where  $k = k_1 \cdot b$  Integration of this equation leads to the formula  $k = \frac{1}{t} \cdot \log_e \frac{a}{a-x}$ , in which, as already indicated, a is the initial concentration of sucrose, and a-x is its concentration after the inversion has proceeded for t units of time

In order to test the validity of the formula  $k = \frac{1}{t} \log_{e} \frac{a}{a - x}$  as applied to the inversion of sucrose, it is only necessary to ascertain the amount of sucrose still present in the reaction mixture at intervals during the progress of the inversion, and then to see whether the amount of sucrose varies with the time in the manner required by the formula The simplest way of following the course of sugar inversion is to use The reaction mixture, that is, the polarimeter sucrose solution containing a catalytic agent such as hydrochloric acid, is put in the polarimeter tube, which should be provided with a water-jacket in order to secure a constant temperature during the progress of the inversion The angle of rotation is determined at the beginning of the change, at subsequent intervals, and finally when the change is complete. If we indicate by  $\alpha_0$ ,  $\alpha$ , and  $\alpha_{\infty}$ , the initial angle of iotation, the angle at time t from the start, and the final angle respectively, then  $a_0 - a_{\infty}$  is a measure of a, the total sucrose undergoing inversion, and  $\alpha - \alpha_{\infty}$  is similarly a measure of a-x, the sucrose which has still to undergo inversion after time t. Hence  $\frac{a}{a-x} = \frac{a_0 - a_x}{a - a_x}$ and the formula which should represent the and the formula which blocks  $k=\frac{1}{t}\log_e \frac{a_0-a_\infty}{a-a_\infty}$ From the ascertained values of l,  $a_0$ , a, and  $a_{\infty}$ , it is easy to discover whether the expression on the right-hand side of the equation is constant or not The experimental data recorded in the following table show how far in a particular case the actual course of sucrose inversion corresponds with the velocity formula .-

Inversion of Sucrose at 25° by N/2 HCl.

in minutes	Angle of rotation	$k=\frac{1}{t}$	$\log_{10} \frac{a_0 - a_{\infty}}{a - a_{\infty}}$
0	$+25\ 16^{\circ}$		
56	16 95°		0 00218
116	10 38°		0 00218
176	5 46°		0 00219
236	1 85°		0 00219
371	$-3.28^{\circ}$		0 00221
œ	-8.38°		

The expression evaluated in the last column is  $\frac{1}{t}\log_1\frac{a_0-a_\infty}{\alpha-a_\infty}$  mistead of  $\frac{1}{t}\cdot\log_2\frac{a_0-a_\infty}{\alpha-a_\infty}$ , but, obviously, if the value of the former expression is constant, the value of the latter must be so also. The figures in the last column are satisfactorily constant, and the figure 0 00219 may therefore be taken as the velocity coefficient for the inversion of sucrose under the specified conditions, viz at 25° and in presence of N/2 HCl. The variation of the velocity coefficient with temperature and with the concentration of the acid will be discussed later.

Reactions, in which only one molecule of a single substance undergoes change, are termed unimolecular reactions, or reactions of the first order The course of all such reactions, apart from possible disturbing factors, is represented by the formula  $k = \frac{1}{t} \log_e \frac{a}{a - x}$ Examples of strictly unimolecular changes, to which the foregoing formula has been found applicable, are the transformation of acetochloranilide into p-chloracetanilide, and Beckmann rearrangement, and the decomposition of nickel carbonyl. The inversion of sucrose is, strictly speaking, not a unimolecular but a bimolecular reaction, for both water molecules and sugar molecules are involved in the change The reaction takes place, however, in aqueous solution, and, as already indicated, the consequence is that the course of the inversion conforms to that characteristic of a strictly unimolecular change In many other similar cases, a bimolecular reaction proceeds in accordance with the formula  $k = \frac{1}{t} \log_{e_{\alpha}} \frac{a}{-x}$ Examples of this are the hydrolysis of methyl acetate and the

It is desuable here to emphasise certain features which are characteristic of unimolecular reactions, features which can indeed be read out of the velocity formula, but are most clearly seen by the consideration of experimental data In the first place, for all unimolecular reactions the amount of change occurring in a given interval of time is a constant fraction of the unchanged substance still present This is a necessary consequence of the fundamental velocity equation, as is clear when it is written in the form  $\frac{dx}{a-x} = kdt$ , but the proposition is also in harmony with observation, as will be seen by a consideration of the following data bearing on the inversion of sucrose (Armstrong and Caldwell, Proc Roy. Soc. A 1905, 74, 199) A sucrose solution was inverted at 20° with hydrochloric acid, and the angle of rotation (a) was determined from time to time, with the results shown below

decomposition of diazonium salts

Time	$+21^{\circ}55^{\circ}$
15	20 40°
120	13 75°
135	12 95°
225	8 62°
240	8 02°
οc	−7·18°

The decrease in rotation during the first 15 minutes, viz.  $1^{1}15^{\circ}$ , is a measure of the amount of change during that interval. The average rotation of the solution over this interval may be taken as  $\frac{21^{\circ}55^{\circ}+20}{2}=20\,97^{\circ}$ , and a measure of the unchanged sucrose present is given by  $20\,97+7\cdot18=28\,1b$ . The ratio of the amount of change occurring in the first 15 minutes to the amount of unchanged sucrose present is therefore  $\frac{115}{28\cdot15}=0\,041$ . If now the intervals from 120 to 135 minutes, and from 225 to 240 minutes are similarly considered, it will, be found that the ratio of the amount of change occurring in the 15-minute interval to

the amount of unchanged sucrose present is 0 039 in each case, practically the same value as for the first 15 minutes of the inversion. The experimental data, therefore, bear out the statement that for a unimolecular reaction the amount of change occurring in a given interval of time is a constant fraction of the unchanged substance still present

Another feature of unimolecular reactions is that the amount of substance changed in a given time is always the same fiaction of the total amount of substance present at the beginning of the reaction, however this latter amount be varied. An illustration of this is furnished by the following data, referring to the inversion of sucrose in very dilute aqueous solution under the influence of invertase.

Grams sucrose per 100 c c.	Grams sucrose inverted in 60 mins
1 00	0 249
0.50	0.129
0.95	0.060

This experimental result is implied in the formula for a unimolecular reaction, for if  $y = \frac{x}{a}$  is the fraction of the total sucrose which has been inverted up to time t, the formula may be written  $k = \frac{1}{t} \log_e \frac{1}{1-y}$ , and it is plain that the value of y depends merely on t, and is independent of a

For bimolecular reactions, that is, reactions in which two molecules are concerned, the fundamental velocity equation is  $\frac{dx}{dt} = k(a-x)(b-x),$  as indicated in the argument above. Integration of this equation leads to the formula  $k = \frac{1}{(a-b)t} \log_e \frac{b(a-x)}{a(b-)x}$  If, however, the two reacting substances have the same initial concentration, that is, if a=b, the integrated formula is  $k = \frac{1}{t} \frac{x}{a(a-x)}$ .

A typical case of a bimolecular reaction, or reaction of the second order, is the saponification of an ester by an alkali. Under suitable conditions of temperature and concentration, the velocity of saponification is measurable, and the progress of the reaction can be determined by extracting samples of the reaction mixture from time to time and titrating for free alkali. The figures in the following table, referring to the saponification of ethyl acetate by sodium hydroxide at 24 7°, will serve to show how far the experimental data are in harmony with the formula just recorded The reaction mixture in this case was N/40 in relation both to ester and alkalı, and the figures under a-x in the table are the volumes of a standard acid solution required to neutralise 10 c.c. of the reaction mixture -

11 c		
<i>t</i> (min )	a-x	$ka = \frac{1}{t} \frac{x}{a-x}$
0	8.04	
4	5 30	0 129
6	4 58	0 126
8	3 91	0 132
10	3 51	0 129
12	3 12	0 131
15	2 74	0.129
20	2.22	0.131

The figures in the last column are satisfactorily constant, and confirm the application of the law of mass action to a bimolecular reaction.

Reactions of the third and higher orders are known and the formulæ applicable to these are obtained on the lines already indicated Cases of such reactions, however, are comparatively rare, and it is not proposed to discuss them here Investigation has shown that frequently a reaction which a general knowledge of the facts would lead us to regard as a reaction of a high order turns out to be one of a low order result is undoubtedly due to the apparently complex reaction being really a series of successive changes of a simpler kind Under these circumstances, the velocity of the complex re action is determined by those of the component reactions which are comparatively slow for instance, one of the latter is incomparably slower than all the others, then the order of the complex reaction will be the order of this slow component reaction

Influence of Temperature —It is well known that a chemical reaction is markedly accelerated by even a slight rise of temperature, but a definite measure of the influence of temperature on a given reaction can be obtained only by determining the velocity coefficient of the reaction at different temperatures The value of the temperature coefficient of reaction velocity, deduced in this way, is remarkably independent of the nature of the particular reaction under investigation For homogeneous reactions of the most varied character, the factor by which the velocity coefficient at To must be multiplied in order to give the velocity coefficient at  $T+10^{\circ}$ , lies, as a rule, between 2 and 4 Speaking Speaking generally, one may say that the velocity of a chemical reaction is doubled or trebled for every rise of 10° It is a striking fact that the temperature coefficient of various vital processes, such as vegetable respiration, is of the same order as that found for chemical reactions generally.

Chemical equilibrium. The reactions discussed in the foregoing section have all been changes which proceed from left to right until at least one of the reacting substances has disappeared. There are many reactions, however, which do not belong to this type, masmuch as they come to a stop while the reacting substances are still present in the reaction mixture Suppose, for instance, that the reaction between two substances A and B is of this description, and that C and D are the products of the reaction, then the change proceeds until a state of equilibrium is attained at which all four substances are present It is further found that if the products C and D are brought together, they react to form the substances A and B, while the final state of equilibrium reached is the same as in the previous case Such a reaction is known as a balanced or reversible reaction, and in the corresponding equation a double arrow is substituted for the usual sign of equality, thus  $\cdot$  A+B $\geq$ C+D.

The progress of a reversible reaction towards its equilibrium position may be regarded as the

side react to form those on the right side of the equation, and the other the velocity  $(v_{i})$ with which the substances on the right side react to form those on the left side of the equation. If we take  $A+B \ge C+D$  to represent the reversible reaction in question, and suppose that at some particular moment the concentrations of the four substances in the reaction mixture are a, b, c, and d respectively, then at that moment  $v_1 = k_1 ab$  and  $v_2 = k_2 cd$  The observed between  $v_1$  and  $v_2$  If now the change has proceeded at constant temperature until the equilibrium position is reached, and the concentrations of the four substances are ae, be, ce, and  $d_e$  respectively, then  $v_1 = k_1 a_e b_e$ , and  $v_2 = k_2 c_e d_e$ . Since there is equilibrium, the forward reaction is exactly balanced by the back reaction, so that  $v_1 = v_2$  and  $k_1 a_e b_e = k_2 c_e d_e$ , or  $k_1 = \frac{c_e}{a_e} \frac{d_e}{b_e}$  If the ratio  $\frac{k_1}{k_2}$  is replaced by the one constant K, we have  $K = \frac{c_e}{a_e} \frac{d_e}{b_c}$ . K is known as the equilibrium constant, and its numerical value defines the relationship and its numerical value defines the relationship which must exist between the equilibrium concentrations of the substances involved in a reversible reaction The argument employed above might obviously be extended to reversible reactions other than  $A+B \rightleftharpoons C+D$  · the result in all cases would be an equilibrium formula involving a constant ratio between the product of the equilibrium concentrations of the substances on the right side and the product of the equilibrium concentrations of the substances on the left side, however the values of these concentrations might vary individually - It ought, perhaps, to be pointed out here that, in the equilibrium formula, the concentration of any substance, n molecules of which take part in the reaction, must be raised to the nth power.

In discussing the application of the law of mass action to reversible reactions with the help of the equilibrium formula, we shall deal first with cases in which the reaction system is homogeneous As an example, the equilibrium between carbon dioxide, hydrogen, carbon monoxide, and water vapour may be considered, the reaction in question is represented by the equation  $CO_2 + \hat{H}_2 \gtrsim CO + H_2O$ , and is obviously of the type A+B C+D In Hahn's investigation of this equilibrium (Zeitsch physikal. Chem 1903, 44, 513), platinum was used as a catalytic agent, and on this ground the objection might be raised that the reaction as studied by that investigator is not really homogeneous. A true catalytic agent, however, as will be shown in greater detail at a later stage, does not affect the position of equilibrium in a reversible reaction, but merely lessens the time required for the attainment of equilibrium. The reaction which takes place between carbon dioxide and hydrogen, or between carbon monoxide and water vapour in contact with platinum, may therefore be regarded as a homogeneous reaction. In Hahn's experiments, mixtures of the gases were passed through a resultant of two opposed velocities, one the velocity  $(v_1)$  with which the substances on the left spongy platinum. Provided that the rate of

passage was slow enough to allow the four gases | to come into equilibrium with each other, analysis of the issuing gas gave the equilibrium concentrations,  $C_{CO_2}$ ,  $C_{H_2}$ ,  $C_{CO}$ , and  $C_{H_2O}$ . The relationship between these required by the law of mass action is  $K = \begin{pmatrix} C_{OO} & C_{H_2O} \\ C_{OO_2} & C_{H_2} \end{pmatrix}$ , and the validity of the law in the case of this reaction is shown by the fact that the value of K obtained is, for a given temperature, the same when carbon dioxide and hydrogen, in varying proportions, are allowed to react, as when carbon monoxide and water vapour are taken as the initial sub-A few figures obtained by Hahn at stances 986° will serve to support this statement Mixtures of carbon dioxide and hydrogen, in the proportions shown in the following table, were passed through the reaction vessel, and from analysis of the issuing gas the values of K were calculated by the above formula

Initial	mixture	Equilibrium mixture			
$CO_2$	$H_2$	('O <sub>2</sub>	('O=H2	O H <sub>2</sub>	K
10 Ï	89 9	0.70	9 46	80 38	1.59
30.1	69 9	7 18	$23\ 00$	46.82	1.58
49 1	51.9	$21\ 36$	27.88	22.88	1.59
60 9	39.1	34 20	$26 \ 61$	12.58	1 64
70.3	297	47.66	22.79	6.76	1.61

Experiments were made, also at 986°, in which the initial mixture contained carbon monoxide and water vapour the mean value of K, deduced from these experiments, was 155, slightly lower than the average of the figures recorded in the table. The discrepancy, however, is not great, and the numerical data quoted suffice to show that the balance established between the four gases, whatever be their initial concentrations, is adequately defined by the mass action formula

A reversible reaction of great technical importance is the one which forms the basis of the sulphuric acid contact process

and consideration of this case from the standpoint of the mass action law throws light on many points connected with the process. The reaction may be regarded as a homogeneous one, for the catalysts used in the technical process do not affect the final balance between the gases, but only accelerate the attainment of equilibrium

The application of the law of mass action, in

this case, leads to the result  $\frac{\binom{2}{80_3}}{\binom{2}{80_2}\binom{6}{0_2}} = \text{const}$ , in which  $\binom{C}{80_3}$ ,  $\binom{C}{80_2}$ , and  $\binom{C}{0_2}$  are the equilibrium concentrations of the respective substances. It is convenient, however, to work with the re-ciprocal of the foregoing expression, and to regard the equilibrium constant as defined by

 $K = \frac{C_{SO_2}^2 \cdot C_{O_2}}{C_{SO_2}^2}$  The accuracy of this formula may be tested with the help of the experimental data obtained by Bodenstein and Pohl (Zeitsch.

Elektrochem. 1905, 11, 373) These investigators passed a mixture of sulphur dioxide and oxygen over spongy platinum, contained in heated quartz tubes, and determined the equivor. II.—T.

librium concentrations by analysing the issuing gas. The figures in the following table, obtained at 727°, show that the value of K, worked out from the equilibrium concentrations, is independent (1) of the relative proportions of sulphur dioxide and oxygen passed into the apparatus, (2) of the presence or absence of introgen—

Initial gas ratio	
SO <sub>2</sub> O <sub>2</sub> N <sub>2</sub>	K×10
0 21 . 1 . 0	349
0.62:1 0	3 59
1 20 1 0	3.48
168 1 0	3 51
$3.97 \cdot 1 \cdot 0$	3 67
1 23 . 1 3 76	3 60
$1\ 31:1\cdot 3\ 76$	3 54
$1.55 \cdot 1 \cdot 3.76$	3.52

The experiments showed also that the value of K obtained for a particular gas mixture was independent (1) of the direction in which the equilibrium position was approached, (2) of the rate at which the gaseous mixture was passed over the catalyst. The latter result is the guarantee that the equilibrium position was really attained.

Similar results were obtained at various other temperatures, and it was found that the value of K increased rapidly with rising temperature, as shown by the following figures —

Temp C	K×10
$528^{\circ}$	0.013
$579^{\circ}$	0.077
$627^{\circ}$	0.32
680°	1 12
$727^{\circ}$	3 54
$789^{\circ}$	12 6
832°	28 0
897°	81.6

This increase means that, as the temperature rises, the position of equilibrium is shifted in favour of the system  $2SO_2 + O_2$ , in other words, the dissociation of sulphur trioxide becomes greater For each set of conditions, the extent of the dissociation is defined by the corresponding numerical value of K, deduced from a formula based on the foregoing table It is possible, then, for a given temperature and given proportions of sulphur dioxide, oxygen and nitrogen in the initial gaseous mixture, to calculate what will be the relative quantities of trioxide and dioxide in the equilibrium mixture, that is, to calculate the 'yield' obtainable The results of such calculations for various proportions of the gases and for various temperatures, are embodied in the following table numbers recorded in the last four columns are the percentages of sulphur dioxide convertible into sulphur trioxide under the specified conditions :-

Initial gaseous mixture SO<sub>2</sub> O<sub>2</sub> N<sub>2</sub> 400° 500° 10 1 p c 5 05 p c 84 85 p c 96 2 83 2 59 I 319 70 100 83 0 99 3 93.4 73.3 42 5 14.6 814 99.4 94.9 78.3 48.1 40 800 99 5 95 6 80 5 51 3 180

oxygen over spongy platinum, contained in These figures bring out clearly one other point heated quartz tubes, and determined the equi-

the influence of the partial pressure of the oxygen. If the equilibrium formula is written in the form

$$\frac{\mathrm{C_{80_{3}}^{8}}}{\mathrm{C_{80_{3}}^{2}}} = \frac{1}{\mathrm{K}} \cdot \mathrm{C_{0_{2}}} \text{ or } \frac{\mathrm{C_{80_{3}}}}{\mathrm{C_{80_{3}}}} = \frac{1}{\sqrt{\mathrm{K}}} \cdot \sqrt{\mathrm{Co_{2}}}$$

it is plain that the yield at a given temperature can be raised by increasing the partial pressure of the oxygen, and this conclusion is borne out by the foregoing table. The figures show also that the lower the temperature the better is the yield, but it must be remembered that from the technical point of view the time necessary for the attainment of equilibrium is also an important consideration. Fortunately, with platinum as catalyst, the union of sulphur dioxide and oxygen takes place with satisfactory rapidity, even at temperatures as low as 400°-500°, at which the dissociation of the trioxide is comparatively slight. With less active catalysts, however, such as ferric oxide, a higher temperature is required to secure a satisfactory velocity of reaction, and this involves a reduction of the obtainable yield.

Another reaction which is of exceptional interest from the standpoint of chemical equilibrium, and which has assumed great technical importance in recent years, is the synthesis of ammonia from nitrogen and hydrogen Although, as Deville showed 50-60 years ago, even prolonged exposure of ammonia to electric sparks leaves a trace of the gas undecomposed, and a minute quantity of ammonia is formed, when a mixture of nitrogen and hydrogen is passed through a heated tube, it was not until the early years of the present century that the reversibility of the reaction was properly appreciated and an attempt made to apply the principles of chemical equilibrium. The physico-chemical investigation of the equilibrium N<sub>2</sub>+3H<sub>2</sub> 2NH<sub>3</sub> has been carried out mainly by Haber and his collaborators (see Zeitsch. Elektrochem 1914, 20, 597; 1915, 21, 89 128, 191, 206, 228, 241), but this research, conducted originally on purely scientific lines, has developed in a remarkably short space of time into a large scale process for the production of ammonia from its constituent elements

Granted that there is a genuine equilibrium between nitrogen, hydrogen, and ammonia, Le Chatelier's principle indicates clearly that at any given temperature increase of pressure will shift the equilibrium position in favour of ammonia. The formulation of the equilibrium constant gives definite expression to this pressure effect, and for the present purpose the equilibrium concentrations of nitrogen, hydrogen and ammonia, but in terms of their equilibrium partial pressures  $p_{N_2}$ ,  $p_{\Pi_2}$ , and  $p_{NH_3}$ .

On this basis  $\frac{p_{NH_3}^2}{p_{N_3} \cdot p_{H_2}^3}$  has a constant value at a given temperature, or alternatively,

$$\mathbf{K} = \frac{p_{\mathbf{NH_3}}}{p_{\mathbf{N_2}}^{\frac{1}{2}} \cdot p_{\mathbf{H_2}}^{\frac{1}{2}}}$$

Since at high temperatures the equilibrium concentration of ammonia is relatively small no

great error is made, subject to that condition, by writing  $p_{\rm N_2}+p_{\rm H_2}={\rm P}$ , where P is the total pressure. If, further, the nitrogen and hydrogen have been taken in the exact proportions required by the chemical equation,  $p_{\rm H_2}=3p_{\rm N_2}$ . When these relationships are coupled with the expression for the equilibrium constant it follows that  $p_{\rm NH_3}=0.325{\rm K}\times{\rm P}^2$ . Hence, for low concentrations of ammonia, the partial pressure of this gas in the equilibrium mixture is proportional to the square of the total pressure

If x is taken to represent the volume percentage of ammonia in the equilibrium mixture,

 $x=\frac{p_{\rm NH_3}}{P}\times 100=32~5{\rm K}\times {\rm P}$  This relationship, according to which the volume percentage of ammonia, for low concentrations, should be proportional to the total piessure, is confirmed, for example, by some of Haber's experiments at  $800^\circ$ , in which for P=1 atmosphere, x was found to be 0 012, while for P=30 atmospheres x was 0 34

The shift of the ammonia equilibrium with temperature is shown very clearly by the following table, in which the values of K, based on measurements carried out at a pressure of 30 atmospheres, are recorded for a number of temperatures—

$$t^{\circ}$$
 C 561° 620° 700° 722° 801° 901° 952° K  $\times$  104 21 3 12 6 6 80 5 82 3·56 2·13 1·68

From the graph based on the foregoing values it is possible to work out for various even temperatures and even pressures the maximum quantities of ammonia obtainable by the interaction of introgen and hydrogen under various conditions. A selection of such figures, constituting a summary of the influence of pressure and temperature on the ammonia equilibrium, is embodied in the following table (valid for I vol introgen + 3 vols hydrogen):—

## EQUILIBRIUM PERCENTAGE OF AMMONIA

Temp	at	at	at	at
Cent.	1 atmo	30 atmos	100 at mos	200 at mos
400°	0.44	10 7	25 1	36.3
500°	0 129	362	10 4	17 6
$600^{\circ}$	0 049	1 43	4.47	8.25
$700^{\circ}$	0.022	0 66	2 14	4 11
800°	0 012	0 35	1.15	2 24
$900^{\circ}$	0.0069	0.21	0.68	1 34
1000°	0 0044	0 13	0 44	0 87

From the figures just quoted it is clear that the highest percentage conversion of nitrogen and hydrogen into ammonia is secured by working at a high pressure and a low temperature. In large-scale work, however, there is obviously a limit to the practicable pressure, and the pressure commonly employed in the technical process has been 150–200 atmospheres. A lower limit is likewise set to the temperature which can profitably be employed in practice by considerations of velocity. By themselves, nitrogen and hydrogen combine very slowly at temperatures below 1000°, and it is only in the presence of catalysts, such as osmium, uranium, and iron that the reaction is reasonably rapid at temperatures where the yield of ammonia is moderately satisfactory. A big yield and a

high velocity of reaction cannot be achieved simultaneously, and a balance has to be struck at the temperature which gives the best economic results. On the technical scale the temperature employed is generally 500°-600° C., and the mixed compressed gases are circulated over the heated catalyst in such a way that the ammonia formed is continuously removed by refrigeration or absorption It should be pointed out that in the manufacturing operation the rate of passage of the gases over the catalyst may be too rapid to permit the reaching of equilibrium at each stage, it may be economically preferable to mcrease the rate of circulation and to be satisfied with a correspondingly smaller conversion at each contact with the catalyst (see Maxted, J Soc Chem. Ind. 1918, 37,

Many other dissociation equilibria, similar in type to the cases just discussed, have been successfully attacked from the standpoint of the law of mass action. One instance is the equilibrium N<sub>2</sub>O<sub>4</sub> ≥2NO<sub>2</sub>, a case in which a physical method, namely, the determination of the vapour density, must be employed to find the relative proportions of the reacting substances in the equilibrium mixture. Obviously, no direct chemical method of analysis is permissible in any case where the equilibrium shifts rapidly at the ordinary temperature, for such analysis involves the removal of one of the substances involved, and this at once upsets the equilibrium.

Another technically important reaction, studied from the standpoint of the mass action law, is that which forms the basis of the Deacon process (see von Falckenstein, Zeitsch physikal Chem 1907, 59, 313, 1909, 65, 371) When a mixture of hydrogen chloride and air is passed through a heated chamber containing bricks impregnated with cupric chloride, the hydrogen chloride and oxygen react, producing chlorine and water vapour, but the reaction comes to a stop before all the hydrogen chloride disappears; the reaction, in fact, is a reversible one, and may be represented thus

Experiments have shown that the equilibrium is defined by an equilibrium constant

$$K = \frac{C_{Cl_2}^2 \cdot C_{H_2O}^2}{C_{HOl}^4 \cdot C_{O_2}}$$

the value of which, at a given temperature, is the same, whether the initial gaseous mixture taken is hydrogen chloride and oxygen (air), or chlorine and water vapour. The value of K diminishes as the temperature rises, hence the extent to which hydrogen chloride can be converted into chlorine also diminishes with rising temperature. If x represents the fraction of hydrogen chloride convertible into chlorine, then the value of x can be calculated for any given temperature from the corresponding value of K and the partial pressure of the oxygen. For a dry mixture of 76·1 p.c. HCl and 23·9 p.c.  $O_2$ , the value of x is 0.865 at  $352^\circ$ , 0.79 at  $430^\circ$ , and 0.55 at  $650^\circ$ . If air is substituted for oxygen so that the x-ratio of hydrogen chloride and oxygen remains the same, the value of x is 0.71 at  $430^\circ$ . This is approximately the temperature employed

in the technical process, and the yield obtained is about 70 p.c. The use of lower temperatures, which would increase the yield, is precluded practically because of the much longer time required for the attainment of equilibrium

The cases of equilibrium discussed so far have been those in which gases alone are involved. There are, however, many homogeneous reversible reactions in which liquid or dissolved substances take part. A classical example is the reaction between ethyl alcohol and acetic acid, represented thus:

If I mol of acid and I mol of alcohol are heated in a scaled tube at 100° for a sufficient time, examination of the reaction mixture shows that it contains \{ \} mol each of acid and alcohol, and \{ \} mol. each of ester and water. If then I mol of ester and I mol of water are mixed and treated in the same way, the equilibrium mixture finally obtained has the same composition as in the first case. The reaction therefore is truly reversible and the equilibrium constant

is given by the equation  $K = \frac{C_e}{C_{ac}} \frac{C_w}{C_{al}}$ , where  $C_e$ ,  $C_w$ ,  $C_{ac}$ , and  $C_{al}$  are the equilibrium concentrations of the four substances. If v represents the volume of the equilibrium mixture in litres, then for the case where 1 mol. each of acid and alcohol are taken initially  $C_e = C_w = \frac{2}{v}$  and  $C_{ac} = C_{al} = \frac{1}{v}$ , whence K = 4. It should be pointed out that the composition of the

be pointed out that the composition of the equilibrium mixture may safely be determined by titrating the free acetic acid, for the velocity of the reaction between ethyl alcohol and acetic acid is negligibly small at ordinary temperatures

If the law of mass action is strictly applicable to the reaction under consideration, then the value of K obtained in experiments in which alcohol and acid are taken in other than molecular proportions should also be 4. Suppose, for instance, that m mols of alcohol are allowed to act on 1 mol of acid, and that after equilibrium has been reached, the fraction x of a mol of ester has been produced; then  $C_a = C_{ty}$ 

mod of ester has been produced; then 
$$C_e = C_w$$

$$= \frac{x}{v}, \quad C_{ac} = \frac{1-x}{v}, \text{ and } C_{al} = \frac{m-x}{v}; \text{ so that } K$$

 $= \frac{x^{-}}{(1-x)(m-x)}.$  Instead of seeing whether the insertion of the known values of m and x in this formula gives the value 4 for K, the applicability of the mass action law may be tested by taking K=4 and ascertaining whether the value of x calculated by the formula for a given value of x is in agreement with the value of x determined experimentally. This procedure has been adopted in the actual investigation of the case, with the following results:—

m	$\boldsymbol{x}$ found	x calc.
0.08	0.078	0 078
0 28	0 226	0.232
0.50	0.414	0.423
0.67	0.519	0.528
1.2	0.819	0 785
2.24	0 876	0.864
8.0	0.966	0.945

The excellent agreement of the figures in the second and third columns furnishes a convincing proof of the applicability of the law of mass action. The influence of 'mass' or concentration in affecting equilibrium is very clearly illustrated by the numbers quoted in the table, for it will be observed that when the amount of alcohol is great compared with the amount of acid, the latter is almost quantitatively converted into ester, in other words, the 'yield' of ester from acid is nearly theoretical

According to a widely accepted view, an electrolyte dissolved in water is dissociated into positively and negatively charged particles, called ions, and investigation of the conductivity of electrolytic solutions and of the abnormal effect of electrolytes on the freezing-point and boiling-point of water supports the contention that the degree of this ionic dissociation increases with the dilution of the solution, and diminishes when the solution becomes more concentrated. The equilibrium, therefore, between the undissociated molecule of an electrolyte and the ions may be regarded as reversible

and can be represented thus:  $AB \rightleftharpoons A + B$  If this view is correct, then, as Ostwald pointed out, the equilibrium should be governed by the law of mass action, and the relationship between the

concentrations of AB, A, and B at a given temperature must be defined by an equilibrium constant. Suppose, for instance, that acetic acid is the electrolyte in question, then the equilibrium is represented by

$$CH_3 COOH \rightleftharpoons CH_3 COO + \overset{\leftarrow}{H}$$
 and the equilibrium formula will be  $K = \overset{C_1}{C_2} \overset{C_2}{C_3}$ 

where C, C1, and C2 are the concentrations of

the undissociated molecules and of the two ions respectively Since, however, the ions are produced in equivalent quantities, C<sub>1</sub>=C<sub>2</sub> and  $K = \frac{C_1^2}{C}$ . If we are dealing with a solution containing I gram-mol of acetic acid in V litres of solution, and if we take a to indicate the fractional extent to which the molecules are dissociated, then in V litres there is  $1-\alpha$  gram-mol of undissociated acetic acid, and accordingly  $C = \frac{1-\alpha}{V}$ . Similarly,  $C_1 = \frac{\alpha!}{V}$ , so that  $K = \frac{\alpha^2}{(1-\alpha)V}$ . For all binary electrolytes which, like acetic acid, dissociate into two ions, exactly the same formula would be obtained. The equation is the algebraic expression of what is known as Ostwald's Dilution Law, and K is usually termed a dissociation constant or an ionication constant: it is also called an affinity constart

The determination of  $\alpha$  is based on the relationship  $\alpha = \frac{\Lambda}{\Lambda_{\infty}}$ , where  $\Lambda$  is the equivalent conductivity of the electrolyte at the dilution V, and  $\Lambda_{\alpha}$  is the limiting maximum value of the equivalent conductivity. The application of the law of mass action to the equilibrium between acctic acid and its ions and to other similar cases is justified by the fact that the value of  $(1-\alpha)V$  is independent of the dilution at a given temperature. In support of this

statement, the following figures for acetic acid may be quoted:—

v	$K \times 10^6$
16	1.79
32	1 82
64	1 79
128	1 79
256	1.80
512	1.80

An equally satisfactory constancy of the expression  $\frac{\alpha^2}{(1-\alpha)V}$  has been observed in the case of all acids and bases which are dissociated to a comparatively small extent, and for these the validity of Ostwald's Dilution Law may be regarded as established. For some reason, however, which has not yet been adequately explained, highly dissociated electrolytes, such as strong acids and bases and neutral salts, do not obey Ostwald's Dilution Law, aithough in the case of potassium chloride Weiland (J. Amer Chem. Soc. 1918, 40, 131) seems to have established the validity of the law for this compound at extreme dilutions

Keeping in view this limitation to the validity of the formula  $K = \frac{a^2}{(1-a)V}$ , we may ask What is the significance of the constant K? The answer will be plain if two feebly dissociated acids, HA<sub>1</sub> and HA<sub>2</sub>, are compared at the same dilution V Since the acids are feebly dissociated, it is a very close approximation to the truth to put  $1-a_1=1$  and  $1-a_2=1$ , so that  $K_1=\frac{a_1^2}{V}$  and  $K_2=\frac{a_2^2}{V}$  A comparison of the equations shows that the relative value of the dissociation constants is closely related to the degree of dissociation; to put it generally, the dissociation constant is a measure of the ability of an acid to yield hydrogen ions, which, according to the modern view, are responsible for the characteristic properties of acids The value of K for an acid is, therefore, a measure of its strength, of its power to manifest those properties which are associated with acids set of cucumstances in which the relative strength of two acids is an important factor is realised when one gram equivalent of a base, such as sodium hydroxide, is added to a solution containing one gram equivalent of each of the two acids. The base is insufficient to neutralise both acids, and the result is a competition between the two acids, each securing a fraction of the base A theoretical discussion of this problem shows that if x is the fraction of the base appropriated by the first acid  $HA_1$ , and 1-x accordingly the fraction appropriated by the other acid HA2, then, provided the dilu-K, tion is not too great,  $\frac{x}{1-x} = \sqrt{\frac{K_1}{K_2}}$ . If, therefore, the values of  $K_1$  and  $K_2$  have been

HA<sub>1</sub> HA<sub>2</sub> z calc. z found
Dichloracetic acid Lactic acid 0.95 0.76

Butyric acid 0.54 0.53

determined in the way already described, it is

possible to calculate the distribution of the available base between the two competing acids.

That this can be done in good agreement with

experiment is shown by the following figures .-

It is evident, then, that a knowledge of the dissociation constant of an acid enables us to calculate relatively the affinity or avidity of this acid for a base. There are other methods for ascertaining the relative affinity or avidity of an acid, methods available in the case of strong acids which do not obey the dilution law, and to which, therefore, no definite value of K can be Among these methods are the determination of the heat effects accompanying neutralisation (Thomsen), the measurement of the density changes (Ostwald), and the study of the influence of acids in accelerating the inversion of sucrose or the hydrolysis of methyl The order of magnitude of the values obtained by these and other methods for the relative affinity of acids is the same, as will be seen by an inspection of the following table -

		deduced from	
Acid	K×100	Sucrose	Density

СН, СООН	0 0018	04	1

The manner in which a dissociation equilibrium is affected by excess of one of the products of dissociation has already been referred to in connection with the sulphuric acid contact process. It was there shown that as the equilibrium concentration of the oxygen is increased, so the extent to which the sulphur dioxide is converted into trioxide is increased also other words, the dissociation of sulphur trioxide into sulphur dioxide and oxygen is diminished in presence of excess of oxygen, one of the products of dissociation An analogous statement may be made in connection with the electrolytic dissociation of an electrolyte, such as acetic acid. If to a solution of this acid a quantity of CH<sub>3</sub> COO ions is added, the dissociation of the acid is diminished to a large extent, ie the concentration of the hydrogen ions is very much reduced, and the acid character of the solution almost disappears. It is true that CH, COO ions cannot be added by themselves, but a solution of the sodium salt of acetic acid serves the purpose, for such a salt, to judge from its conductivity, is highly dissociated into CH<sub>3</sub>·COO ions and sodium ions That the effective acidity of an acetic acid solution almost disappears on the addition of a little sodium acetate solution is very clearly seen by comparing the effects of (1) the acetic acid solution, (2) the acetic acid solution + sodium acetate, on the inversion of sucrose It has been found that the velocity of inversion in presence of

$$\frac{N}{4}$$
CH<sub>2</sub>·COOH+ $\frac{N}{4}$ CH<sub>3</sub> COONa

in about  $\frac{1}{75}$  what it is in the presence of  $\frac{N}{4}$  CH<sub>8</sub>COOH alone. Not only is this influence of a neutral salt on the effective acidity of a weak acid to be expected on the basis of the mass action law, but it has also been found possible, with the help of the equilibrium formula, to

calculate accurately the effect produced by adding any given quantity of the neutral salt.

The cases of equilibrium so far discussed have been those which occur in homogeneous systems, but there are numerous cases also of non-homogeneous or heterogeneous equilibrium. The bearing of the law of mass action on reversible reactions of this character will be most readily appreciated by considering one or two examples. The dissociation of calcium car-If this bonate may be taken in the first place substance is heated to 750° in a closed space, it breaks up to some extent into calcium oxide and carbon dioxide: if, on the other hand, carbon dioxide at atmospheric pressure is passed over calcium oxide, heated to the afore-mentioned temperature, the reverse action takes place and calcium carbonate is formed That is to say, an equilibrium is established which may be represented thus  $CaCO_3 \gtrsim CaO + CO_2$ . applying the law of mass action to this case, we are confronted with the question. What is the concentration or 'active mass' of a solid taking part in a reaction? An answer to this question may be reached by supposing that in the gaseous phase of the reaction system there is equilibrium between the calcium carbonate, the calcium oxide, and the carbon dioxide, that is, each of the solid substances concerned in the reaction is supposed to have a definite, if infinitely small, sublimation pressure at a given temperature, and therefore to be represented in the gaseous phase On this basis, the equilibrium at a given temperature would be governed by the formula  $K_1 = \frac{C_1C}{C_1}$ , where  $C_1$ ,  $C_2$ , and C are the equilibrium concentrations of calcium carbonate, calcium oxide, and carbon dioxide in the gaseous phase, respectively If partial pres-

sures are employed instead of concentrations, the formula would be  $K = \frac{\pi_2 \pi}{\pi_1}$ . Now  $\pi_1$  and  $\pi_2$ ,

being sublimation pressures, have fixed values at a given temperature, and are independent of the absolute amounts of calcium carbonate and calcium oxide present. Hence  $\pi = const$ , and since  $\pi_1$  and  $\pi_2$  are negligibly small,  $\pi$ , the partial pressure of the carbon dioxide, is practically equal to p, the total pressure exerted by the system, so that we may write  $p=\mathrm{const}$  The application, therefore, of the law of mass action to the dissociation of calcium carbonate leads to the result that at each temperature the reaction system exerts a definite pressure—the dissociation pressure, as it is termed. This statement is valid only on the understanding that the substances involved in the reaction are kept in contact with each other; if provision is made for keeping the pressure of the carbon dioxide permanently below or above the equilibrium value, then a reaction proceeds until the calcium carbonate (in the first case) or the calcium oxide (in the second case) has disappeared By artificial alteration of the pressure at constant temperature, therefore, any reaction of the same type as CaCO<sub>3</sub>  $\gtrsim$  CaO+CO, may be made to proceed either from left to right, or vice versa. The reaction 2BaO<sub>2</sub> ≥ 2BaO+O<sub>2</sub> is also a case where two solids and a gas are in equilibrium

with each other, and it may be treated in the same way as the dissociation of calcium carbonate.

Perhaps the chief point that emerges from the foregoing is that the active mass of a solid taking part in a chemical reaction is constant. The correctness of this conclusion has been confirmed by the investigation of various heterogeneous reactions different in type from the dissociation of calcium carbonate One of these may be considered here, viz. the equilibrium  $3\text{Fe}+4\text{H}_2\text{O} \gtrsim \text{Fe}_3\text{O}_4+4\text{H}_2$ by (see Deville, Compt. rend 1870, 70, 1105, 1201, 71, 30; Preuner, Zeitsch physikal. Chem. 1904, 47, 385) On the assumption that the active masses of the iron and the iron oxide are constant, the application of the law of mass action

obviously leads to the result 
$$\frac{p_{\rm H_2O}}{p_{\rm H_0}} = {\rm const}$$
 ,

 $p_{\rm H_{2}O}$  and  $p_{\rm H_{2}}$  being the partial pressures of the water vapour and the hydrogen when equilibrium has been established at a definite temperature. This relationship is verified by the experimental results, some of which are quoted in the following table. The experiments consisted in exposing iron in an electrically heated closed system to the action of water vapour kept up to a constant pressure  $(p_{\rm H_{2}O})$ . From the total pressure reached at equilibrium— $p_{\rm H_{2}O}+p_{\rm H_{2}O}+p_{\rm$ 

$p_{_{\mathrm{H_2O}}}$	$p_{_{ m H_2}}$	$\frac{p_{_{\rm H_2O}}}{\overline{p_{_{\rm H_2}}}}$
8 8	13 5	0 65
12 7	18 0	0.71
21 5	30 6	0.70
35 0	52.0	0 67
49:3	71.8	0.68

When the difficult nature of the experiments is taken into account, the numbers in the last column may be regarded as satisfactorily constant and as demonstrating the applicability of the mass action law to this case. Although in a closed system an equilibrium is reached in the way described, yet if provision is made for removing the hydrogen as fast as it is formed, and thereby keeping its partial pressure permanently below the equilibrium value, the reaction will proceed until the iron is all converted into oxide

There are many reversible reactions involving a solid substance and a liquid, or a solid and a dissolved substance. Here also the active mass of the solid is constant at a given temperature, solubility and sublimation pressure being analogous quantities. The equilibrium formula undergoes, therefore, a similar simplification to that illustrated in the foregoing paragraphs

that illustrated in the foregoing paragraphs.

Influence of Temperature.—In general, a reaction system which is in equilibrium at a given temperature is no longer in equilibrium when the temperature is altered. A measure of this influence of temperature on chemical equilibrium is found in the change of the equilibrium

constant, and an illustration of the extent to which K may change with temperature has already been given in connection with the oxidation of sulphur dioxide to trioxide. The exact relationship between temperature and equilibrium is defined by a formula associated with the name of van't Hoff, according to which  $d(\log_e K)$ 

 $r' = -\frac{1}{RT^2}$ . The symbol K is the equilibrium constant, that is, the ratio between the product of the equilibrium concentrations of the substances on the right side of the equation and the product of the equilibrium concentrations of those on the left side; q is the heat evolved when the reaction goes completely from left to right, T is absolute temperature, and R is the gas constant The theoretical basis of van't Hoff's formula need not be discussed here, but one or two points involved in it may be indicated. It is evident, in the first place, that when the heat effect of a reversible reaction is small, the variation in K is also small, i e. the position of equilibrium is but slightly shifted on altering the temperature. An instance of this is furnished by the reversible reaction between ethyl alcohol

and acetic acid. Again, if q is positive,  $\frac{d}{dT}$  is negative, so that K diminishes with rising temperature, corresponding to a shifting of the equilibrium in favour of the substances on the left side of the equation. If, on the other hand,

 $d(\log_e K)$ 

$$q$$
 is negative,  $\frac{(d\log_e \mathbf{K})}{d\mathbf{T}}$  is positive, and a rise of

temperature, therefore, involves a displacement of the equilibrium in favour of the substances on the right side of the equation. It will be observed that in both cases, whether q is positive or negative, a rise of temperature involves a shifting of the equilibrium in the direction which means absorption of heat

As an illustration of the applicability of van't Hoff's formula in an individual case, the reaction  $2SO_3 \geq 2SO_2 + O_2$  may be taken From the values of the equilibrium constant obtained for this reaction at different temperatures (see p. 161), the values of q over narrow intervals of temperature were calculated by the formula. It was found that q is a linear function of the temperature, and may, in fact, be represented by the equation q = -47300 + 4". If this expression for q is inserted in the formula  $\frac{d(\log_2 K)}{dT} = -\frac{q}{RT_2}$ , and the equation is integrated, the following formula is obtained.—

$$\log_{10}\mathrm{K} \!=\! -\frac{10373}{\mathrm{T}} \!-\! 2\ 222\ \log_{10}\!\mathrm{T} \!+\! 14\ 585$$

The relation between K and T expressed in this formula is almost exactly that observed in the experimental investigation: this appears from the following figures:—

t∘ C	log K found	log K calc.

832	-1553	-1573
897	-1089	-1.083

Catalysis. No discussion of reaction velocity or chemical equilibrium would be complete without a reference to the phenomenon of catalysis. It very frequently happens that a chemical reaction, which of itself is extremely sluggish, proceeds with comparative rapidity in presence of some foreign substance—a catalyst, as it is called. Cases of such an acceleration of a chemical reaction have long been known, and in both laboratory and technical processes catalysts are in common use

A rational quantitative study of catalysis is possible only on the basis of the law of mass action. In the velocity coefficient, as already explained, we have a definite measure of the rate of a chemical change under given conditions For a given reaction, therefore, which is catalytically accelerated, the value of the velocity coefficient at a given temperature is a measure of the efficiency of the catalyst, and by comparing the values obtained for the velocity coefficient in different experiments, one can find out how the efficiency of a catalyst varies with the conditions under which it works, and how the efficiency of one catalyst compares with that of another working under the same conditions

General Characteristics of Catalysts -One very common and striking feature of catalysis is that the quantity of the catalyst is so small compared with the quantities of the main reacting sub-As a rule, too, the activity of the catalyst at the end of the reaction which it has accelerated is unimpaired. An illustration of these features of catalysis is furnished by the influence of colloidal platinum in promoting the union of hydrogen and oxygen at the ordinary temperature. In some experiments made by Bredig, 25 c c of colloidal platinum solution (containing 017 milligram of platinum) were shaken with electrolytic gas, with the following results -

Time in minutes 10	Decrease in the volume of gas 17 8 c c	Decrease per minute 1 78
20	358 ,,	1 80
30	548 ,,	1 90
40	72.4 ,,	1 76
50	90 2 ",	1 78

The average of the figures in the last column is a measure of the catalytic efficiency of the colloidal platinum in the early stages of its The same colloidal platinum was activity. then shaken intermittently during 14 days with the mixture of hydrogen and oxygen, about 10 litres of which disappeared in this time. Not only is the contrast between the minute quantity of the catalyst and the extent of the induced change sufficiently striking, but a determination of the actual rate of disappearance of the gas at the end of the 14 days showed that the rate of decrease, measured over successive 10-minute intervals, was 2 02, 1 87, 1 95, 1.97, and 2.01 cc. per minute From these figures it is obvious that the catalytic efficiency of the colloidal platinum is unimpaired. connection with this case, however, the objection might be raised that hydrogen and oxygen do not combine at the ordinary temperature, and that the platinum ought to be regarded, not as accelerating a change which would take place in its absence, but as actually initiating the re-

The answer is that at 500° hydrogen action and oxygen combine with appreciable iapidity in the absence of a catalyst, but that, in view of the large temperature coefficient of reaction velocity, the rate of union naturally becomes insignificant even at 400°, whilst at ordinary temperatures the two gases appear not to react There is, however, no reason to suppose that there is a definite temperature below which absolutely no combination takes place

The mere fact that the amount of a catalyst may be almost infinitely small compared with the amounts of the substances changed under its influence, shows that the final state of the reactive system must be independent of the catalyst, in particular, if the accelerated reaction is reversible, the state of equilibrium finally attained must be the same as when no catalyst is present. The catalyst, that is, influences only the rate at which the condition of equilibrium is reached, not the position of equilibijum itself Experimental evidence in favour of this proposition is supplied by Turbaba's investigation of the relationship between aldehyde and paraldehyde. The conversion of pualdehyde into the equilibrium mixture, which at 50 5° contains 33 9 pc aldehyde, is accompanied by an expansion, and the course of the change may therefore be followed by means of a dilatometer Various substances accelerate the change, but the difference between the initial and final volumes, as shown by the following figures, is independent of the nature and the amount of the catalyst -

Catalyst Sulphur dioxide	Per cent of catalyst 0 08	Percentage increase of volume 8 20
,, ,	0 07	8 34
,, ,,	0.002	8 19
Zinc sulphate	27	8 13
Hydrochloric acid	0.13	8 13
Oxalic acid	0.25	8.27
Phosphoric acid	0.54	8 10

If the position of equilibrium in a reversible reaction is independent of the catalyst, then K, the equilibrium constant, must be similarly Further, since  $K = \frac{k_1}{k_2}$ ,

mdependent.

 $k_1$  and  $k_2$  are the velocity coefficients of the forward and back reactions, it follows that the catalyst must accelerate the forward and the back reaction in the same proportion. This has been demonstrated in connection with the catalytic effect of acids on the action between an acid and an alcohol and the reverse change. It should further be pointed out that the amount of energy transformed during a chemical change, being dependent only on the initial and final states of the system, is independent of the The latter may be compared to the

energy derivable from the fall of the weight. Another point of great interest is the relationship between the value of the velocity coefficient for a given reaction at a given temperature and the concentration of the catalyst. In many cases the relationship is a linear one The rate of inversion of sucrose by acids, for instance, is proportional to the concentration of

oil which facilitates the sliding of a weight down an inclined plane, without affecting the total

the hydrogen ions, provided that this concentration is low, on the basis of this proportionality, in fact, it is possible to calculate the velocity of inversion by dilute acetic acid from the velocity observed with dilute hydrochloric acid. In other cases, however, the relationship between reaction velocity and concentration of catalyst is not a linear one. The decomposition of hydrogen peroxide under the influence of colloidal platinum is an illustration of this The course of the decomposition can be followed by extracting a definite volume of the reaction mixture from time to time and titrating with potassium permanganate. The course of the change is in harmony with the formula for a unimolecular reaction, and for such concentration of platinum a definite value of k, the velocity coefficient, can be obtained The velocity coefficient, can be obtained The following table contains the values of k corresponding to various concentrations of platinum -

Platinum concentration	$\boldsymbol{k}$
$21.0 \times 10^{-6}$	0.072
10 5×10-6	0.024
5 2×10-6	0 0084
$2.6 \times 10^{-6}$	0 0027

From these figures it appears that when the concentration of the catalyst is doubted, the velocity of decomposition is trebled

Catalysis and the law of mass action—The general characteristics of catalysts have been discussed in the foregoing paragraphs, but it must be admitted that the phenomena associated with catalysis are frequently more complex than has been suggested. It appears that the catalyst often works in such a way as to mask the operation of the law of mass action altogether. Although a detailed discussion of these peculiarities of catalytically accelerated reactions is

not possible here, a brief consideration of some typical cases will be found useful

An investigation has been made of the rate at which sulphur dioxide and oxygen unite in presence of platinum (see Bodenstein, Zeitsch physikal Chem 1907, 60, 1), and the results show that the velocity of union is independent of the oxygen concentration (except when it is extremely small), proportional to the concentration of sulphur dioxide, and inversely proportional to the square root of the trioxide concentration This behaviour is obviously quite different from what would be expected under the law of mass action The explanation adopted by Bodenstein is that the factor which really determines the velocity of reaction is the rate of passage of the sulphur dioxide through a layer of sulphur trioxide, absorbed at the surface of the platinum From this point of view, what is measured is a diffusion velocity, not a reaction velocity, for it is supposed that the sulphur dioxide and the oxygen, when they have reached the platinum, react with great rapidity stein has further shown that the rate of union of the two gases under the influence of other catalysts is governed by the same factors. only so, but it has been found that the rate of change in many other heterogeneous catalytic reactions is, in all probability, determined by the physical process of diffusion This is the case with the union of hydrogen and oxygen in contact with heated porous porcelain (see Bone and Wheeler, Phil. Trans. 1906, 206, 1); in this

instance, the rate of union of the gases appears to be determined to a large extent by the rate of occlusion of hydrogen.

Additional support of the view that the velocity of a heterogeneous catalytic reaction may be determined mainly by a diffusion process, is furnished by the relatively low value of the temperature coefficient in these cases As already indicated, the velocity of a homogeneous chemical reaction is doubled or trebled for every

rise of  $10^{\circ}$ , but the value of  $\frac{k_{\mathrm{T}+10}}{k_{\mathrm{m}}}$  for a hetero-

geneous reaction is frequently not much greater than the value (about 1.3) we should expect it the rate of reaction were determined by a diffusion velocity alone

Among the most important catalytic reactions are those which take place under the influence of enzymes These catalysts are able to promote changes in organic matter which, in their absence, can be effected only with great difficulty. There is a close analogy between enzymes and ordinary morganic catalysts, but it is frequently found that, owing to the operation of various factors, the course of a reaction which takes place under the influence of an enzyme, deviates considerably from what we should expect on the basis of the law of mass In the inversion of sucrose by invertase, for example, the velocity coefficient, calculated by the formula for a unimolecular reaction, increases with the time (Brown, Chem Soc Trans 1902, 373) This is shown by the following table, which refers to the inversion of a 9 48 p c sucrose solution at  $30^{\circ}$ , the symbol x stands for the fraction of the total sucrose inverted by time t —

t min.	x	$\frac{1}{t} \log \frac{1}{1-a}$
30	0 265	$t = 1-x \\ 0.00445$
64	ð 509	0 00483
120	0 794	0 00571
180	0.945	0 00698
240	0.983	0 00737

The departure from the law of mass action becomes still clearer when experiments are made in which a constant amount of invertase is allowed to act for a given time on varying amounts of sucrose in a constant volume of solution Such experiments show that the enzyme, instead of inverting a constant fraction, as required by the law of mass action, has inverted a constant weight of sucrose in the given time, only when the quantity of sucrose is very small is the law of mass action obeyed In the hydrolysis of starch by diastase, and of milk sugar by lactuse, it is similarly found that the amount of change induced by the enzyme is, for the initial portion of the change, a linear function of the time (see Brown and Glendinning, Chem Soc Trans. 1902, 81, 388; E. F. Armstrong, Proc Roy. Soc 1904, 73, 500); the later portion of the change, when the amount of catalyst is larger relatively to the amount of carbohydrate, conforms to the law of mass action.

Another peculiarity about enzyme action, which is frequently observed, is that the activity of the enzyme does not remain constant throughout the whole course of the change which it induces. In the hydrolysis of amygdalin by emulsin, and of milk sugar by lactase, the

products of reaction seem to exert a specific influence in putting the enzyme out of action (see Tammann, Zeitsch. physikal Chem 1892, 13, 271; Armstrong, Proc. Roy Soc 1904, 73, 500). This is indicated by the regular falling off in the value of  $\frac{1}{t} \log \frac{1}{1-x}$  as the reaction proceeds, that is, as the products of the reaction,

accumulate

Mechanism of catalysis - Many theories have been advanced as to the way in which a catalyst exerts its influence According to one very commonly accepted view, a catalyst is effective because it combines with the substrate, and this intermediate compound then breaks up into the final products of change, the catalyst being liberated. Obviously, if this account of catalytic change is to give an adequate interpretation of the phenomena, it must be supposed that the formation and decomposition of the intermediate compound together require a shorter time for their occurrence than the direct change itself. There is a good deal of evidence, largely of an inducet kind, in favour of the view that combination takes place between catalyst and substrate. The increased stability of invertase in presence of sucrose, the specificity of enzymes, and the occurrence of a linear portion in the time curve for the hydrolysis of sugars, are facts which contribute to this evidence In the case of the catalytic influence of molybdic acid on the reaction between hydrogen peroxide and hydrogen iodide, it has been definitely shown that combination takes place between the molybdic acid and the hydrogen peroxide Aluminium chloride also, well known as a catalytic agent, forms definite compounds with the substances the reactivity of which promotes But although we may frequently assume the very probable formation of intermediate compounds in enzyme action and catalysis generally, it is quite impossible, in many cases, to specify the nature of these compounds

There are, moreover, many cases in which the efficiency of a catalyst depends almost certainly on something else than the formation of intermediate compounds. The investigation of non-homogeneous catalytic reactions, such as the combination of sulphur dioxide and oxygen under the influence of platinum, or the union of hydrogen and oxygen under the influence of porous porcelain, has led to the conviction that in these cases occlusion or adsorption of the reacting substances occurs at the surface of the catalyst, and that the higher concentration of the reagents thus secured is responsible for the greater velocity of reaction. It is possible to interpret enzyme action also on this basis, for the solution of an enzyme is, strictly speaking, a non-homogeneous system.

non-homogeneous system.

# CATALYSIS IN INDUSTRIAL CHEMISTRY.

Within the last two decades the applications of catalysis in industrial chemistry have undergone remarkable developments. Many catalytic pro-

cesses are now in operation on the large scale for the production of both inorganic and organic substances, and the steadily increasing amount of research work done in this field of investigation will, without doubt, lead to the introduction of many other methods of manufacture based upon the influence of catalytic agents

Methods of preparation of inorganic substances in which catalysts are employed are as yet comparatively few, but amongst them are included processes for the production of such indispensable materials as hydrogen, chlorine, sulphune acid, ammonia, and nitric acid. In order to meet the growing demand for pure hydrogen various methods for the production of that element from water have been worked out, and several of these are based upon the fact that in presence of suitable catalysts steam and carbon monoxide interact at moderately high temperatures with the formation of hydrogen and carbon dioxide, which, of course, can be easily separated Iron or other metals of the non group serve as catalysts, when the former is employed its activity is increased by the addition of small quantities of 'activators,' such as potassium hydioxide, or by using it in the form of an non-copper couple. The reaction between steam and carbon monoxide may also be effected in presence of heated lime, pre-ferably containing a small admixture of iron, or of a mixture of lime and charcoal

Chloring may be prepared catalytically by the well-known Deacon process, in which hydrochloric acid is oxidised by atmospheric oxygen in presence of cupric chloride at a temperature of about 400°, and also by the method due to Hargieaves and Robinson, in which the reaction between sodium chloride, sulphur dioxide, and oxygen, which results in the formation of sodium sulphate and chlorine, is promoted by the presence of a catalyst such as cupric oxide

In the contact process for the manufacture of sulphuric and the primary reaction, viz the formation of sulphuric anhydride by combination of sulphur dioxide with oxygen, is effected through the agency of platinum, although ferric oxide is also used as a catalyst. In the former case very complete preliminary purification of the gases is essential, since various impurities, and especially arsenic, even in minute quantities, quickly 'poison' the catalyst and

impair or destroy its activity

The synthesis of ammonia is now carried out on a very large scale, since it has been discovered that when a highly compressed mixture of nitrogen and hydrogen is passed over a catalyst maintained at a temperature of 500°-600° the proportion of ammonia produced is sufficiently great to make the process remunerative. Even under the most favourable conditions most of the nitrogen and hydrogen remain uncombined, hence it is necessary to adopt a continuous process in which the residual gases are again passed over the catalyst after removal Many different metals and of the ammonia other substances, e.g. metallic nitrides, have the power of catalysing this reaction, but it is understood that iron is employed in practice; the metal is in a fine state of division and rendered active by the addition of a promoter.

When a mixture of nitrogen with oxygen or air is passed over a suitable catalyst at

temperatures of 500° and upwards nitric oxide is formed; excess of oxygen converts this compound into mtric peroxide, which, when dissolved in water, yields nitric acid and nitric oxide. The catalytic method of manufacturing nitric acid from ammonia is based upon these reactions. Originally platinum was used as the catalyst, but it has been found that iron activated with small quantities of bismuth or other substances is also very efficient. The mixed gases are passed over the heated catalyst with high velocity, hence a relatively small contact chamber suffices for the oxidation of comparatively large quantities of ammonia So far as expenditure of power is conceined, this process is much more economical than the arc process, in which nitiogen and oxygen are caused to combine directly at a very high temperature

Catalysts are also utilised in the manufacture of graphite from charcoal or coke in the electric furnace; in the preparation of carbon tetrachloride; in the elimination of carbon disulphide from coal gas, in the production of sulphur by limited combustion of sulphuretted hydrogen in the ('laus kiln; in the preparation of sulphuryl chloride, of hydrazine, and of aluminium nitride, and in the electrolytic processes for the preparation of hypochlorites, chlorates, and persulphates, and for the regeneration of chromic acid. Moreover, it is claimed that they may be used with advantage in making sodamide, and in the manufacture of alkali cyanides by the action of nitrogen on heated mixtures of alkali carbonates and charcoal.

Largely as a result of the proneer work of Sabatier and Senderens catalytic methods are likely to become of great importance in the domain of organic chemistry Thus, for instance, hydrogen has been found available for many operations of reduction and of hydrogenation when used along with various catalysts the former class of reactions nickel is in general very effective, but as it is sensitive to 'poisons,' particularly the halogens, care must be taken that both the hydrogen and the substance to be attacked must be freed from such impurities. Palladium and platinum, especially when in the colloidal state, are very active catalysts of such The operations may be carried out either at the ordinary or at increased pressure, and either at such temperatures that the reacting substances are vaporised, or at the ordinary temperature with the substances in the liquid state or in solution Among reducing actions of importance carried out at high temperatures may be mentioned the production of methane from carbon monoxide or dioxide, the preparation of aromatic amines from nitro compounds, and the reduction of aldehydes and ketones to alcohols. In the reduction of nitio compounds copper, either alone or with the addition of an activator, is an effective catalyst, but may be replaced by iron, nickel, silver, or gold The hydrogen may be used by itself or mixed with steam, and in place of hydrogen mixtures of carbon monoxide and steam may be employed.

The preparation of indigo white may be quoted as an example of reduction at the ordinary temperature. Indigotin, suspended in a solution of sodium hydroxide, is rapidly reduced by hydrogen at 60°-80° in presence of active mckel; the catalyst is easily removed

by filtration, and the solution of indigo white thus produced has the advantage of being free from any excess of the reducing agent. process is applicable to the preparation of leuco derivatives of other vat dyes.

With nickel as catalyst the addition of hydrogen to unsaturated compounds, when in the state of vapour, is easily effected. Ethylene, for example, is readily converted into ethane at 200°, and the preparation of hexahydro derivatives of benzene and other aromatic compounds is carried out with little difficulty In solution, and especially in presence of colloidal platinum or palladium, various alkaloids have been converted into hydro derivatives, which may prove of value medicinally, and a most useful application of the process of hydrogenation is the 'hardening of fats,' ie the conversion of oils or liquid fats into solid fats This hardening process depends essentially upon the production of the solid glyceride tristearin by addition of hydrogen to the liquid glyceride Nickel is usually employed as the tijolein catalyst, but the oxide of nickel has also been recommended, and the use of a number of other metals (particularly those of the platinum group) and of their compounds has been patented

A number of processes, in which reduction is effected by agents other than hydrogen, are also promoted by various catalysts example, in the reduction of azobenzene with sulphurous acid, the presence of a trace of hydriodic acid has a most beneficial effect, and the remarkable discovery has been made that the reduction of certain dyes with hydrosulphites or formaldehyde-sulphoxylates is greatly promoted by the addition of small quantities of certain other dyes Moreover, in a number of electrolytic reduction processes, the presence of catalysts is advantageous; thus the electrolytic reduction of nitro-, nitroso-, or azo- compounds is facilitated by the addition of titanous salts,

in very small quantity, to the liquid

Many processes of oxidation are also induced or accelerated by catalysts A well-known example of direct oxidation is the production of formaldehyde by passing a mixture of the vapour of methyl alcohol and air through a tube containing heated copper or platinum. Acetaldehyde is rapidly and smoothly converted into acetic acid by the action of a current of air if a little manganous acetate is dissolved in the aldehyde. Anthraquinone may be obtained by heating anthracene with oxygen, under pressure, if some cupie oxide or other catalyst is also present. In oxidations with sulphuric acid, as, for instance, the preparation of phthalic acid from naphthalene, the velocity of the reaction is in many cases greatly increased by the addition of small quantities of mercury or copper. If catalysts are present solutions of alkalı chlorates readily act as oxidising agents in many cases where otherwise the reaction takes place slowly or not at all; thus a trace of vanadium pentoxide has a most advantageous effect in the preparation of aniline black by oxidising aniline with these reagents. Hydrogen peroxide is a most valuable oxidising agent for many hydroxy compounds if traces of ferrous salts are also present, and some processes in which oxidation is effected through the agency of nitrobenzene, e.g. the manufacture of magenta,

CHERRY. 171

re promoted by the addition of ferrous salts hich act catalytically as oxygen carriers. foreover, electrolytic oxidation is frequently ceelerated by catalysts; for example, in this ethod of preparing anthraquinone, a little ceric ulphate or chromic acid is added to the sulhuric acid in which the anthracene is suspended.

Catalysts are capable of promoting processes f dehydrogenation as well as of hydrogenation. Or instance, an excellent method of obtaining cetaldehyde consists in passing the vapour of thyl alcohol over copper heated to about 300°, and in a similar manner ketones may be picared from secondary alcohols, e.g. camphor com borneol, with satisfactory results. Hydrormbons also are dehydrogenated at comparatively low temperatures in presence of metals uch as copper, nickel, or iron, and in this onnection it should be noted that a number of atents have been taken out which cover the mployment of those and other catalysts in he 'cracking' of petroleum for the production f motor spirit, benzene, &c , from heavier oils.

Other reactions in which catalysts are ffective include the hydration and the dehydraon of organic compounds An example of ydration is the preparation of acetaldehyde by iducing the combination of acetylene with ater, which is carried out by passing a current f the gas into an aqueous solution of an acid in resence of a mercury salt which acts as the atalyst. The hydrolysis of esters, which may lso be included in this category, finds practical lustration in the hydrolysis of fats into free itty acids and glycerol by the action of water ontaining a small quantity of a catalyst, eg alphophenylstearic acid. Dehydration is exemhed by the catalytic preparation of ethylene and other unsaturated hydrocarbons. Ethyl scohol breaks down into ethylene and water then its vapour is passed over alumina heated ) a temperature of 360°, and isoprene and other ydrocarbons of the same series can be obtained y a similar dehydration of dihydric alcohols he catalytic influence of mineral acids in ccelerating the formation of esters by the iteraction of organic acids and alcohols is ell known, and it has been found that acetaldeyde and ethyl alcohol readily react with formaon of acetal in presence of calcium chloride and

trace of hydrochloric acid. Moreover, in inny of the processes grouped under the heading condensation,' which find such extended pplication, there is no doubt that the conensing agent plays the part of a catalyst.

Much space would be required if an attempt ore made to illustrate all the other kinds of sactions of organic compounds which are accountably influenced by catalysts, and it must affice merely to indicate the employment of these agents in connection with the following perations: The preparation of aromatic ydrocarbons, e.g. of toluene by the action of iethyl chloride on benzene in presence of luminium chloride; the preparation of halogen

derivatives of both aromatic and fatty compounds, when various catalysts known as halogen carriers are of the greatest service, the preparation of sulphonic acids derived from benzene and other hydrocarbons, from pyridine, &c., the preparation of derivatives of amines or of amino- compounds, particularly of those in which aromatic radicals are introduced into the amino-group, eg the production of phenylanthranilic acid, which is easily effected by the addition of a small quantity of copper powder to a boiling solution of o-chlorobenzoic acid in aniline; the preparation of certain diazo- compounds, and the replacement of the diazo- group by the chlorine, bromine, or cyanogen radical; the preparation of aldehydes and ketones, eg of benzaldehyde from benzylidene chloride or directly from benzene, and of acetone from acetic acid; the preparation of certain sulphur compounds, in which category the important methods of vulcanising rubber may be included. Moreover, in many cases, intramolecular rearrangements and polymerisations are accelerated by catalysts. The transformation of hydrazobenzene into benzidine under the influence of a strong acid, is a familiar example of the former class of change, whilst the latter is exemplified in the synthesis of various kinds of rubber by the polymerisation of butadiene and its homologues, which is promoted by the presence of sodium, acetic acid, and other catalysts, and in the conversion of acetaldehyde into para-acctaldehyde, ethyl acetate, or aldol

Finally, it must be noted that a number of very important operations, for example, the manufacture of ethyl alcohol, are carried out through the agency of that group of catalysts produced by hving organisms which are known as enzymes. In many respects the action of enzymes is similar to that of inorganic catalysts, and especially to that of colloidal platinum or palladium, but is specific in the sense that a definite enzyme is required to bring about a particular transformation.

**CHERRY.** The fruit of *Prunus avrum* (sweet cherry) or *P. cerasus* (Morella cherry). There are many varieties. Konig gives, as the composition of ordinary cherries:

Free Invert Sacch (albo-Water Protein acid sugar arose hydrates Fibre Ash 80 6 1 2 0 7 8 9 0 5 1 8 5 8 0 5

Included in the carbohydrates is 0.6–1.0 p.c. of pentosans (Wittreaun, 1991). A more detailed examination by Keim (Zeitsch, anal. Chem 1891, 30, 401) showed that in the unripe fruit of *P cerasus*, citric, malic, and succinic acids were present; that cane sugar was present, but diminished greatly as the fruit ripened. The ripe fruit contained no succinic acid, but malic and citric acid equal to 0.46 p.c. expressed as malic acid, were present, and the sugars were dextrose, levulose, and traces of inositol. Shaw (Expt. Station Record, 1899) found, as the mean of the analyses of 13 varieties of cherries:

Average	Whole	e fruit Flesh		In the flesh				
weight	Flesh	Stone	Juice	Residue	Water	Protein	Sugai	Ash

Willstatter and Zollinger (Annalen, 1916, 412, 164) find that the colouring matter of the skins of cheries is keracyanin, the chloride of which can be obtained in crystals containing either 4 mols of water (red slender needles) or  $3\rm{H}_2O$  (stout brown prisms). The chloride has the composition  $\rm{C}_{27}\rm{H}_{31}\rm{O}_{15}\rm{C}I$ , and is readily hydrolysed by boiling with hydrochloric acid, yielding cyanidin, dextrose, and rhamnose. Keracyanın is thus a diglucoside of cyanidin C15H10O6, a frequent constituent of the colouring matter of flowers and fruits (v  $H^{-1}$ ANTHOCYANINS.

CHESSYLITE or CHESSY COPPER. (Kup ferlusur, Ger) A blue oxycarbonate of copper, 2CuCO<sub>3</sub> Cu(OH)<sub>2</sub>, found native at Chessy near Lyons (v COPPER)

CHESTNUT. The sweet chestnut is the seed of Castanea vesca, the horse-chestnut that of Æsculus hippocastanum.

Average composition:

Pro-Carbotein Fat hydrates Fibre Ash Water Sweet chestnuts. Fresh kernels . Dried kernels 69 80  $\frac{1}{2}.7$ 58 10 6 100 70 9 Spanish 68 1 10 0 93 7.5 27 Horse chestnuts 38 9 4.6 46.2 48 68.3 (air-dried)

Sweet chestnuts are largely used as human food; the horse-chestnut has been tried as cattle food, with success (Gay, Ann Agron. 1896, 22, 401; Auld, J Soc. (hem Ind. 1913, 32, 173)

The kernels of an aquatic plant, Trapa bispinosa, are extensively used as food under the name of water-chestnut, in the North West Provinces of India, being roasted and pounded to a flour Hooper (Pharm J. Trans. 1894, 53, 22) found this flour to contain .

Sugar Starch Cellulose Ash Water Protein Fat and gum 4.7 4284 1.0 14.4 638 36

The ash of the flour contained a little manganese, which, however, was abundant in other parts of the plant.

The bark of the horse-chestnut, especially in early spring, contains asculin  $C_{15}H_{16}O_{9}$ , the glucoside of asculetin  $C_{9}H_{6}O_{4}$ . Another glucoside, argynascin  $C_{27}H_{12}O_{12}$ , occurs in the seeds of the hor-e-chestnut (Rochleder, J. pr Chem 1862, 87, 1)

From the fat-free cotyledons two acids are obtained, viz. asculic acid, fine needles, in p 214°-215°, insoluble in water, forming yellow amorphous salts, and wsculinic acid, goldenyellow needles, mp. 230°-231°, Lavoiotatory, soluble in water, forming yellow salts (Masson, Bull Sci. Pharmacol 1918, 25, 65)

Sweet chestnuts contain small quantities of resins and tannin, and included in the carbohydrates are sugar, dextrin, starch, and other Very diverse amounts of these have substances been found by different observers In the horse-chestnut, according to Laves (Zertsch In the angew Chem 1902, 1013), there are about 50 p c starch, 14 pc cane sugar, 13 pc glucose, and 0 2 p c tannın

CHESTNUT EXTRACT. The wood of the Spanish chestnut, Castanea vesca, though it contains only 3-6 pc of tannin, is the source of the much-valued chestnut extract The bark contains more tannin than the wood (17 pc), but is not much used. The tree, which grows to from 60 to 80 feet in height, is abundant in Italy, the South of France, and Coisica, where it forms immense forests, and it is also very common in America.

Trimble (The Tannins), who very carefully examined the tannin, obtained analytical data and reactions which indicated that it was identical, or nearly so, with gallotannin, but it is probable that this wood also contains traces of a catechol tannin, for a certain quantity of a redcolouring matter is also present, which resembles in character a phlobophane. Some writers have suggested that chestnut tannin is a methyl ether of ordinary gallotannin, but there is apparently no definite evidence in support of this theory

Chestnut is employed almost entirely in the form of extract, the strength of which varies, but usually contains from 26 to 32 pc of tannin. The extract is frequently decolourised, and sometimes mixed with quebracho extract and other materials. Chestnut tannin is the tannin which is most largely employed for the dyeing of silk. Castanea vesca appears to be frequently confused with the horse-chestnut, Esculus hippocastanum The tannin derived from this latter is, however, of little or no practical value (cf. Pollak, Collegium, 1913, 6, 291; J. Soc. Chem. Ind. 1913, 32, 706). A. G. P.

CHIAN TURPENTINE v. OLEO-RESINS

CHICA RED AND CARAJURA. These are rare pigments prepared by the Indians of Central America from species of Bignonia which are very similar in appearance and may contain as a basis the same colouring matter. A red pigment of this character, evidently 'Chica red,' is referred to in The Travels and Researches of Baron Humbolt (Macgilivray, Edinburgh, 1836, p. 229). 'Red paint is the ordinary decoration The most common kind is of these tribes obtained from the seeds of the Bixa orellana and is called annotto, achoute, or roucou Another more expensive species is extracted from the leaves of the Bignonia chica' According to Crookes (Dyeing and Calico Piinting, 1874, 388) chica is obtained from the leaves of the B chica which the Indians boil with water, and add some particles of the back known as 'arvane' to the decanted liquid which causes the precipitation of the colouring matter

An interesting résumé of what is known of this subject is given by Holmes (Pharm. J., 1901), who states that preparations very similar to carajura are employed by the South American Indians in Brazil, Bolivia, and Guiana These include chica from the leaves of B. chica, from 'ula' leaves derived from an unknown species of Bignonia in Bolivia, and a pigment prepared from the heartwood of the B tecoma in Minas (Brazil). The latter, according to Lee (Chem. Soc. Trans. 1901, 284), is prepared by mixing the dust and shavings of this tree with slaked lime and heating the mass with water. From the B tecoma Lee isolated a considerable amount of a yellow crystalline compound, tecomin Bignonia Tecoma.

Carajura or ('rajura was apparently first examined by Virey (Journ de Pharmacie et Chime (3) 5, 154) The sample experimented with, which came from Para, was soluble in alkalis and was precipitated therefrom by acid, and is stated to have been prepared by the Galibis by boiling with water the stem and leaves of an unknown species of Bignonia when the latter in the autumn had acquired a purple

Crookes states (loc cit) that chica is soluble in 36 pc alcohol, in ether and in alkalis with a vinous red colour, and when heated in a scaled tube with alkali and glucose gives a bluish-red liquid which becomes brown on exposure to air and then yields on acidification an orange-red precipitate.

As the result of an examination of chica red or carajura said to be derived from the leaves of the Bignonia chica, Erdmann (Jahres. 1857, 487) assigned to the colouring matter which he isolated by extraction with alcohol the formula  $C_8H_3O_3$ . This substance was soluble in caustic alkali but not in alkali carbonate solutions, and when oxidised with chromic acid gave anisic acid, whereas with nitric acid pieric acid was produced.

Perkin (Proc Chem. Soc 1914, 30, 212), who examined a sample of 'carajura' obtained from Messrs. Wright, Layman, and Umney of London, and which is referred to in the paper of Holmes (loc. cit.), found this to contain a small quantity of the calcium lake of two colouring matters which had either been precipitated on, or intermingled with a substance of the nature of ground

bark or peat After treatment with hot dilute hydrochloric acid, alcohol removes the colouring matters in the form of a resin, and from this, by means of boiling benzene, carajurin is isolated This compound, to which the formula C<sub>18</sub>H<sub>16</sub>O<sub>5</sub> has been provisionally assigned, separates in ruby needles, melting at 204°-206°, is soluble in boiling dilute alkali with a red colour, and is nearly devoid of dyeing properties With mineral acids it very readily yields oxonium salts, crystallising in bright, orange needles, of which the sulphate, probably C18H16O5 H2SO4. H2O is the most stable, the hydrobromide and hydrochloride being decomposed at 100° the hydrochloude a platinichloride can be prepared. Cold acetic anhydride with a trace of pyridine, after two days, gives an almost colourless acetyl compound, crystallising in needles, whereas bromine gives an immediate precipitate with carajurin in acetic acid, which when boiled with this solvent, separates in orange needles Hydriodic acid converts carajuin with loss of 2 molecules of methyl iodide and probably also of a molecule of water into a substance provisionally termed caraquietin iodide, bright scarlet needles, stable in the presence of cold water, and from this by means of cold pyridine, carapuretin C<sub>16</sub>H<sub>12</sub>O<sub>5</sub>, scarlet needles, melting above 330°, and soluble in alkalis with a reddish-violet colour, is produced By dry distillation carajurin evolves a trace of aromatic oil, resembling anisaldehyde in odour, and when fused with alkali, p-hydroxybenzoic acid and a colourless substance, melting at 185°-187°, as yet unidentified, are obtained In many respects carajurin resembles the anhydrohydroxybenzopyranol compounds described by Bulow and Wagner (Ber 1901, 34, 1199).

That portion of the alcoholic extract insoluble in benzene yields to other carajurone, isolated as a scarlet powder, which readily assumes a beetle-green lustre, and possesses strong dyeing properties. Analysis indicates the presence of more oxygen in this compound than in carajurin A small amount of a similar, but brighter lake from British Guiana, and obtained from the leaves of a 'bushrope,' gave a colouring matter dyeing alizaim-like shades. This preparation, considered to be 'chica red,' appeared to differ in some respects from the 'carajura' above described

Bignonia Tecoma. Tecomin.  $(q \ r)$ A G,P CHICAGO BLUE, -ORANGE, v AZO-COLOUR-

CHICK PEA Creer arretinum, I. A leguminous annual, growing to a height of about 2 feet, largely cultivated in India, where its seeds are used as food for cattle and horses, and, after the removal of the husks, for man.

ING MATTERS.

In some cases the young leaves, fried in oil, are also eaten. Church (The Food Grains of India, 1886) gives, as the average composition of the seeds

Water Protein Fat hydrates Fibre Ash With husk 11 2 19.5 4.6 53 8 7.8 3.1 Husked . 11.5 21.7 4.2 59.0 1.0 2.6

Analyses of various parts of the fresh plant were made by Passerini (Staz. Sper Agrar. 21, 20; Chem. Soc. Abstr 1893, ii. 226).

The fresh substance of the stems, leaves, and

entire pods contained 27.54 p.c., 24.39 p.c., and 19 85 p.c. of dry matter respectively.

The dry matter of the stems, leaves, and seeds contained:

Cellu-Other carbo-Protein Fat lose hydrates Ash Nitrogen 49.0 7.81 Stems 6.35 18 35 0 1.62 Leaves 14:21 4.1 139 58.9 2 27 8 83 Seeds 26 20 5.2 17 63.6 3 30 4 19

The ash contained:

Stems 48 4 0.5 23 6 4.4 2.1 0.03 5 3 5 8 6.2 3.7 Leaves 29 6 0 9 40 6 3 3 3 0 -604411318 Seeds 24 6 1 3 4 5 20 0 2 4 - 39 6 3 4 0 7 2 9

Traces of boron, lithium, and copper were

also present in the ash

A detailed analysis of the dry matter of the seeds was made by Zlataroff (Zeitsh. Nahr. Genussm. 1916, 31, 180), who found—fat, 6 30 p c, starch 50·32 p c., fibre 3·62 p c, ash 2·87 p c, total nitrogen 3 34 p c, protein nitrogen 2 11 p c, nuclein nitrogen 0.10 p.c., ammonia nitrogen 010 pc, amide nitrogen 001 pc, amino-acid nitrogen 0.12 p.e.; total phosphoric acid 0.998 p c, inorganic phosphoric acid 0.118 p c, organic soluble phosphoric acid 0.244 p c, legithin phosphoric acid 0 142 pc, phosphoric acid 0.486 p c Oxalic acid (0.007 p.c), citric acid, betaine, choline (0 02 p c), adenine, inositol and a phytosterol were also present

A gum imported into the United States for the manufacture of chewing gum. A sample from Yucatan contained: Acetonesoluble matter (resins) 400; gutta and carbohydrates 174; proteins 06; sand and foreign matter 2 3; water 35 0; ash 4 7 p.c.

For analytical methods of determining its value, see Dannerth, J. Ind Eng. Chem. 1917, 9,

679; J Soc Chem Ind. 1917, 971

CHICORY or SUCCORY. Cichorium Intybus A perennial plant belonging to the Compositæ, growing to a height of about 3 feet, bearing blue flowers and having a long tap root. It is sometimes grown as cattle food, the foliage being thus used, but more generally it is cultivated for the sake of its root, which, when dried, roasted, and ground, is largely used for mixing The blanched leaves are also used with coffee as a salad

According to Letheby's analysis (quoted by Wynter Blyth, Foods, 359, 1909), fresh chicory

roots contains:

Bitter Cellulose, Gummy extrac-tive inulin, Water matter Glucose Fat and fibre Ash 0.6 9.0 0.8 77.0 1.1

Analyses by Mayer (Bied. Zentr 1885, 828) gave:

Bitter Water minoids Fat Inulin Fibre Sugar extract Ash 5.614 72 1.1 0.212.0 1.4 05 to to to to to to 17.3 1.8 60 0.12 1.9

Wolff (Chem. Zentr. 1899, ii 211) also found that chicory root contains from 13 to 15 p.c. of inulin, and an optically mactive sugar, synan-throse. He states that drying the roots has little or no effect upon the sugars, but during | Phosphorus pentoxide 10.0

roasting the reducing sugars are increased, a large portion of the inulin is changed, and caramel and dextrin are formed.

Even by storing a portion of the inulin is converted into inulide and some of the less readily fermented inulides undergo further degradation and are converted into the more readily fermented inulides. Wolff (Compt. rend. 1916, 164, 514) finds a substance which he calls inulo-coagulase in the root, which coagulates the mulin in the expressed juice. It is more abundant in the outer than in the central portions of the root and is destroyed by heating to about 60° It does not coagulate starch, milk or pectin In a later paper, Wolff and Geslin (Compt rend. 1917, 165, 651; 1918, 166, 428) state that inulin breaks down, under the influence of an enzyme present in chicory root, to levulose with intermediate formation of inulides

The bitter principle is believed to be a glucoside of levulose and a pyrocatechuic derivative, probably the aldehyde (Grafe, Biochem. Zeitsch 1915, 68, 1) The determination of cupric reducing power affords a means of detecting the presence of chicory in coffee. The extractives of roasted coffee contain from 19 to 26 p.c of reducing sugars, whilst the extractives of roasted chicory contain from 25.2 to 27.7 pc. When the extractives of a coffee decoction yield more than 3 p c. of their weight of reducing sugars the presence of chicory is indicated. The addition of cane sugar to the coffee does not affect the results and its presence may be detected by the polarimeter

The presence of beetroot in ground chicory may be detected by washing the suspected sample with sodium hypochlorite solution until all soluble colouring matter has been removed, when the particles are to be examined under the microscope If beetroot is present the particles will be seen to contain numerous black cells filled with crystals of calcium oxalate. The cells are oval or elongated and are more numerous near the ligneous vessels of the woody portion of the root (Collin Ann. Falsif. 1916, 9, 271)

Petermann (Bied. Zentr 1883, 843) found

pure roasted chicory to contain:

Soluble in water, 74.2 p c. Dextrin Colouring Water Glucose and mulin Protein matter Ash 16 3 26.1 9.632 16.4

> Insoluble in water, 25 8 p.c Fat Cellulose Protein 3.2 5.7 123 4.6

The ash of chicory root and leaves, according to Wolff, contains:

Root Leaves 60.0 0 7 3.2 14 3 — 9.0 9 0 1.0 1.7

Wynter Blyth (Foods, 359, 1909) gives as the main differences between the ashes of coffee and chicory, the following :-

-	Coffee ash	Chicory ash
Silica and sand .		10·7-35·9 p.c.
Carbon dioxide .	14.9	1.8-3.2
	0.44-0.98	3.1-2.3 ,,
	0.26-1.1	3.3-4.9 ,,
Phosphorus pentoxide		5.0-6.0

The soluble ash of chicory may be taken as about 1.74 p.c., that of coffee as about 3 0 p.c.

Chicory has about three times the tinctorial power of ordinary coffee, and this has been proposed as the basis for a rough estimation of the

amount of chicory present in a mixture of coffee and chicory (Leebody, Chem. News, 30, 243).

The sp gr. at 15 5° of a solution, made by boiling a quantity of the substance with ten times its weight of water, affords a ready method of approximately determining the amount of adulteration The following table gives the specific gravities of infusions made in this way from the various substances :-

Spent tan					1.00214
Acorns					1 00730
Peas .					1 00730
Mocha coffe	90				1 00800

oted by Wŷr		vth.	Foods.	3	60).

(quoted by Wynter Blyth, Foods, 360).

Hehner and Skertchly propose a determination of furfural (a measure of pentosans) as a means of examining suspected coffee Coffee gives about 5-5 5 p c, chicory about 2 5 p c of pentosans (Analyst, 24, 178) H 1.

CHINA BLUE. Syn Water Blue, Cotton Blue, Opal Blue v. Triphenylmethane colouring MATTERS.

### CHINA CLAY or KAOLIN v CLAY.

CHINA GRASS. Rhea Ramie fibre. This substance is the fibre of two (or perhaps more) species or varieties of the genus Boehmeria, nat ord. Urticaceæ, shrubs allied to the nottle (Urtica), but possessing no stings, namely, Boehmeria nivea (Hook and Arn ) with a white hairy under surface to the leaf, and B. utilis [B. tenacissima (Gaud.)] with a green (Blume) under surface (more or less hairy only on the nerns) to the leaf It is the Tchou-ma of China and the Rheea of Assam. The plants grow to a height of from three to five feet, throwing up numerous straight shoots as thick as the little finger, and covered with short soft hairs. Its leaves grow upon long foot-stalks and are broadly heart-shaped, about six inches long by four broad It is a native of China and Sumatra, where, as in India, it has long been cultivated.

Its manufacture into mats used for making sails, foot-mats, &c., is carried on in Southern China, where three crops of Tchou-ma are taken each year, of which the second is the best. For this purpose the grass is sorted into bundles, which are soaked in water for two or three days and then dried in the sun. If a red colour is desired, the grass is steeped in a decoction of sapan wood; if yellow, in a decoction of the seeds and flowers of the common Chinese plant mi-fa, or in one of Sophora japonica, to which a little alum is added as a mordant. Other vegetable dyes are also employed; but of late years aniline colours have in a measure taken their place.

By processes of manufacture an exceedingly fine fibre is produced on separating the filaments of the stalk—a fibre distinguished by its strength, which is nearly three times that of Russian hemp; by its length, which is greater than that of any bast product; and by its lustrous, silky Great efforts have been made, with more or less success, to render the use of the fibre in European textile manufactures commer-It will be seen from the folcially profitable lowing remarks that there are difficulties in the way In the first place, the method of separating the bast by hand was tedious, and could only be performed whilst the stems were quite fresh, thus limiting its production to the immediate neighbourhood of the plant's growth. In China the bark is stripped from the stems and the fibre scraped off with a knife, a process which removes the whole so-called grass if performed while the stem is still quite fresh, but leaves a large portion if it has become at all dry Even under the best conditions a very skilful operator can collect only two pounds of grass per day, the average quantity obtained being only half a pound to one pound. It is further found that, owing to the large amount of pectinic substances contained in these Urticacca, the long steeping or retting processes used with flax and hemp cannot be practised on account of the ensuing excessive fermentation, which injures the fibre Experiments made in India with unskilled workers gave about four ounces per day each as the result of their labour Attention has consequently been given to mechanical processes for separating the fibres from the bark in the green and in the dry state. With this in view, the India Office some years ago submitted samples of the dried article to Dr Forbes Watson, who reported that he did not find it at all difficult to obtain the fibre from stems which were quite The difficulty in the case of India is that the best crops are obtained during the rainy season, when it is all but impossible to dry the stems except by expensive artificial means, while, as above pointed out, the liability of the plant to ferment resulted in the spoiling of the crops when its treatment was delayed. The Government of India has followed up its inquiries and encouraged inventors to competition in producing a machine capable of dealing with the green crop. It may be said that this encouragement has resulted in an approximation to success; thus, in one instance of a machine consisting of a cylinder with beaters revolving at a high speed against the stems upon which meanwhile a jet of water is poured, Dr. Watson estimated the cost of producing the fibre to average 4l. to 5l per ton The yield from the machine was from 1 to 2 tons of green stalks per day, estimated to produce about 100 lbs. of cleaned fibre.

In the treatment of green stalks by hand the Favier's process consists in subjecting the plants to the action of steam for 15 to 30 minutes, after which the bark is easily stripped. Those stems also which have been standing some time after being cut can also be treated | without leaving any appreciable amount of fibre on the stalks.

The operation of scutching the dried stems presents no difficulty when steam power is applicable and when the quantity of material to be treated is sufficiently large. The next process, however, of 'ungumming' has given a little trouble Since ('hina grass contains from 22 to 28 or, in some cases, up to 35 pc of gum, it is necessary to remove this constituent of the fibre before it can be spun into yarn For this purpose many partly mechanical and partly chemical processes have been devised. It may sufficiently describe the lines which these various systems take to say that they resemble generally the processes adopted in the scouring and bleaching of cotton goods—that is to say, by subjecting the material to pressure under the application of steam, and to alternate treatment of alkaline and acid agents

American inventors have devised means by which the fibre can be spun in ordinary cotton machinery. Rossi, of Naples, has patented a method by which China grass can be retted without chemical agents. When chemically degummed name is manufactured in combination with cotton and dyed and printed, the goods possess a silky lustre which enhances the

colours on both fibres

China grass has little or no attraction for dyes, and consequently the methods adopted in the dyeing of cotton or of jute are applicable to it It is found that mineral colours, such as chrome yellow and orange, destroy the peculiar lustre of China grass, the yellow dye obtained with cadmium sulphide, however, is not open to this objection Alizarin mordanted with Turkeyred oil destroys the lustre, whilst aniline colours fixed with the same mordant do not Rosaniline derivatives and azo- colouring matters may be It is recommended that the used satisfactorily grass should be dyed immediately after retting and before spinning, to preserve the characteristic sheen

The textiles formerly associated with China grass were such articles as handkerchiefs and grass cloths,' imported direct from China, but recent efforts to introduce the manufacture as well as the growth of China grass into Europe have led to other developments Thus at the manufactory of Zittau in Saxony, the fibre has found application in tapestry and dress goods, table-cloths, damasks, lace, fancy knitting yarns, It is also used in the manufacture of incandescent gas-mantles

A number of other species of Boehmeria also supply bast fibres

CHINA INK v. INDIAN INK CHINAPHENIN. Trade name for phenetidine-quinine carbonic ester Formed by treating p-phenetidine with phosgene and combining the product with quinine

CHINA-STONE. A granitic rock, having its felspathic constituent more or less decomposed, but not completely kaolinised, and with an absence of coloured minerals, such as biotite and tourmaline. As the felspar still retains part of its alkali, and as some micaceous mineral is generally present, the stone is fusible; hence it is largely used in the manufacture of porcelain, and when free felspar is not introduced

it forms the only vitrifiable constituent of the China-stone is sometimes known as 'Cornish stone' in consequence of its being largely quarried in Cornwall, where it was discovered by W Cookworthy, of Plymouth, about 1750. He first noticed it at Tregonning Hill. near Breage, and described it under the local name of 'growan' or 'moor-stone' It is now obtained principally from the neighbourhood of St. Stephens, near St Austell In this area it occurs as a local modification of the granite, and is sharply marked off from the normal granite and from the china-clay rock. It is too hard to be worked like the china-clay rock, and has to be blasted and quarried like ordinary granite, in fact it has been used locally as a building stone The rock requires no preparation, but is sent direct from the quarry to the potteries (For an account of the occurrence of china-stone in Cornwall, see Mem Geol. Survey, Bodmin and St Austell District, 1909; and the Handbook by J A Howe, quoted below)

The following commercial varieties are

recognised

I 'Hard purple,' a hard, white rock with a faint purplish tinge due to the presence of fluor-spar
2. 'Soft' or 'Mild purple,' similar to the

last, but softer

3 'Dry white stone,' a soft, white variety.

4 'Bufl stone,' similar to the last, but iron stained

The following analyses by W Pollard and E G Radley are given by J A. Howe, A Handbook to the Collection of Kaolin, China-clay and China-stone in the Museum of Practical Geology, London, 1914 I 'Hard purple' china-stone from Goonvean, near St Stephens, 'Buff' china-stone from the same locality; III China-stone from Jersey ('Jersey stone')

Jersey stone is a decomposed partly kaolinised granite quarried in Jersey Granite-pegmatite in France, granite-aplite at Meldon, near Okehampton, Devonshire, porphyrite in Saxony; liparite in Japan; and felsite in China are all rocks that are applied for the same purpose

It has been proposed by J. H. Collins (Hensbarrow Granite District, Truro, 1878) to distinguish china-stone under the name petunzite, a word suggested by the Chinese pe-tun-tse. In the early part of the 18th century a Jesuit missionary named D'Entrecolles, residing at King-te-chin, sent to Réaumur, in Paris, samples of the raw materials used in China. These were the first specimens of their kind that had ever reached Europe, and they led to the foundation of the manufacture of porcelain at Sèvres. The china-stone was described by D'Entrecolles as po-tun-tse, and the china-clay as kaolin; but it appears that the former name, if not both, must have been erroneously applied. Ascording to the Chinese scholar, Stanislas Julien (Hist et Fabric, de la Porcel. Chin Paris, 1856, preface xx.), pe-tun signifies 'white paste,' while the isemerely a diminutive applied to the material when worked up into small cakes. Hence, petun-se is really the name of small blocks of white clay or prepared paste, and not of the granitic rock. Nevertheless, custom in this country has justified the use of the term pe-tun-tse as synonymous with china-stone.

CHINEONAL. Trade name for a compound of quinine and veronal Used as a hypnotic

CHINESE BLUE. (Porzellanblau, Ger) Several compounds are sold under this name, of which the following are examples: ultramarine and flake white; cobalt blue and white lead; and a double cyamide of non (Prussian blue) (v. Pigments).

CHINESE GREEN OF LOKAO V LOKAO CHINESE LAKE OF SCARLET LAKE V PIGMENTS.

CHINESE VEGETABLE TALLOW is the hard fat which coats the seeds of the Chinese tallow tree, Stillingia sebifera (Willd.), Stillingia sinensis, Croton sebiferum, Sapium schiferum, (Roxb), Excecaria sebifera (F Mull), Carumbium schiferum), a tree growing wild in China, and largely cultivated there, as also in Indo-China and the North of India, where the tree thrives luxu-In China the stillingia tree is exploited for both its leaves and seeds. In Tonkin the tree is only cultivated for the sake of its leaves, a decoction of which furnishes a colouring matter used for dyeing silk In China the fat is only a by-product. The tree commences to produce at the age of 4-5 years, and when it has reached its full development it yields about 24-30 kilos of seeds a year. The fruit yields about 30 pc of a mixture of vegetable tallow and of stillingia oil, half of this quantity consists of vegetable tallow alone, and the other half of stilling a oil, the yield of the latter from the kernels being about 62 p c. The fruit consists of three oval seeds surrounded by a thick tallowlike mass, the true vegetable tallow. This is recovered by placing the seeds in perforated cylinders and steaming them, so that the fat melts and runs off. Another method is to pass Another method is to pass the seeds between fluted rollers, which scrape off the outer fat coating without breaking the seed proper The scraped-off mass is pressed in the hot primitive wedge presses, and sold under the Chinese name of 'pi-ieou' or 'pi-yu'; it is known in Europe as 'prima' vegetable The seeds which have been bared from their fat coating, are then crushed separately and yield the stillingia oil, a drying oil known in China as 'tsé-tiéou' or 'ting-yu.' In another process, the seeds, together with their coating of fat, are crushed, and thus a mixture of vegetable tallow and stilling is oil is obtained. • The product Vol. II.-T.

thus prepared is naturally much softer than the true vegetable tallow, and has therefore a lower melting-point and a much higher rodine value. This second quality is sold in Europe as 'secunda' vegetable tallow, and represents a mixture of 'pi-yu' and 'ting-yu.' It is sold in China under the name 'mou-feou'

The saponification value of commercial samples of vogetable fat varies, therefore, according to the mode of preparation, from 179 to 207 Similarly, the iodine value varies considerably, and numbers ranging from 19 to 32 have been recorded. The composition of vegetable tallow has not yet been definitely ascertained Stearie acid is absent (Hehner and Mitchell), and it is probable that the fat consists in the main of palmitin and olem.

The oil has an iodine value of about 155, and yields 20 p c of an insoluble bromide (m p 147°), whereas the fat does not form an insoluble compound with bromine

Vegetable tallow plays, in China, an important rôle as an article of commerce, it is largely used in the manufacture of candles. During recent years considerable quantities have been exported. The bulk of the vegetable tallow is used in the candle and soap industries. According to Diedrichs (Zeitsch Nahr Genussm 1914, 27, 132) the fat, if properly purified, can be used for food, but soon acquires a bitter taste and unpleasant odour. It is frequently adulterated by the Chinese.

CHINESE WAX or INSECT WAX v WAXES CHINESE YELLOW (King's yellow) v Pig-

**CHINOCOL.** Trade name for a compound of hydroxyquinoline and potassium sulphate, used as an antiseptic and disinfectant v

CHINOFORM. Trade name for quinine formate

CHINOLINE v QUINOLINE

**CHINOSOL.** Trade name for the potassium salt of 8-hydroxyqunoline-5-sulphonic acid  $C_9H_6\mathrm{NOSO}_3\mathrm{K},H_2\mathrm{O}$ , a pale-yellow crystalline powder with a saffron-like smell and a burning taste; in p 175°-1775°, readily soluble in water, sparingly soluble in alcohol, insoluble in ether, with ferric chloride gives an intense green colour, yellowish needles with copper salts, and a white precipitate with barium chloride. Used as an antiseptic. At a concentration of 1 in 1000 its solutions possess as great a bactericidal action as mercuric chloride solutions of the same strength.

CHINOTROPIN. Trade name for urotropine quinate.

CHINOVOSE v CARBOHYDRATES.

CHIOLITE. A double fluoride of aluminum and sodium 3AlF<sub>3</sub> 5NaF, closely akin to cryolite AlF<sub>3</sub> 3NaF, but crystallising in the tetragonal system. Found at the Ilmen Mountains in the Southern Urals and with crystals in Greenland.

L. J. S.

CHIRETTA. Chirata, BP Is the plant Swertia chirata (Buch. Ham.) collected when in flower and dried Japanese chiretta is Swertia chinensis (Franchet). Hohn (Archiv. d. Pharm. 1869, 215) found two bitter constituents in Indian chiretta, viz. chiratin and ophelic acid.

CHITENINE. An oxidation product of

•

178 CHITENINE.

quinine, found in the urine after the administration of quinine. Crystallises from dilute alcohol in prisms, m.p.  $281^{\circ}-282^{\circ}$  [a] $_{\bar{\rm D}}^{17}-122$  6°. Chitin, Chitose v. Carbony drates.

CHLOANTHITE. Native nickel arsemide,  $N_1As_2$ , isomorphous with smaltite (CoAs<sub>2</sub>) (q.v), there being no sharp line of demarcation between the two species. Found as cubic crystals and compact masses at Schneeberg in Saxony and Riechelsdorf in Hesse, where it was formerly mined as an ore of nickel. L J. S.

CHLORACETIC ACIDS v. HALOGEN ACETIC ACIDS

CHLORAL Truchloracetaldehyde CCl, CHO

Chloral was first prepared by Liebig, who obtained it by the continuous chlorination of absolute alcohol (Annalen, 1, 189) It was further examined by Dumas (Ann Chim Phys [2] 56, 125), who determined its composition, and by Stadeler (Annalen, 61, 101) Although a chlorinated aldehyde, it cannot be prepared by treating acetaldehyde with chlorine, unless water is present together with calcium carbonate to neutralise the hydrogen chloride formed, since butyric chloral results when dry materials are employed (Pinner, Ber. 4, 256)

Industrial preparation. The process by which chloral is manufactured is divided into three stages the preparation of chloral alcoholate, conversion of this into chloral, and the

formation of chloral hydrate

In a large glass balloon 60 kilos of alcohol, completely dehydrated as possible, are subjected to the action of a current of chlorme, the escaping hydrochloric acid being absorbed by water. The introduction of the chlorino lasts a considerable time, in some works 10 to 14 days At first the balloon must be cooled, for, if the temperature is not properly regulated, the yield is much reduced After a time the reaction becomes less violent, the mixture is then warmed to 60°, and finally to 100° When the liquid is completely soluble in water, the current of chlorine is stopped, and on cooling, a white mass of the alcoholate is obtained. In this operation Springmuhl recommends the use of iodine as a chlorine carrier, Page, the addition of crystallised ferric chloride (Annalen, 1884, 225, 209), and in either case the ethyl halide is easily recovered.

In the ordinary process the chlormated liquid is not allowed to cool, and is transferred to an enamelled still holding 150-200 kilos, where an equal volume of strong sulphuric acid is added in small quantities. The temperature is raised to boiling, the condensed vapours being returned to the still During the chullition there is an evolution of hydrochloric acid gas, the cessation of which indicates the termination of the decomposition of the alcoholate Fractional distillation follows, this ceasing when the thermometer has reached 100°. The distillate is again rectified, the portion coming over above 94° being pure chloral. In some works the final purification is carried out by distilling over chalk or sodium bicarbonate. Ethylene dichloride, ethylidene chloride, and chlorinated ethylene dichloride (b p 115°) are also formed as by-products in this reaction (Kramer, Ber 3,

quantity of water and the product of the reaction at once poured over a smooth surface, when it solidines; in this state it is sent into commerce To obtain crystals the warm mass (heat is disengaged in this reaction) is mixed with one-third of its volume of chloroform, and the mixture allowed to cool in closed vessels; crystallisation is complete in a week mother liquers serve for a second crystallisation, and the crystals are dued at the ordinary Fluckiger temperature (Zeitsch. [2] 6, 432) recommends crystallisation from warm carbon disulphide or turpentine, and Martius from benzene Other methods, which have been described, differ from the pieceding in that the chlorinated mixture, after solidification and pressure, is sublimed or distilled with calcium chloride (Detsényi, Dingl poly J. 209, 224; Trillat, J Pharm Chim 5, 218).

The following method has been devised for the continuous production of chloral and its hydrate are the most volatile products of the action of chlorine on alcohol, and may therefore be removed by continuous distillation. A special apparatus is described; chlorine and chlorinated alcohol are introduced into a vessel heated in a water-bath, from which the vapours pass into a second and then into a third heated vessel The residual chlorine is absorbed in a cylinder provided with bafile plates rectifier, which also acts continuously, is provided with baffle plates, it is fed at the middle with chloral, and at the top with sulphuric acid (66° B) The final rectification is carried out as already described The same apparatus may be used for converting chloral into chloroform (Besson, Eng Pat. 17202, U.S. Pat 774151; J. Soc Chem Ind 1901, 1139)

Chloral is formed when ethyl alcohol is allowed to drop into the anode compartment of a cell in which an alkaline chloride is being

Theories to explain the action of chlorine on alcohol and the subsequent production of chloral have been proposed by Lucben (Ber 3, 910), Wurtz and Vogt (Compt rend 74, 777), Jacobsen (Ber 15, 601), and Brochet (Bull. See chim

17, [3] 228)

Chloral is a colourless pungent liquid, which solidities at -75° (Berthelot, Ann Chim Phys [5], 12, 536), at --57 5° (Van Rossem Zeitsch. physikal Chem 1908, 62, 681), and is readily soluble in water, alcohol, and other Its b p is 97 7° (corr) and sp gr 1 54175 at 0° (Passavant, Chem. Soc. Trans 39, 55, Thorpe, thid 37, 191), bp 96°-97° at 750 mm, and sp gr 1 5121 at 20°/4° (Bruhl, Annalen, 203, 11), bp 97° at 740 mm (Van Rossem, tc.) Three hydrates exist (1) a semihydrate 2C<sub>2</sub>HCl<sub>3</sub>O,H<sub>2</sub>O, true m p is about 49°, the highest observed 80°; (2) the ordinary monohydrate existing in two pseudo-syminetrical modifications: true m p 47 4°, highest observed 54°, (3) a heptahydrate, mp. -14° (Pope, Chem Soc Proc 1896, 142; and Van Rossem, l.c). According to Wolf (J. Phys. Chem. 4, 21); there is only one modification, the difference in melting-points being due to dissociation Nascent hydrogen reduces it to aldehyde (Personne, Annalen, 157, 113), which it closely resembles in reducing ammoniacal silver nitrate solution (Stadeler, Annalen, 106, 253), and in The chloral is shaken with the theoretical forming crystalline compounds with sodium CHLORAL 179

disulphite (ibid); with ainmonia (v. chloral | Weiner Med. Presse, 1899, 1361) ammonium); with hydrogen cyanide (Bischoff and Pinner, Ber 5, 113; Annalen, 179, 77), with amides (Wallach, Ber 5, 251; Sulzbeig, DRP. 198715; J. Soc ('hem Ind 1908, 958), and with amines (Wallach, *lc*, Rugheimer, Ber 1906, 1653; Wheeler, Amer Chem. J 1902, 1063, 1908, 136, 1909, 937).

When heated with aqueous alkalis it decomposes into chloroform and an alkaline formate. and a similar reaction occurs when alcoholic potash or soda is employed (Kekulé, Annalen, 119, 188) Chlorine, bromine, or rodine and aluminium chlorido convert chloral into hexachlorethane (Mouneyrat, Bull Soc chim 17, [3] 796) Furning nitric acid converts it into trichloracetic acid, and, according to Grabowski (Bei 6, 225), fuming sulphuric acid combines with it in the cold, but on heating converts it into chloralide C<sub>5</sub>H<sub>2</sub>Cl<sub>6</sub>O<sub>3</sub> (compare Grabowski, Ber. 8, 1433, Stadeler, Annalen, 61, 114, Wallach, ibid 193, 1) Chloral condenses with succinic acid by means of acetic anhydride to form tuchloromethylparaconic acid (Fittig and Miller, ibid. 255, 43)

Derivatives Chloral ammonium C<sub>2</sub>H<sub>4</sub>Cl<sub>3</sub>NO is prepared by the action of ammonia on a solution of chloral in chloroform (Schiff, Ber. 10, 167) It is a white crystalline solid, resembling chloral hydrate in taste and colour; it melts at 64°, and is slightly soluble in water, more readily soluble in alcohol (Personne, Annalen, 157, 113, Compt rend 71, 228) Nesbit recommends the use of chloral ammonium instead of methane and chloral hydrate, since the action of chloral hydrate on the respiration centres and the heart is retaided by the introduc-(J Soc. Chem Ind 1889, 413, 1890, 889) By heating chloral ammonium on the water-bath, chloroform and ammonia distil off, and the residue consists of formamide and chloralimide C2H2Cl3N, the latter of which is extracted with alcohol Isochloralimide is also formed, and according to Schift (Gazz chim ital 21, 490), dimolecular and trimolecular imides exist Chloralimide can also be prepared by heating chloral and chloral ammonium until chloroform is no longer evolved, and by the reaction between chloral hydrate and ammonium acetate (Schiff,  $\ell\,c$  , Pinner and Fuchs, Ber 40, 1068 , Årends, Chem Ind 16, 78, Béhal and Choaz, Compt rend. 109, 817, 110, 1270). It has remarkable antipyretic and analgesic properties chloralimido compounds have been described by Moschelles (Bei 24, 1803)

Chloralamide or chloral formamide C3H4Cl3NO2 is produced by gently heating chloral and formamide in molecular proportions (J F von Mering, Eng Pat 7391; D R P 50586; J Soc Chem Ind 1890, 413). When recrystallised, it forms colourless crystals melting at 115°-116°, it is soluble in 9 parts of water, or in 11 parts of 96 pe alcohol It is without smell, and has a slightly bitter taste, when heated above 60° it is decomposed; aqueous or alcoholic solutions are unaffected by weak acids or by silver nitrate, but are rapidly decomposed by alkali hydroxides, more slowly by alkalı carbonates. As a hypnotic it has been proved superior to chloral hydrate, and is of most value in cases of nervous insomnia and similar disorders (Hagner and Hubner),

It has no corroding action, does not affect the digestion, nor disturb the heart. It may be taken internally as a powder, prepared by triturating 1-3 grams of the amide with 1 gram of fenneloil sugar (Ellwosaccharum Fæniculi) (Merck's Bull. 1889, 85)

Chloralose C<sub>8</sub>H<sub>11</sub>Cl<sub>3</sub>O<sub>6</sub> is obtained by heating equal parts of chloral and glucose, both anhydrous, on the water-bath. The vitreous mass is boiled with water to remove the chloral, and the concentrated aqueous solution deposits a crystalline compound, from which chloralose is extracted by alcohol. On treating the residue with other, a compound isomeric with chloralose, termed parachloralose, is obtained. Chloralose melts at 187°, and is a powerful hypnotic, whilst parachloratose melts at 227°, and possesses no hypnotic properties. By oxidising these compounds with nitric acid, followed by potassium permanganate, the corresponding chloralic acids permangulate, the corresponding emoralic acids are obtained, in p. 212° and 202° respectively (Hanriot and Richet, Bull Soc chim [3] 11, 37, 12, 303, Compt rend. 116, 63, 122, 1127, 148, 1265; Meunier, ibid. 122, 142, Petit and Polonovski, Bull. Soc. chim. 3, [3] 861)

Chloral-acetonechloroform  $C_nH_n()_{\downarrow}Cl_n$ prepared by heating molecular quantities of chloral and acctonechloroform. It melts at 65°, and has a faint odour and taste resembling camphor (Hoffmann-Laroche, US Pat 778277; J Soc Chem. Ind 1905, 150).

Chloral-bromal-carbamide is obtained by mixing usea with molecular quantities of chloral and bromal, or equivalent quantities of their hydrates in the presence of concentrated hydrochloric or sulphuric acid (Kalle & Co. D. R. P. 128462, Chem Zentr 1902, 1 547). Chloral hydrate in saturated aqueous solution combines with utotropine and caffeine, forming in each case two compounds according to the proportions of the reagents employed

Monochloralurotropine, CaH12N4, C2HOCl3, H2O, crystallising in Thombohedia, and dichloralwrotropine, C6H12N4,(C2HOCl3,H2O),, crystallising in needles, resemble one another in their properties They are colourless and odourless, and very soluble in alcohol and water volatilise at about 100° without melting. They are both neutral substances, which reduce copper solutions and ammoniacal silver nitrate mineral acids they yield formaldehyde, and with alkalis the chloral is attacked, giving chloroform in the cold and carbylamine on heating.

Dichlorakafferne,

$$C_5H_{10}O_2N_4, H_2O_7(C_2HOCl_3, H_2)_2$$
,

mp 72°-73°, slowly loses 1 mol. of chloral and passes into monochloral cafferne,  $C_8H_{10}O_2N_4$ ,  $H_2O_3C_3HOCl_3$ ,  $H_2O$ , in p. 92° 93°. The latter compound dissolves in water, and in solution slowly dissociates, the caffeine separating out. In hot alcoholic solution it is completely dissociated When heated at 100° all the chloral is driven off, leaving pure caffeine (Leulier, J. Pharm Chim 1912 [vii ] 6, 18)

The following condensation products of chloral have been prepared: chloralacetone, chloralacetophenone, and chloraldol (Gigli, Gazz. chim. ital. 28, [2] 83; Konigs, Ber. 1892, 792; 1893, 554; Wislicenus, Kircheisen, and Sattler, 180 CHLORAL.

vorm. F. Bayer & Co. D. R. P. 121223, Chem. Zentr. 1901, n. 69); chloral mirte (Bertom, Gazz. chim ital. 24, n. 20); the compounds with aminoazobenzene (Betti, vbid. 28, 241); with amidooxybenzoic esters (Kalle & Co. D. R. P. 112216; Chem Zentr 1900, n. 791); with aromatic hydrocarbons (Biltz, Ber 1893, 1952; Dinesmann, Compt rend. 1905–141, 201); with hexamethylenetetramine (Lederer, Eng. Pat. 17693, J. Soc Chem Ind. 1897, 1039), with hydroveratine (Frankforter, Amer Chem. J. 20, 358); with methylpropanoldialkamino-acids (Poulene Frères & Fourneau, Fr. Pat. 382787, D. R. P. 203643, J. Soc Chem. Ind. 1908, 246), with menthol and terpinol (Wagmitz, Eng. Pat. 19103; J. Soc Chem Ind. 1899, 856, Schmitt, Compt. rend. Soc. Biol. 1890, 678); and with resoreinol (Causse, Bull. Soc. chim. 3, [3] 861, Hewitt and Pope, Chem. Soc. Trans. 1896, 1265)

Polymerides. Two polymerides of chloral are known, an insoluble and a soluble substance. When pure, chloral is perfectly stable, but traces of impurities, and particularly of sulphuric acid (Byasson, Compt rend 91, 1071) convert it into metachloral, a white amorphous solid It may be prepared by leaving chloral hydrate in contact with half its weight of concentrated sulphune acid for several hours, until a pasty mass is After pouring off the acid, the residue is introduced into a well-cooled solution of hydrochlorie acid, and the product, which now becomes solid, is washed and dired over sulphuric acid. Chloral alcoholate may be substituted for chloral hydrate in this preparation (Gartner, D R P 170534, Chem Soc Abstr. 1906, i. 628) Another method is to add 7 parts of anhydrous aluminium chloride to 100 parts of well-cooled anhydrous chloral, the temperature being kept below 40° In the course of an hour the whole mass solidities In the After 24 hours the hard mass is broken up, extracted with dilute hydrochloric acid, washed with alcohol, and dried at a moderate temperature (Erdmann, D R P 139392, Chem Zeit 27, It is insoluble in alcohol, ether, water, (20) 223) and acids, but soluble in sodium carbonate solution On warming with alcohol, it yields chloroform, and on distillation at 180°-250° is reconverted into chloral (Kolbe, Annalen, 54, 183 [footnote]) It is tasteless, and can be employed as an anæsthetic, unlike chloral hydrate, it has no irritating effect on the mucous membrane of the stomach.

The soluble polymeride is obtained by treating chloral with pyridine or any other amine in the cold, and then acidifying. It is a slightly volatile anæsthetic substance, volatilising without melting, converted by hot water or hot alcohol into chloral hydrate and chloral alcoholate respectively, and decomposed by alkalis into chloroform and formic acid. It is soluble in water (Gartner, D. R. P. 165984; U.S. Pat. 768744, Chem. Soc. Abstr. 1906, 1.

Chloral hydrate CCl<sub>3</sub>·CHO+H<sub>2</sub>O or CCl<sub>3</sub>·CH(OH),.

Properties.—Chloral hydrate crystallises in monoclinic tables (Groth, Ber. 5, 676), and has a peculiar odour and sharp taste Its m.p. is 57° (Meyer and Dulk, Annalen, 171, 75),

47.4° (Van Rossem, Zeitsch. physikal. Chem. 1908, 62, 681); b p 97.5°; and sp gr. 1.818 (m powder) and 1848 (crystallised) (Schroder, Ber. 12, 562). It dissolves readily in water, 1 part of water dissolving 4.7 parts of chloral hydrate at 17.5° (Mauch, Arch Pharm 240, 113), a label of the schloreform turrentum and light alcohol, ether, chloroform, turpentine, and light petroleum, and its solubility in carbon disulphide is given by Fluckiger (l.c.) as 1 in 45 at 156-18° and 1 in 4 5 at the boiling-point Concentrated sulphuric acid decomposes it into chloral and water, and alkalis act upon it as upon chloral A modification of the hydrate, melting at 80°, is obtained by rapidly evaporating an acetic acid solution of anhydrous chloral over sulphuric acid (Meyer and Dulk,  $l\,c$ ), this is probably the semihydrate described by Van Rossom (l.c) Under the influence of light and air, chloral hydrate is decomposed, the decomposition products being hydrochloric acid and carbon dioxide or monoxide, or water, chlorine, and carbon dioxide, the amount of available oxygen determining the products (School and Van den Berg. Ph Weekblad. 43, 42).

Chloral hydrate should be free from alcoholate. which has not the same physiological properties, and when warmed with twice its volume of water it should give a clear solution, free from oily drops and not precipitated by silver nitrate When carefully heated, it should volatilise completely, and the vapours should not be inflammable, when gently warmed with 3 vols of strong sulphuric acid the mixture should remain On warming chloral hydrate with potassium hydroxide, turbidity is caused through the separation of chloroform, the clear portion is decanted, and rodine dissolved in potassium rodide added So soon as the liquid begins to turn yellow, it is cooled, when the presence of alcohol and consequently of chloral alcoholate, is indicated by the formation of a precipitate of 10doform (Trillat, J. Pharm. Chim 5, 218). Chloral alcoholate may also be detected by the Zeisel method for the estimation of ethoxyl (Schmidinge, Monatsh 21, 36) Chloral hydrate is converted into alcoholate when dissolved in alcohol, and similarly, chloral alcoholate is very slightly soluble in water, dissolving slowly to form chloral hydrate Potassium carbonate is a good antidote to chloral poisoning, if it has not reached the blood (Klar, J Soc Chem. Ind. 1896, 555)

Physiological Action — Compare Liebieich (Ber 2, 269); Personne (Compt rend 78, 129), Byasson (whid 78, 649), Tomaszewicz (abstracted, Chem Soc Tians 1874, 814), Tanret (J Pharm Chim [4] 20, 355), and Trillat (lc). Mering, Zeitsch, physiol Chem 6, 1882, 480. According to the last-named authority is reduced to trichlorethyl alcohol (CCl<sub>3</sub> CH<sub>2</sub> OH) in the body and not into chlorofoim, as suggested by Liebieich, who first proposed its use as an hypnotic.

Estimation.—4 grams of the sample are treated with 30 c.c. of normal caustic soda in a stoppered bottle, and shaken vigorously for a few minutes without the application of heat. On titrating back with normal sulphuric acid, using litmus as an indicator, 5.8 c.c. should be required for complete neutralisation (Alcock and Thomas, Pharm. J. 63, 236; and Sargeant, ibid.). Owing to the secondary reaction CHCl<sub>3</sub>+3NaOH = 3NaCl+CO+2H<sub>2</sub>O, this titration with acid is

CHLORAL. 181

slightly inaccurate. Modifications of the method have been devised by Trillat (l.c.); Hinrichs (Pharm. J. 70, 530); Desgrez (Compt. rend. 125, 780; Analyst, 23, 76); Self (Pharm. J. 79, 4); and Garnier (Chem. Zentr. 1908, 1. 1492). Another method is to heat 03 gram of the sample with 1 gram of aluminium powder, or 2 5 grams of zine filings, 15 c c of glacial acetic acid, and 40 cc of water under a reflux condenser for half an hour. The mixture is filtered and washed, and the chlorine estimated volumetrically or gravimetrically as silver chloride (Self, l.c.). Wallis (Pharm J 76, 162) treats the chloral hydrate with caustic soda in a bottle, and then estimates the chlorine as silver chloride It may also be determined indometrically (Rupp, Arch. Pharm. 241, [5] 326)

Chloral hydrate may be detected by means of the green colour formed on the addition of antimony trichloride to a solution in castor oil (Covelli, Chem Zeit 31, 342); or by the colours formed when it reacts with resorcinol in the presence of sulphuric acid (Jaworowski, Zeitsch anal Chem 37, 60) Another method is to add a solution of ammonium sulphide, when a pinkish or yellow precipitate is obtained, and an oil having the odour of walnuts (Lesinsky and Grundlich, Amer Chem. J. 19, 603). It may also be detected by the reducing action of the formic acid into which it may be converted In presence of compounds containing the CCl, group, eq chloroform and trichloracetic acid, the substance dissolved in water and slightly acidulated with sulphuric acid is treated with zinc in the cold When the evolution of hydrogen has ceased, a strip of filter paper, soaked in a solution of sodium nitroprusside and 5 pc piperidine solution is hung over the liquid, which is gently warmed, when the acetaldehyde formed colours the paper blue 1 part of chloral hydrate in 20,000 may thus be detected Chem 1912, 61, 57) (Jona, Giorn Farm Chloral hydrate is valuable for extracting alkaloids from plants containing much resin, essential oils, &c (Schaer, Zeitsch anal Chem. 37, 469), it is used in rubber analysis (Weber, J. Soc. Chem Ind. 1903, 576), in microchemical investigations (Schaer, Chem Soc Abst 1908, 1 62); and in qualitative analysis (Mauch, Arch Pharm 240, 166)

Derivatives - Chloral antipyrine is obtained by the condensation of chloral hydrate with antipyrine (Béthal and Choaz, Ann Chim Phys. 27, 319).

Chloral caffeine is formed when chloral hydrate and caffeine are brought together in aqueous or alcoholic solutions in molecular pro-It is recrystallised from warm water at 30°, and owing to its easy solubility as opposed to the difficult solubility of caffeine, is of medicinal value (Chem Fab auf Act vorm E Schering, D R P. 75847; J. Soc Chem. Ind. 1895, 987)

Chloral tannin is prepared by the condensation of chloral hydrate with tannin in the presence of sulphuric acid. It is a greyish-brown amorphous powder, having valuable dermatological properties (Farb vorm Fried. Bayer & Co. D. R. P. 98273; Eng Pat. 2882; J. Soc Chem Ind. 1899, 172).

Chloraldoxime is prepared by treating chloral hydrate (1 mol.) with hydroxylamine hydrochloride (4 mols) and a little water; mp

39°-40° (Meyer, Annalen, 264, 116; Tarugi, Gazz. chim. ital. 21, ii. 6)

Chloralhydroxylamine is obtained by triturating molecular quantities of chloral hydrate. sodium carbonate, and hydroxylamine hydrochloride, dissolving the mass in a little water, and extracting with other, mp 98° (Hantzsch, Ber 1892, 701)

Compounds with formaldehyde are described by Pinner (Ber 1898, 1926)

Chloral alcoholates. The preparation of chloral ethylalcoholate has already been described It may also be obtained by the action of chloral on absolute alcohol (Martius and Mendelssohn, Ber 3, 444) It crystallises in needles, melts at 44°-46° (Meyer and Dulk, Annalen, 171, 78), at 46° (Lieben, Ber 3, 907), boils at 115°; is sparingly soluble in water, more soluble in absolute alcohol, I part of alcohol dissolving 4 4 parts of chloral alcoholate at 17 5° (Mauch, Arch Pharm 240, 113) Sulphuric acid decomposes it into chloral and alcohol Chloral propyl alcoholate, b p 120°-122°, and chloral \*\*opropylalcoholate, m p 47°, and b p 108°, have been described by Gabutti (Gazz chim ital 31, 1. 86), and Vitoria (Chem Soc Abst 1905, i. 110), chloral amylalcoholate by Gadamer (Arch Pharm 243, 30), and Kalle & Co (D R P 115251; Chem Zentr 1900, 11 1141) Other alcoholates have been prepared by Jacobsen (Annalen, 157, 224), and Kuntze-(Arch Pharm 246, 91)

Butyl chloral CH, CHCl CCl, CHO; more correctly, tri-chlor-butyric-aldehyde; b p 164°-165° at 750 mm; sp gr 1 3956 at 20°/4° (Bruhl, Annalen, 203, 20) It is a colourless oil, having a characteristic chloral odour, formed by the action of chlorine upon ordinary aldehyde or paraldehyde (Kramer and Pinner, Ber 3, 383) Chloracetaldehyde CH\_Cl CHO is first formed, and this condenses with another molecule of acetaldehyde, forming a-chlorerotonaldehyde CH, CH CCI CHO and water, and this, by the action of more chlorine, forms the butyl chloral.

Preparation —Chlorine is led through cooled paraldehyde (or aldehyde cooled by a freezing mixture), water is then added, and the liquid neutralised with calcium carbonate The mixture is then distilled on the oil-bath in a current of steam, and the hydrate is thus obtained. This is then purified by recrystallisation from water, and decomposed by distillation in a stream of hydrochloric acid gas (Pinner, Annalen, 179,

Butyl chloral is converted by fuming nitric acid into aaß-trichlorbutyric acid. Phosphorus pentachloride converts it into a body C4H4Cl4, which boils at 200°. It combines with zincethyl to form a compound which is decomposed by water with formation of trichlorobuytl alcohol

The ammonia compound

## CH, CHCl CCl, CH(OH)NH,

m p 62°, is formed by leading ammonia into a cooled mixture of 1 part of butylchloral, and 1; parts of chloroform (Schiff and Tassmari, Ber 10, 1783). It forms a solid mass, insoluble in water, soluble in ether, alcohol, and chloroform. Is readily decomposed on heating.

Butyl chloral has a strong affinity for water,

and readily forms

182 CHLORAL.

+H<sub>2</sub>O. This compound, which is also known as butyl chloral, is prepared by passing chlor-ine into paracetaldehyde (Freundler, Compt. rend. 143, 682). It forms white crystalline trimetric plates of a peculiar odour, with difficulty soluble in cold, more readily in hot water; very readily soluble in alcohol; mp. 78°, with partial dissociation, and sp gr 1 694 (Schroder, Ber 12, 562) For some years after its discovery in 1870, it was regarded as crotonchloralhydrate It is decomposed by distillation into the chloral and water Alcohol and potassium cyanide convert the hydrate into ethyl a-chlorerotonate Zine and hydrochloric acid, or zinc-dust and water, produce mono-chlorcrotonaldehyde, and finally crotonaldehyde (Sarnow, Annalen, 164, 108) With acetic acid and iron filings, butyraldehyde, normal butyl alcohol, and crotonyl alcohol are produced (Lieben and Zeisel, Monatsh 1,840). It is a valuable anodyne in cases of neuralgia, facial rheumatism, periostitis, &e The following composition is recommended: butyl chloral hydrate, 2-5 grams, alcohol, 10 grams; glycerol, 20 grams, and distilled water, 120 grams (J Soc Chem Ind 1889, 476; 1890, 889) It is frequently adulterated with the cheaper chloral hydrate, from which it may be distinguished by the following reaction: A solution of pyrogallol in pure 65 p c. sulphuric acid gives, when gently and carefully warmed, a blue colour with chloral, a ruby colour with butyl chloral and a more or less violet-to-blue colour with mixtures of the two compounds On addition of a large quantity of water, the blue colour obtained with chloral changes to yellowish-brown, and the ruby colour obtained with butyl chloral to a more or less deep-violet colour (Galbutti, J. Soc. Chem. Ind. 1894, 273)

Derivatives —Butylchloralantipyrine, yellow crystals, mp 70°-71° (Calderato, Chem Zentr 1902, ii 1387); butylchloraldoxime (Tarugi, Gazz chim ital 21, ii 6)

CHLORALUM v DISINFECTANTS

CHLORAMINE-BLUE, -GREEN, v Azo-colouring matters

CHLORAMINE-T (Sodium - p toluenesulphochloramide CH<sub>3</sub>C<sub>6</sub>H<sub>4</sub>SO<sub>2</sub>NNaCl), first obtained by Chattaway (Chem Soc Trans 1905, 87, 153), has been shown by Dakin to be a valuable antiseptic in military surgery for the treatment of infected wounds, and has been employed in cases of cerebrospinal meningitis, diphtheria, &c It may be obtained from p-toluene sulphonic chloride, a by-product in the manufacture of saccharm (q v.), or, directly, from toluene by sulphonation and transformation of the sodium salt into the sulphonic chloride by the action of phosphorus pentachloride or a mixture of the pentachloride and phosphoryl chloride, and conversion of the sulphonic chloride into sulphonamide by treatment with ammonia or ammonium carbonate. To convert the amide to chloramine, one molecular proportion is dissolved in a warm strongly alkaline solution of sodium hypochlorite (1.3 to

Butylchloral hydrate CH<sub>3</sub>·CHCl·CCl<sub>2</sub>·CHO 2 0 N strength), when on cooling the greater 4.0. This compound, which is also known butyl chloral, is prepared by passing chlorinto paracetaldehyde (Freundler, Compt. d. 143, 682). It forms white crystalline metric plates of a peculiar odour, with iculty soluble in cold, more readily in hot ter; very readily soluble in alcohol; mp. total miles of hypochlorite and 1 mol. of sodium hydroxide Known also as chlorazene and total miles of the chloramine separates out, and the part of the chloramine separates out, and the part of the chloramine separates out, and the remainder can be obtained by evaporation. It is important to have an excess of caustic soda; for each mol of amide about 1 05 to 1 1 mols. of hypochlorite and 1 mol. of sodium hydroxide Known also as chlorazene and the chloramine separates out, and the part of the chloramine separates out, and the part of the chloramine separates out, and the remainder can be obtained by evaporation.

Dichloramine T, toluene-p-sulphodichloraamide CH<sub>3</sub>C<sub>4</sub>H<sub>4</sub>SO<sub>2</sub>NCl<sub>2</sub>, is also employed as an antiseptic. It is prepared by dissolving ptoluenesulphonamide in bleaching powder solution or by acting on chloramine T by hypochlorous acid—Insoluble in water but dissolves in chlorinated parafin or chlorinated eucalyptol which is then diluted with parafin oil.

The persistent odour which clings to the hands after immersion in hypochlorite solutions appears to be due to protein chloramine combinations (Briggs)

CHLORAMINE-YELLOW v. PRIMULINE AND ITS DERIVATIVES

CHLORANIL v QUINONES

CHLORATE OF POTASH, SODA v CHLORINE. CHLORAZENE. Syn for Chloramine T (q v)

CHLORAZIDE. N<sub>3</sub>Cl A gas obtained by mixing solutions of sodium azide N<sub>3</sub>Na, and sodium hypochlorite, and acidifying with acetic acid. Chlorazide is highly explosive, slightly soluble in water, and insoluble in caustic alkalis (Raschig, Bot. 1908, 4194).

CHLORAZOL-BROWN, -DEEP BROWN, -BLUE, -VIOLET v Azo- colouring matters

CHLORENE C<sub>48</sub>H<sub>26</sub> A green hydrocarbon obtained together with decacylene and fluorocyclene by heating accomplishment with lead oxide at 350° and extracting with benzene and light petroleum in the cold. It crystallises in small dark green scales. Dilute solutions are pure deep green in colour but become brownishing of exposure to sunlight. Concentrated solutions appear purple-red by a bright transmitted light. (Direwonski and Suknatowski, Ber 1918, 51, 457).

CHLORETONE " ACETONECHLOROFORM CHLORIDE OF LIME, POTASH, SODA "

CHLORINE. Symbol Cl At wt 35 46. HISTORICAL Chlorine was first obtained by Scheele in 1774 by the action of hydrochlorine acid upon manganese dioxide, and was termed by him dephlogisticated manne acid air' In 1785 Berthollet suggested its use for bleaching vogetable fibres, and this application continued until 1789, when this very objectionable gas, and its equally objectionable aqueous solution, were replaced by an unobjectionable solution prepared by dissolving the gas in an alkali; the hypochlorites so prepared have been used for bleaching from then to this day

The idea that it was a compound substance prevailed until 1809, when Gay-Lussac and Thénard suggested that it was probably an elementary body, a supposition confirmed by the investigations of Davy in 1810 (Phil. Trans. 1811, 1, 32) Davy gave it its present name, from χλωρόs, greenish-yellow, in allusion to its characteristic colour.

OCCURRENCE Chlorine is never found free in nature, it always occurs combined with metallic elements Sodium chloride occurs to

the extent of 3 p.c. in sea-water, and as rock salt in large quantities in Galicia, Tyrol, Transylvania, Spain, and in England (particularly in Cheshire) (v Sodium Chloride, art. Sodium) Potassium chloride is found as sylvine (q.v), and in association with magnesium chloride as carnallite KCl MgCl2,6H2O (q.v.) in the saltbeds of Stassfurt, and in a few parts of North France, and in sea-water. Other naturally occurring chlorides are matlockite PbCl. PbO. horn silver AgCl, atacamite Cu2Cl(OH)8, calomel HgCl, &c. Ferrie chloride Fe<sub>2</sub>Cl<sub>6</sub> and sal ammoniae are occasionally found native as products of volcanic action. Magnesium chloride is found in considerable quantity in seawater and in many natural waters Calcium chloride is found in certain brines

Sodium and potassium chlorides are present in most animal secretions, and free hydrochloric acid is met with in the gastric juice. Many plants, growing in proximity to the sea, and many inland plants contain notable quantities

of chlorides

Preparation for Laboratory Purposes The oldest mode of preparing chlorine for laboratory purposes consists in heating manganese dioxide with hydrochloric acid, or by heating a mixture of manganese dioxide, common salt, and sulphuric acid

$$\begin{array}{l} {\rm MnO_2 + 4HCl = Cl_2 + MnCl_2 + 2H_2O} \\ {\rm 2NaCl + MnO_2 + 3H_2SO_4} \\ {\rm = Cl_2 + 2NaHSO_4 + MnSO_4 + 2H_2O} \end{array}$$

It is readily prepared by slowly dropping a clear strong solution of bleaching powder into concentrated hydrochloric acid. Bleaching powder made commercially into small cubes may be used in a Kipps' gas generator containing strong hydrochloric acid. If required in rather large quantity it is most easily obtained from liquid chlorine supplied commercially in steel

cylinders

PROPERTIES OF CHLORINE At ordinary temperatures and pressures chlorine is a greenish-yellow gas, which becomes darker in colour as it is warmed, under strong pressures the colour becomes orange-yellow; its absorption spectrum shows numerous dark lines in addition to complete absorption in the blue and violet. Even when largely diluted with air, the gas possesses a characteristic pungent and irritating smell, it rapidly attacks the nasal and lung membranes, and in such cases the best relief is obtained by breathing alcohol vapour or a little chloroform vapour and keeping in a warm room

The sp gr of chlorine gas shows a gradual diminution up to 240°, when its density becomes normal, viz 2 4502 (Jahns, Ber 15,

1242)

By the application of either suitably increased pressure, or of a suitable low temperature, chlorine gas is readily liquefied to a dark greenish-yellow liquid of sp.gr. 1.33, b.p.  $-34.5^{\circ}$ . The critical temperature is  $144.0^{\circ}$ , the critical pressure 76 l atm, and the critical density 0.573. The density of liquid chlorine may be represented by the formula :

$$d_t = 0.687014 + 0.0002379(144 - t) + 0.0622109 \sqrt{144 - t}$$

The ratio of the critical density to that calculated from the simple gas laws is 3 635, and the value of Trouton's constant, that is the quotient of molecular heat of evaporation and the absolute temperature of the boiling-point, is 20 67, indicating that chlorine behaves as a normal substance. The specific heat between 0° and 24° is 0 2262, and the heat of evaporation at 8° is 62 7. The vapour tension is in atmospheres.

It can be solidified at a low temperature Liquid chloring is not miscible with water, its refractive index is lower than that of water, and it is a non-conductor of electricity

Chlorine gas is readily soluble in water, its absorption coefficient between 10° and 415°, according to Schonfeld (Annalen, 93, 26, 96, 8),

$$3.0361 - 0.046196t + 0.0001107t^2$$

by means of which the following table showing the volume of chlorine at  $0^{\circ}$  and 760 mm absorbed by 1 vol of water at varying temperatures from pure chlorine gas having a pressure of 760 mm is calculated:

The volume of chlorine absorbed from a mixture of that gas with an indifferent gas, as hydrogen or carbon dioxide, is greater than that calculated from the law of partial pressures (Roscoe, Chem Soc Trans 8, 14)

Chlorine-water has the characteristic smell and colour of the gas, in daylight, and especially when exposed to sunshine, it gradually loses its colour owing to the action of the chlorine on the water, the main reaction being

$$H_0O+CI_0=2HCI+O$$

Chlorine Hydrate A solution of chlorine in water below 9° deposits crystals of so-called chlorine hydrate of a light-yellow colour, which become almost white when cooled to --50° By gently heating the crystals in a sealed tube, they are readily resolved into water and free chlorine, which may be thus obtained as a liquid

GENERAL CHEMICAL PROPERTIES—Chlorine is an active chemical agent, and combines with many of the elements even at the ordinary temperature Phosphorus ignites spontaneously in the gas, forming phosphorus trichloride. Finely divided arsenic, antimony, copper, tin, lead, and iron burn in chlorine, forming the respective chlorides, but most of these metals, when presented in bulk, behave quite differently, as the trace of solid chloride formed acts as an impervious layer and the reaction can proceed no further, but metallic tin forming a liquid chloride Sn(14 is entirely converted into that chloride. Chlorine and hydrogen may be mixed together in the dark without combining, but such mixtures explode violently in bright daylight or when heated During any of the above acts of combination much heat is evolved

Certain of these reactions are modified if the chlorine is absolutely free from moisture. Wanklyn (Chem News, 20, 271) found that sodium might be melted in dry chlorine without action, although the metal readily burns in chlorine as ordinarily prepared. Cowper (Chem Soc Trans. 43, 153) found that Dutch metal, zinc, and magnesium were unacted upon by dry chlorine, silver and bismuth were only slowly attacked. The indifference of dry chlorine to steel and brass enables liquid chlorine to be manufactured and shipped in vessels made of those metals.

With many inorganic chemical compounds chlorine also combines directly, thus it unites with sulphur dioxide, carbon monoxide, phosphorus trichloride, ferrous chloride, stannous chloride.

With very many organic non-saturated compounds chlorine also "combines directly, eg with ethylene, acetylene, and benzene (under certain circumstances), and additive compounds are formed; in the case of acetylene the reaction is so energetic that it becomes explosive; lignocellulose also readily combines with chlorine

With saturated organic compounds as maish gas and the paraffins, acetic acid, alcohol, &c, chlorine forms one or more substitution products, and the eliminated hydrogen is simultaneously converted into hydrochloric acid

With such organic compounds as benzene and toluene, chlorine may react either to form addition or substitution products, or both simultaneously, and such reactions are largely influenced by the temperature and by the presence of other substances as ferrous chloride, iodine, &c

With turpentine chlorine reacts so readily that the oil inflames spontaneously, and much of it is totally destroyed with the production of free carbon and hydrochloric acid

In presence of water chlorine acts on many substances, both morganic and organic, as a powerful oxidising agent, and these reactions may be explained by the assumption that the mixture reacts to a small extent to form hypochlorous acid, that is HOH+Cl2=HOCl+HCl3, hypochlorous acid is an intensely active substance, capable of converting manganous oxide into permanganic acid, chromium trioxide into chromic acid The oxidising action of chlorine and water often becomes more energetic in the presence of bases. In this way monoxide of lead may be converted into dioxide, manganous oxide into manganese dioxide, sulphur into sulphuric acid, ferrocyanides into ferricyanides, manganates into permanganates, and many organic substances and colouring matters may be more or less completely oxidised.

## INDUSTRIAL PREPARATION OF CHLORINE

Chlorine gas has been prepared on the small industrial scale by the addition of strong sulphuric acid to a mixture of sodium chloride and manganese ore (which is essentially manganese peroxide) and heating

The commercial processes of preparing chlorine to-day are described in the following account in detail, in the order of their development:—

(a) The action of an aqueous solution of hydrochloric acid on one or other of the higher oxides of manganese, or their compounds at temperatures below 100°:

 $4HCl (solution) + MnO_2 = Cl_2 + MnCl_2 + 2H_2O$ 

(b) The action of hydrochloric acid gas on atmospheric oxygen in the presence of catalysts (as copper compounds) at temperatures just below a red heat:  $4HCl+O_2=2Cl_2+2H_2O$ .

(c) The electrolysis of metallic chloride (as sodium chloride, potassium chloride, zinc chloride), which are occasionally anhydrous and fused, but are much more generally employed in aqueous solution 2NaCl=Cl<sub>2</sub>+2Na, and ZnCl<sub>2</sub>=Cl<sub>2</sub>+Zn; the energy absorbed in these reactions is supplied electrically

A number of proposals or non-important

methods are briefly enumerated

(a) The Aqueous Hydrochloric Acid and Manganese Oxide Method —The solution of hydrochloric acid used is obtained in the manufacture of sodium sulphate that is salt cake. It is known as 'Commercial Hydrochloric Acid,' or as 'Muriatic Acid' The solution used should be as strong as possible, because complete exhaustion of the acid by manganese peroxide is impracticable, and a residual liquor containing a considerable amount of unavailable acid is always left. The stronger the hydrochloric acid solution to start with the smaller the percentage of the total HCl which is lost (for actual figures, see below)

The manganese ore used for the generation of chlorine should contain a high percentage of MnO<sub>2</sub>. The two next lower oxides of manganese also liberate chlorine, but only a smaller proportion of the total chlorine employed as shown by the following equations —

$$\begin{array}{l} MnO_2 + 4HCl = Cl_2 + MnCl_2 + 2H_2O \\ Mn_2O_3 + 6HCl = Cl_2 + 2MnCl_2 + 3H_2O \\ Mn_3O_4 + 8HCl = Cl_2 + 3MnCl_2 + 4H_2O \end{array}$$

Pyrolusite is the manganese ore generally used; it usually occurs in distinctly crystalline masses of a fibrous structure, its sp gr is 47-5, and its colour iron-black to dark steel-grey with a metallic lustre, it also occurs as amorphous friable masses that soil the fingers It has been mined in North Wales, and occurs in quantity in Germany, Bohemia, Transylvania, Russia, India, Australia, Japan, and the United States of America

The chief source of the industrial pyrolusite used in this country is Southern Russia. The ore varies usually from 75 p c. to 85 p c.  $MnO_2$ . An average analysis of the Russian ore is . 80 p c  $MnO_2$ , 1 p c MnO; 3 p.c  $H_2O$ .

It is customary to buy and sell manganese

ore on the percentage of MnO<sub>2</sub> only.

The higher the percentage of MnO<sub>2</sub>, the more valuable the ore, as the impurities, even if substances such as BaSO<sub>4</sub> and SiO<sub>2</sub>, do harm by coating the particles of MnO<sub>2</sub> and preventing the action of the HCl, and also by adding to the amount of waste material to be handled. If the impurities are carbonates (CaCO<sub>3</sub>, BaCO<sub>3</sub>, &c), they not only waste hydrochloric acid, but the CO<sub>2</sub> evolved during their solution harms the bleaching powder into which the bulk of industrial chlorine is made.

The physical condition of the manganese ore is also important, the softer ores being preferable

to the harder ones, which are more slowly acted on by the hydrochloric acid

For generating somewhat small quantities of chlorine the generating vessel, or still, may be made of stoneware Fig 1 shows one of the

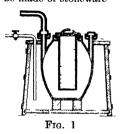

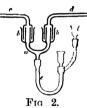

Fig 1 shows one of the best-known forms of stoneware stills, intended for heating from the outside in a water-or steam-bath, made of wood or masonry. The manganese is placed in the perforated cylinder, which holds about 1 cwt, and is put in and out by means of specially shaped tongs, through the large open-

ing The small necks serve for introducing the acid and taking away the gas. At the end of the operation the still liquor is drawn off by a siphon, or by a discharge pipe passing through the steam-jacket. Such small stills permit of careful and economical working so far as materials are concerned, since the acid is not diluted by condensed steam.

Fig 2 shows a contrivance which allows the chlorine pipes and the main pipe to be instantly connected or disconnected. There is a Y-shaped lead pipe a, the upper arms of which are converted into hydraulic lutes by 'burning' an outer pipe, bb, on to them. The ends of the gas pipes, both that leading from the stills c, and that leading to the gas main d, are widened out into cups dipping into the water

which fills the annular space at b. The rubber pipe c and its attached cup contain sufficient water to fill and thus stop the gas-way a whenever the pipe and cup are raised

For generating large quantities of chlorine the stills are made of silicious sandstone or other stone

not acted upon by acids, not pervious to them, and not liable to crack by rapid changes of temperature. Such stone is found at Southowram, and is known as 'Yorkshire flag'.

A small old-fashioned stone still is shown in Fig 3, which represents it cut through in the middle. The bottom is formed by a stone, 10 to 12 inches thick, with grooves for the sides The sides are stone slabs, 5 to 6, or even 8 inches thick, and joined at the corners on the 'feather and groove' principle. The end stones project both ways over the sides, which fit into grooves cut in the end stones The joints are made tight by dressing a small groove into the two adjoining faces, and placing a 5-inch india-rubber cord in the channel thus formed. The lid consists of one or more stones laid in a rebate, and the joint is made gastight by partly filling the rebate with a putty of linseed oil and china-clay. The diagram shows how the still is fitted with the following parts. A false bottom a; a pipe b, for the introduction of hydrochloric acid, sealed at the bottom by the acid in a small earthenware bowl; a leaden steam pipe, c, connected at the bottom with a stone or stoneware steam column

d, which is provided with side holes (not shown in the figure) situated a short distance above the bottom slab, for the issue of the steam into the acid, and at the top by the loop e with a tap f (the loop protecting the tap to some extent against the action of the chlorine), the earthenware or leaden gas pipe g, the connection of which with the gas main h can be opened or

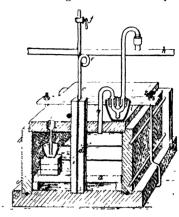

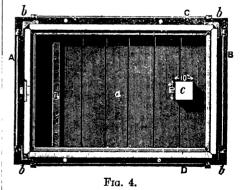

Fig 3

shut off at will by putting more or less water into the pot i. The man hole for charging the still and the discharging hole must be assumed to be provided in that half of the still not shown in the diagram. These stills are made  $7 \times 5 \times 3$  feet, inside measurement, and upwards

Fig. 4 shows a still of the bevel-joint type, seen from above, with the cover removed, a are the flags forming the false bottom, one of which, a', is made to stand up; c is the steam stone, but the long central hole and the radial short holes for the passage of the steam are not shown, A, B, C, D are the rods binding the stones together by means of the cast-iron corner

pieces b, b. The joints are made by the compression of the stones on to round rubber cords shown as black dots in each corner joint in the figure. The cord for the bottom joint may be one inch diameter, that for the upright joints may be \(^2\) inch diameter; the junctions of the several cords with each other are made liquortight by boring with a cork borer a comparatively

small hole in one cord, and then inserting the end of the other cord into the broad end of a hollow conical steel needle, which is smeared with glycerin, the second cord may be passed through the hole in the first cord and the small

projecting end neatly cut off

The Process—In order to work the stills, those of smaller sizes, Fig. 1, where the manganese is contained in a sieve, are usually first charged with the requisite quantity of acid. The sieve containing the manganese (about 1 cwt) is then put in, the cover is at once put on and made tight by water-luting or cementing, and the evolution of chlorine begins forthwith. When it slackens, heat is gradually supplied by turning on the steam till the acid is exhausted. The stills are then allowed to cool down, usually till the next morning. They are then opened, the sieve is lifted out, the manganese remaining in it is washed and replenished by more ore, the liquor is siphoned or run out of the still, fiesh acid is run in, and a new start can be made at once.

The large stone stills are charged with from 6 to 10 cwts of manganese broken up into pieces, which must be smaller in the case of hard ores, but should not be too small, lest too much is washed down below the false bottom, The manhole is then closed and acid is run in, at first quickly, afterwards gradually, so that it takes several hours to run in the full charge All this time chloring is given off, much heat being generated in the process, of course much more with concentrated than with somewhat dilute acid. When the evolution of gas becomes slow, steam is injected into the still, but very cautiously, as otherwise the water might be thrown out of the lutes, and only at intervals, for instance for 10 minutes every hour much steaming causes too rapid an evolution of chlorine, and the volatilisation of much acid and water. The temperature of the stills ought never to get above 90°. It is preferable not to steam all the stills of a set at the same time, but in regular rotation, to produce a more continuous current of chlorine. Chlorine stills ought to be kept going at least 24 hours, but large stills are better kept going for 48 hours, as more of the acid will then be utilised

When the waste liquid, 'still liquor,' is run off it emits an intolerable stench of chlorine, so that this operation is most irksome, both for the workmen and those people who live near the The 'still liquor,' even after being works freed from its muddy constituents by settling, is, on account of its acidity, one of the worst nuisances for any watercourse into which it may be run These nuisances have been completely overcome by the introduction of the Weldon process, where the still liquor from the fresh manganese ore is run into the Weldon stills, as described a little later on, and at works where chlorine is made on too small a scale to permit of applying the Weldon process, the still liquor now has to be run into a closed tank, and neutralised by chalk or limestone dust before running it away, even in a very diluted form.

The chlorine evolved in the stills is always contaminated with hydrochloric acid gas, and a considerable amount of aqueous vapour on account of its high temperature. To remove

these impurities the gas is passed through a long string of earthenware or lead pipes, externally cooled by air (or, if needful, by water), so that the water vapour condenses, and the water produced dissolves the hydrochloric acid gas, and both are then drained away by

trapped escape pipes

The Chemistry of the Process.—The first reaction taking place in the chlorine stills is:

MnO<sub>2</sub>+4HCl=MnCl<sub>4</sub>+2H<sub>2</sub>O or (more probably)

2MnO<sub>2</sub>+8HCl=Mn<sub>2</sub>Cl<sub>6</sub>+4H<sub>2</sub>O+Cl<sub>2</sub>. (There is some discrepancy of opinion as to which of these two chlorides of manganese is formed. (Compare W. W Fischer, Chem News, 37, 250;

U. S Pickering, ibid. 39, 225; Berthelot,

Compt rend. 91, 251.)

These chlorides, MnCl<sub>4</sub> and Mn<sub>2</sub>Cl<sub>6</sub>, form a dark-brown solution which quickly decomposes even at the ordinary temperature into MnCl<sub>2</sub> and free chlorine, so that the ultimate result is: MnO<sub>2</sub>+4HCl=MnCl<sub>2</sub>+2H<sub>2</sub>O+Cl<sub>2</sub>, but this reaction is only completed at about 100° and with a certain excess of hydrochloric acid Theoretically for 100 parts by weight of MnO<sub>2</sub>, or an equivalent quantity of manganese ore, almost exactly 170 dry HCl or 530 acid of 32° Tw, ought to be consumed; practically, at least, 10 pc mole is used, and with low-strength acid, hard manganese, direct steaming, &c., twice the theoretical quantity of acid may be required to be present

The still liquor contains chiefly manganous chloride, free hydrochloric acid, the chlorides of other metals present in the ore, and a little

chlorine

Black's analysis of still liquor, in a well-conducted works, showed how incompletely the acid is utilised

MnCl					-10.6
HCl					66
$Al_{s}Cl_{g}$					0.6
Fe,Cla .					0.5
Cl <sub>2</sub> .			not d	leter	mined
H <sub>2</sub> O (by di	ff)	•	•	•	81.7
					100.0

On the assumptions that all the manganese in the ore was in the form of MnO<sub>2</sub>, and that no hydrochloric acid gas was carried away by the chlorine, it follows that out of every 100 parts of HCl added 33 6 parts had been left untouched.

The free acid is tested for in daily practice by an easy but approximate method, namely to a measured volume of still liquor, standardised caustic soda liquor is run in from a burette till the formation of flakes of Fe<sub>2</sub>(OH)<sub>6</sub>, which do not dissolve on shaking, indicates the saturation of the free acid.

TREATMENT OF STILL LIQUOR FOR RECOVERY OF THE MANGANESE AND THE METHOD OF USING THE RECOVERED MANGANESE Many suggestions have been made and tried with this object, but one process has proved superior to all others, and is now universally adopted. The first foundations of this process were laid in 1837, when Gossage precipitated the still liquor with lime, ran off the supernatant liquor, and agitated the precipitate with air; the oxidation was, however, very slow, and was never so much as half complete. In 1866 Walter Weluon made his first attempts, and

by 1869 his new process was in commercial use at Messrs Gamble & Co's works at St Helens, and by 1871–1873 had been so improved as to be adopted by all English and continental alkali works. The apparatus employed has received but few modifications, but the conduction of process, which in the critical part is complicated, and still not thoroughly explained, has been more modified. In the following the apparatus and process are described together, and in the sequence of events occurring when starting up a new plant.

Fig 5 shows the plant in elevation.

The process is commenced in the stone still E, which has been already described in construction and process by Figs 3 and 4 and the accompanying text. The only changes demanded by the Weldon process are. (1) That the acid employed should be as free as possible from sulphuric acid, because when subsequently the liquor is treated with calcium carbonate the voluminous crystalline needles of CaSO<sub>4</sub> 2H<sub>2</sub>O that are formed entail extra labour and expense in filter pressing and removing the filter cakes, and there is an accompanying loss of manganese chloride solution (2) That the run-off pipe for the still liquor, instead of leading into a neutralising well, leads into a mud still D, which is shown in section in Fig 5 The utility of this last change does not arise until a later stage in the process, and the special construction of this large mud still p will therefore not be now described

The still liquor may be at once run from D into one or other of the two neutralising wells G, G by means of pipes or coveted channels not shown in the figure, and charge after charge of native manganese ore is dissolved in E in the same way, filling the wells G,G alternately and repeatedly for the next operation.

The neutralising wells a, a are sunk in the ground on a bed of puddled clay, and after being built are surrounded by puddled clay to prevent possibility of leakage, they are built of large stone slabs of acid-proof Yorkshire flag, as already described for the still E, except that it is much larger and is octagonal in shape, their dimensions are, depth 6 feet, diameter 15 feet. On the top of the wells two large timber beams are seen supporting the agitators composed of wooden gates driven by short vertical shafts (situated above the liquor level), and large crown wheels and pinions situated above the timber beams, the pinions are driven by one horizontal shaft and the small steam engine situated between the two left-hand mud stills D, D. The liquor, while continuously agitated, is slowly treated with crushed chalk or powdered limestone, which is preferably very finely ground. The free HCl is first acted very finely ground upon, yielding calcium chloride, which is an essential component for the remaining processes, and carbonic acid gas, which in escaping carries away the small quantity of dissolved chlorine gas; these two objectionable gases are prevented from escaping freely into the air by covering the wells with strong planks well tarred and by connecting them to the suction of the nearest chimney by an earthenware pipe Towards the end of the operation the additions are made slowly, and with frequent testing of samples, by seeing if they effervesce when

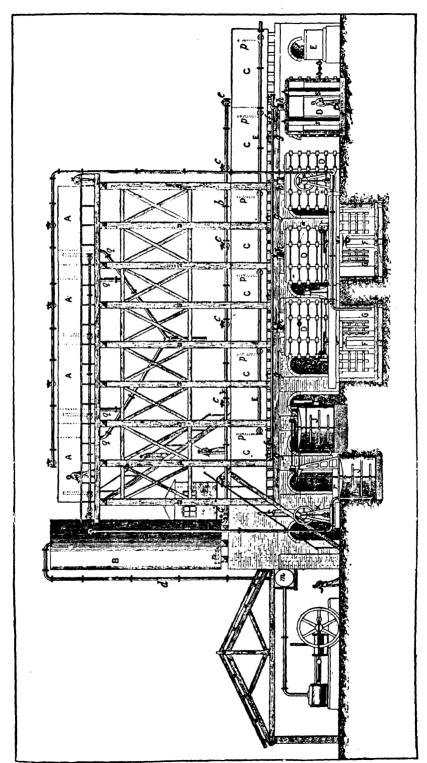

poured on to ground chalk. When the free acid has been neutralised the ferric chloride, and aluminium chlorides shown in the preceding analysis are also converted into calcium chloride and ferric and aluminium hydroxides, and these last carry down as ferric arsenate any arsenious acid originally present in the muriatic acid During this treatment any sul-phuric acid present in the muriatic acid is converted, as already mentioned, into CaSO<sub>4</sub>,2H<sub>2</sub>O. Complete neutralisation is necessary to remove all the impurities named, and also to prevent corrosion of the settling tanks A, A, into which the liquor is next pumped, but the excess of CaCO, employed should be the smallest possible to reduce the cost of the subsequent settling and filtering operations and their loss of manganese liquor

As soon as the neutralised liquor in one of the wells a 13 ready a swivel pipe is lowered from above into the liquid, as shown in Fig. 5, in the left-hand well, and the turbid liquor is then piped to the force pump shown in the figure in front of the third tank p from the left The internal working parts of this pump are made of gun metal. The figure shows the delivery pipe rising to the top of the plant, then running horizontally and discharging through control cocks into one or other of the four chloride of manganese settlers A, A, A, A As soon as the well a is emptied and the pump stopped, a small valve is opened at the base of the pump delivery pipe, and the pipes thus drained back into the well; the swivel pipe taking the liquor from the well is also withdrawn, these things are done to prevent The well is then ready corrosion of the pipes to receive its next charge, and so on

The chloride of manganese settlers are made of 3-inch thick boiler plates, and are 18 feet by 12 feet and 6 feet deep, and therefore are carried by a very strong timber framework that rests upon the strong brick walls that carry the settlers c, c, c As the stock of liquor in A does not fill the tank, and is moreover not sufficient for the next operation, the processes already described must be repeated until at least one settling tank A is quite full. After making the last addition a few hours' settling should allow the liquid to settle quite clear, it is important that the liquor going forward to the next operation should be quite clear, otherwise the charge in the next operation is apt to froth over, and also the recovered manganese will consume an undue amount of acid

As the correct proportioning of the manganese chloride liquor and the milk of lime in the following process are admittedly the key to the rapidity of the subsequent absorption of oxygen, and as no practical method of regulating this proportion is described in Lunge's standard work, "Sulphuric Acid and Alkali," and as it is admitted that milk of lime differs very considerably in its initial action on manganese chloride liquor, according to the source of the lime and the manner of making it into milk, the usual description is here slightly modified so as to contain a means of ascertaining and controlling the proportions of MnCl<sub>2</sub> and CaO used.

Having correctly measured the length and width of the settler A and the position of the

710. 57

surface of the liquor, and recorded these measurements, and having also taken a sample of the liquor for analysis as shortly described, the clear liquor may be drawn off from the settler by lowering a swivel pipe just under the surface of the liquor, where the open end of the pipe can be inspected and the liquor above it can be seen to be quite clear. The bottom end of the swivel pipe is attached to the side of the tank about a foot above the bottom of the tank, so as to leave plenty of room for the mud to collect and to be stored pending its removal Outside the tank the flow of the clear liquor is controlled by a cock, and cocks control its entrance into the oxidising tower B, shown in Fig. 5, or into a second similar tower situate just behind it. The treatment of the mud left in the tank will be described later, as it is first allowed to accumulate.

The oxidising towers is are made of 3-inch thick boiler plates, and they may be 8 feet diameter and 28 feet high, the bottom is flat, and the top is quite open. The pipe bringing the manganese chloride liquor enters the tower about 6 feet from the top of the tower, and as the tower shakes considerably during the subsequent operations, the connection between the tower and the clear liquor main is made through a short piece of indiarubber pipe diameter and height of the tower being carefully measured, its capacity when half full is calculated, and a further reckoning gives the new position the surface of the liquid will occupy in the settler a when the tower has been half tilled, and as the liquor approaches this level the top of the swivel pipe may be set to give exactly the desired amount of liquor. When the liquor ceases to run the cocks are closed, and the residual liquor in the settler is reserved for the finishing of the charge as explained later

The manganese chloride liquor should be tested for MnCl<sub>2</sub> by diluting a measured sample with boiling water, adding zine oxide until the mixture is white as milk, and, lastly, adding standard potassium permanganate with occasional boilings, until the supernatant clear liquor shows a pink flush, the reaction yields a manganite exactly like the Weldon process under consideration ZnO+MnO+O=ZnO MnO2, and the necessary oxygen is obtained from the permanganate similarly

3ZnO+2KMnO<sub>4</sub> =K<sub>2</sub>O·ZnO+2(ZnO MnO<sub>4</sub>)+3O The percentage of manganese chloride having been calculated from the analysis, the lbs. of manganese chloride in the batch is then easily reckoned.

The temperature of the manganese liquor in the tower will be above atmospheric temperature, and in subsequent operations will be still more so, but experience has shown that if it is below 55° C, it should be heated to this point by blowing in steam The steam pipe is not shown in the figure, and because of the shaking of the tower it must pass over the top of the tower, and terminates at the bottom of the tower in several branches containing perfora-tions. The temperature is ascertained by drawing a sample from a sampling cock situated in the cabin there is easy access to all other parts of the plant.

The manganese chloride liquor during the above heating may be agitated, and for the subsequent operation must be well agitated. This agitation is effected by a blast of air The blowing engine-house is shown on the left hand of Fig 5 The right-hand cylinder and fly-wheel constitute the steam engine, the steam supply pipe being shown descending to the centre of the cylinder. The left-hand cylinder is the blower, the air is taken in on the ends of the cylinder through numerous valves of the flap type, faced with rubber, and is delivered through the pipe shown leading to the air pressure regulating vessel m, and thence by the 7-inch diameter pipe d over the top of the tower B, because of the considerable shaking of the tower during the subsequent operations, and thence to the bottom of the tower, where it ends in a cross or a gridion of pipes, marked n in Fig 5, that contain a multiplicity of perforations on their underside, so that the pipes keep themselves clear from the liquor and mud treated in the tower. When used for agitating purposes alone the blast of air required is not great, but the blast can be regulated as desired, and as described later, can be increased very considerably

Milk of hime is required for the next operation, and it is prepared in the upper of the two tanks, J, J, shown in Fig 5 Each of these tanks is made of boiler plate, and is provided with an agitator, the drive being effected by a small steam engine affixed to the right-hand side of the upper tank J, and transmitted by a shaft and two small bevel pinion wheels to either or both of the bevel crown wheels seen on the tops of the two agitator shafts upper tank only contains a lime cage, the bottom of which is indicated by a horizontal line above the third agitator blade, the cage is built of iron rods or perforated metal plates on the bottom and sides, the top of the cage is quite open. The tank is filled with water while steam is being also blown in, until the hot water stands well above the level of the bottom of the cage Quicklime is selected so as to contain less than 1 p c of magnesia, it should be well burnt, but not over-burnt. The magnesia is very objectionable, because it accumulates during the repetition of the following processes, and in the generation of the chlorine it neutralises acid to no purpose, the method of iemoving it is described later. Well-burnt lime does not contain more than 2 pc. carbonic acid, and it slakes quickly and completely, giving a milk that is particularly free from git. Over-burnt lime slakes exceedingly slowly, and the resultant milk contains large quantities of minute grains of unslaked lime, that react only exceedingly slowly with water or the manganese calcium chloride liquor, and so remain mert until the chlorine is generated, when they neutralise acid to no purpose. The selected quaklime in the form of large lumps is put into the cage. it soon slakes, generating thereby much heat, and this addition is continued until the milk registers 50° on Twaddell's hydrometer, the test jar being gently rotated the while; the milk then contains 20 lbs. CaO per cubic testing cabin, shown in the figure, from which foot, and is as strong as can be conveniently

prepared. The milk is then run from a valve at the bottom of the tank on to a wire sieve (not shown in the figure), and thence into the bottom tank J, which is used as a combined store and measuring tank After cleaning out the cage and the wire sieve the upper tank J is then ready for the next operation.

The next operation is the addition of milk of lime to the hot and agitated manganese calcium chloride liquor in B. The agitation of the lower tank J being stopped for a minute, the exact position of the surface of the liquid is noted, and the internal diameter of the tank measured. the agitation being re-started, a sample is taken, from which, while constantly being stirred, a pipette is filled and, after washing the exterior, the contents are titiated with standard hydro-chloric acid till neutral. It is now possible to calculate the position of the surface of the liquid in the tank J when enough milk has been removed to (1) theoretically precipitate all the MnCl2, and to (2) increase the total amount to 16 times the theoretical, as long experience with the process and the due consideration of opposing considerations, namely, the rapidity of oxidation, the completeness of the oxidation, the economy of lime and of hydrochloric acid, the settling quality of the recovered manganese, and the avoidance of 'stiff batches' have shown that this figure gives the best result second addition is called the excess lime, and the amount desired is accordingly 0.6

The pump k is now put into operation, and the milk pumped into the tower by the pipes shown, due regard being had to the means already described of overcoming the effect of the shaking of the tower on the end of the pipe During this operation the utmost vigilance is required in the testing cabin, samples being drawn, filtered, and tested as rapidly as possible The first test is simply that for alkalinity with red litmus paper, but as manganous hydroxide is to some extent soluble in calcium chloride solution, the alkalı test is not proof that all the manganese chloride has been decomposed second test is therefore made by adding to the filtered sample a strong solution of bleaching powder, which produces a brown precipitate or colour if any manganese is still present Should manganese still be present, either more milk of lime must be added, or a little more time given for that already added to react. When sufficient lime has been added to just remove all the manganese from the solution the addition is stopped, and the amount that has been added is measured and recorded.

The amount of lime so far added is always found to exceed that expressed by the simple equation MnCl<sub>2</sub>+Ca(OH)<sub>2</sub>=Mn(OH)<sub>2</sub>+CaCl<sub>2</sub>, because of the solubility of Mn(OH)<sub>2</sub> in CaCl<sub>2</sub> solution already mentioned, and because milk of lime always contains larger particles, or mactive particles, that only react very slowly, and for these reasons the excess lime may vary from 0 10 to 0 45 (the theoretical lime named above being 100); but it is fairly constant for any one source of supply of the quicklime, and for a routine method of working

The amount of calcium chloride present profoundly alters the solubility (and hence the reactiveness) of the calcium hydrate, as is shown by the following figures for 60° C.:

Percentage CaCl2 in solution 100 c c dissolve 09 '11

19

17 .22 38

and whereas in the two weaker solutions the solubility decreases with further rise of temperature, in all the other solutions the solubility increases, and the more so the stronger the solution. The solubility is more than mechanical, as on cooling very long crystalline needles of the oxychloride

### Cl·Ca·O Ca OH+7H<sub>2</sub>O

separate and from strong hot solutions so much that the mixture becomes apparently solid and can be inverted, and this has been assumed to be one of the reasons for the production of stiff batches' mentioned later

The amount of calcium chloride in the batch may be readily determined with sufficient accuracy from the sample drawn when the precipitation of the manganese was found to be complete, by filtering and taking the degrees Twaddell of the filtrate and applying a correction of 0 07° Tw per 1° temperature variation, and the table

Percentage CaCl,

grams of CaO

10 15 20 Twaddell at 186° c 15° c -01 80 165 255 348 446 546

In the present batch from native manganese the liquor will contain about 18 p.c. only, and because of the low solvent power of this strength of calcium chloride on the free lime in the excess lime already added, it is not permissible to add any more excess lime until some of the free lime has been removed by converting it into calcium manganite

For this purpose the blast of air from the blowing engine is increased to its maximum and continued until the end of the operation. The fixation of the oxygen causes the temperature to rise a few degrees, and the reaction CaO+MnO+O=CaO MnO2 reduces the amount of free lime and changes the colour of the precipitate from light yellow to brown, and then to black After about a quarter of an hour a quarter of the remaining excess time desired is added, and these additions repeated after three more periods of blowing

This procedure is necessary to prevent the batch going 'stiff,' ic changing from a freeflowing turbid liquid to a pasty liquid, or even to a paste so thick that it stops the blowing engine, and the whole plant has to be stopped while the paste is dug out The cause of this stiffening is the separation of crystalline compounds said not to be the calcium oxychloride already mentioned, but rather a very basic calcium manganous manganite

## 2CaO 2MnO·MnO<sub>2</sub>

To attempt to cure a stiff batch the excessive bases must be reduced by running in more manganese chloride, and increasing the blast to its utmost.

If, on the other hand, a sufficient supply of free base is not present when the blast is turned on full, then the manganous hydroxide is not converted into a manganite at all, but into the oxide Mn<sub>3</sub>O<sub>4</sub>, which may be written MnO Mn<sub>2</sub>O<sub>3</sub>, and the batch turns 'red' or foxy, and no amount of blowing or of further base will subsequently convert it into a manganite.

During the blowing, samples are taken each half-hour and tested for the amount of MnO by adding to a measured quantity a measured solution of standardised ferrous sulphate and sulphuric acid, so that the manganites are all dissolved, when the excess of ferrous sulphate determined by titiation with standard permanganate solution. By the repetition of this test the time required for the blowing is found, that is the time required for the MnO. per cubic foot to attain its maximum; three hours should suffice During the progress of the blowing filtrates from samples will show a diminution of and then the disappearance of the free lime. The simultaneous oxidations of the mixture (CaO+MnO) and of the excess MnO to form (Ca OMnO<sub>2</sub>) and (MnO MnO<sub>3</sub>) is now complete, and continued blowing has no further offect

But a new reaction is now brought into play by the addition of a second supply of manganese chloride liquor to the blowing tower, namely 2(CaO MnO<sub>2</sub>)+Mn(I<sub>2</sub>

 $= (CaO 2MnO_2) + CaCl_2 + MnO$ 

and by continuing the air blast the MnO is converted into (MnO MnO2), as in the first part of the operation The addition of the manganese chloride is continued only until a sample filtered and tested with hypochlorite gives a reaction for manganese samples show that as a result of the continued blowing this reaction soon ceases, whereupon a little more manganese chloride is added ' blowing out' of the manganese becomes slower with each addition, and when it becomes too slow, no more is added, and the whole operation The effect of this last operation is to ıs ended increase the amount of chlorine that can be manufactured from the mud, without increasing the amount of acid required for that manufacture.

The mud, consisting of calcium dimanganite  ${
m CaO~2MnO_2}$ and manganeso manganite MnO MnO<sub>2</sub>, suspended in a calcium chloride solution is now run from the base of the oxidising tower by the cock and main c, c, Fig 5, into the mud settlers C, C, similar in construction to the settlers a above. After a few hours settling is complete and the clear supernatant calcium chloride liquor may then be run away through the main E, E by opening the cock near the bottom of the tank and gradually lowering the swivel pipe p, until the black mud below is reached

The manganese mud is now ready to be used in the manufacture of chlorine. It differs from native manganese in that it is entirely soluble in hydrochloric acid and that it dissolves very much more readily. The generating tank therefore does not require a false bottom, and it is made very large. Fig. 5 shows four such stills D, D, that may be 12 feet diameter and 12 feet deep. They are octagonal, but otherwise resemble in construction the native manganese still shown by Fig. 4. The right-hand end still is shown in section, the two columns s, s are the perforated stone blocks for blowing in steam. The outlet liquor pipes are not shown, nor are the gas outlet pipes, nor the acid inlet pipes

Into the still is charged any liquor available from the still E, because though it is not strong enough to act further on native manganese, it

will act on recovered manganese mud, and this is one of the advantages of the Weldon process Muriatic acid is then also run into the still till the acid liquors are 2 feet deep. The settled mud in the settler tank c may then be stirred by a hand rake, to make it a little more fluid, and run through a cock q situated in the bottom of the settler, into the main f, f, and thence through another cock into the luted trap h, whence it runs into the still. The chlorine is given off very readily, and the rate of evolution of the chlorine is regulated by regulating the admission of the mud. As the acid becomes exhausted steam is blown in to raise the temperature, and the further additions of mud are made with caution, until samples taken from the still by an earthenware cock, not shown, cease to be clear yellow, and become a clear coffee colour that is not removed by further steaming A sample tested with standard caustic soda solution will then show the presence of about 0.5 p.c. of free acid. The waste manganese liquor is now run, as before described, into a neutralising well a by opening an earthenware cock and the Weldon recovery process is repeated, but with the following alterations

The manganese chloride liquor contains a large quantity of calcium chloride, but is comparatively free from ferric chloride, aluminium chloride, and free hydrochloric acid, and therefore requires much less limestone dust to neutralise and purify it. There is accordingly much less deposit in the settling tanks A, A. The liquor charged into the oxidising tower B contains an increasing amount of calcium chloride, and this may amount to nearly three times as much as the manganese chloride with advantage, as instead of adding the residue of the 'excess' hme in small repeated portions as previously described, the whole of the residue may be added at once, and by adopting the method of testing already described the whole of the lime may be added at once without discriminating between the 'theoretical lime' and the 'excess lime,' thus saving time in blowing and labour in testing

When sufficient mud has accumulated in settlers A, A, a long-handled plug (indicated by a dotted line in each of the tanks) is lifted, and the mud is run through pipes q to filter presses (not shown in the figure), where as much manganese chloride liquor as is possible is recovered, and the cakes of stiff nearly dry mud are then thrown away

When sufficient manganese chloride liquor has been made from native manganese in the still E to sufficiently stock the settlers A and C and to give working charges in G, B, and D, then only so much native manganese requires to be dissolved in E as will counterbalance the unavoidable losses in the whole of the Weldon plant.

(b) The Gascous Hydrochloric Acid and Almospheric Oxygen Method — After many unsuccessful attempts made by Oxland (1840), Jullion (1846), Binks (1860 and 1862), Dufrené (1865), and others, the labours of H Deacon and F Hurter, in the years from 1868 on, produced an entirely successful chlorine process which is founded on the direct oxidation of the H in HCl by atmospheric oxygen, and which utilises much more of the HCl than any process employing

either native or recovered MnO<sub>2</sub> Some processes patented after theirs (Henderson, 1871; Weldon, 1871, Wigg, 1873, &c.) proceed on the same lines, but have not been practically successful.

The Deacon process starts from the wellknown fact that a mixture of hydrochloric acid gas and oxygen at a temperature just below a red heat, especially in contact with porous substances, partially changes into chlorine and water:  $2HCl+O=H_2O+Cl_2$  This decomposition is very much assisted by the employment of substances which serve as oxygencarriers, and of these the salts of copper (previously employed by Vogel, 1855, Gatty and Laurent, 1860, Mallet, 1866), have been found most useful Probably in all cases cupile chloride is formed, which at once splits up into The Cu2Cl2 cuprous chloride and free chlorine combines with oxygen to form oxychloride CuO CuCl<sub>2</sub>, and this acts again upon HCl, yielding water and reforming cupric chloride, so that the reactions can begin over again:

(1) 
$$2CuCl_2 = Cu_2Cl_2 + Cl_2$$
  
(2)  $Cu_2Cl_2 + O = Cl - Cu - O - Cu - Cl$   
(3)  $Cu_2OCl_2 + 2HCl = H_2O + 2CuCl_2$ 

Theoretically, all the HCl would thus be converted into chlorine, but in practice, under the best conditions, about two-thirds of this decomposition is effected. The undecomposed HCl is, however, not lost, but is recovered and can be utilised for other purposes, eg for the Weldon process

From a diagram constructed by Hurter, showing the affinity of technically available elements for oxygen, chlorine, and hydrogen, it appears that no other metal than copper forms two oxides and two chlorides, in which the combination is of so loose a character. It is therefore almost a certainty that a cheaper and equally efficient catalyst cannot be found, and that the Deacon process is the best for the direct conversion of gaseous HCl into free chlorine.

Deacon's process deals with the gaseous hydrochloric acid, as it is evolved in decomposing common salt by sulphure acid without condensing it into liquid acid. This is evidently a great advantage in one way, but when the salt cake is made in the ordinary handworked pot and furnace, it has the drawback that in the beginning of each operation much more HCl, and hence more Cl, is got than afterwards. In practice, only the gases from the decomposing pots, say 68-70 pc. of the total HCl, are used for the Deacon process, those coming from the roasters being too dilute and containing too much sulphuric acid. In order to equalise the operation to a certain extent, the gases from two salt-cake pots can be mixed and the pots worked alternately, so that the strong gas from the early part of one charge is mixed with the weak gas from the latter part of the other charge.

The quantity of air necessary to form chlorine enters through the joints of the doors and dampers. It is regulated by the speed of the aspirator (a Root's blower) or cast-iron fan, which is placed at the end of the whole apparatus and produces the movement of the gases through it. Usually there are 4 vols. of air to 1 vol. of

HCl. An excess of air is less injurious than a deficiency of it, in which case there is a poor decomposition.

The gases leaving the pot are first cooled by a long string of pipes and a scrubber; thus much of the water and about \( \frac{1}{2} \) or \( \frac{1}{2} \) of the HCl is removed. A patent by Deacon and Hurter (Eng Pat 2104, 1888) provides for cooling the gas and drying it in a sulphuric-acid tower before it enters the decomposer, such complete drying being very advantageous for the process. The gases now enter the heating apparatus. This is a furnace, 16 foet \times 10 feet, in which twenty-six vertical pipes, 12 inches wide and 9 feet high, are arranged in two sets of twelve each, connected like the 'breeches pipes' in the blast-heating stoves, formerly used in nonworks and now replaced by brick heaters.

The gases are here heated up to 500°, the waste heat of the furnace is sufficient for heating the decomposer, which does not possess any fire of its own.

The gases now pass into the decomposer (Fig. 6) This is an upright cast-iron cylinder, 12 to 15 feet wide.

It contains a cylindrical ring of broken bricks D, D, supported by two cylindrical cast-iron rings of shutters placed concentrically one within the other The gases enter at the circumference

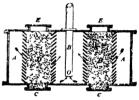

Fig 6.

at A, pass radially across the decomposing mass n into the inner space, and are led away through the pipe ob. The annular space between the shutters is 3 feet wide, and is divided into six compartments, one of which is emptied every fortnight This is done by means of the discharging doors c, c below the cylinders Fresh decomposing material is then thrown in from above through E, E, this material consists of buint clay broken up into lumps, or ordinary bricks broken, freed from dust, and dipped into a solution of cupric chloride The mass contains about 06-07 pc of metallic copper. After the active substance has served once, that is, for 10 to 12 weeks, it is thrown away Each cwt of clay produces about 10 to 12 cwts of bleach It has been found useless to attempt utilising the contact substance by redipping it in the copper solution or in any other way. The cost of copper for the contact substance does not exceed is per ton of bleach produced.

The temperature, both in the heating apparatus and in the decomposer, must be most carefully regulated, for which purpose special pyrometers have been constructed (cf. Hunter on Pyrometers, J. Soc Chem Ind 1886, 625). In the decomposer, it ought to range from 480° to 500°.

When the gases leave the decomposer, they consist of a mixture of HCl, free Cl<sub>2</sub> and steam. In the best case, two-thirds of the HCl is converted into chlorine, but sometimes only one half. The hot exit gases are now cooled by passing through a long string of earthenware or glass

through a long string of earthenware or glass pipes, and are then freed from HCl by washing with water in the ordinary acid condensers,

consisting of stone towers filled with coke, combined or not combined with acid cisterns, Woulff's jars, &c. By properly managing this process, all the acid can be obtained in the strong state, as required for the Weldon process

and other purposes

The gases can now be employed directly for making bleach liquor or chlorate liquor from milk of lime. If, however, bleaching powder is to be made, they must be freed from water because the ratio of water to chlorine is so great that strong bleaching powder could not be made; the amount of water depends on the temperature, and can be found from tables of the tension of aqueous vapour, the amount of chlorine is at most 10 pc by volume. The water is removed by passing the gases through a lead tower packed with coke, down which sulphuric acid of not less than 140°Tw is kept flowing.

As will be seen from the description, there is theoretically no loss of HCl in the Deacon process, the whole of the acid evolved from the salt being either converted into chlorine or recovered by condensation as liquid hydrochloric acid. In practice, of course, some losses occur, but they are not necessarily large, and their amount depends principally on the efficiency of the draughting arrangements and the avoidance of low-level escapes at the salt-cake pots and furnaces. The fuel used per ton of bleaching powder to heat the decomposing apparatus depends naturally on the efficiency of working of the process, and varies from 6 to 10 cwts per ton of bleaching powder

During the early years of its existence, the Deacon process had many difficulties to contend with, and the working results were disappointing

and unsatisfactory

The fact that the impurities accompanying the gaseous HCl were sufficient to seriously affect process was not realised. The impurities are sulphuric and sulphurous acid, arsenious

acid, water, and carbon dioxide

The sulphure acid and sulphurous acid carried along with the gaseous HCl, especially when attempts were made as they frequently were in the early days, to utilise the roaster or furnace gas as well as the pot gas, converted the CuCl<sub>2</sub> into CuSO<sub>4</sub>, which requires a higher temperature and gives a lower decomposition than CuCl,

The arsenious acid derived from the As<sub>4</sub>O<sub>8</sub> in the sulphuric acid used forms arsenate of copper, which is even less reactive than the CuSO<sub>4</sub> The presence of these impurities necessitated the frequent renewal of the decomposing material. Water is one of the products of the decomposition, and hence, when present in the inlet gases, increases the partial pressure of the products of the reaction and lowers the maximum p.c. decomposition obtainable under the conditions of the process

Carbonic acid derived from the fuel gases, either of the salt-cake furnaces or of the decomposing furnace itself, was a serious obstacle to, and frequently entirely prevented, the production of strong bleaching powder. This difficulty has been overcome by greater care in the construction of the apparatus and testing for leakage.

It will be noted from the above description worked.

Vol. II.-T.

that only the gaseous HCl from the salt-cake pot is dealt with by the Deacon process, and that allowing for the liquid acid collected after the decomposers, about 60 p c of the total acid is obtained in the liquid form, and has to be sold as such or used in some other way such as by the Weldon process.

193

Hasenclever, however (Eng. Pat. 3393, 1883), describes a process for gasifying the HCl in the liquid acid by mixing with strong hot sulphuile acid in a series of earthenware vessels through which air is blown. By this means, a steady continuous stream of gaseous HCl is evolved with an easily regulated supply of air passing through the series of vessels, the vitriol diluted with the water contained in the liquid hydrochloric acid has to be reconcentrated to the original sp gr. The concentration is generally performed in long, lead brick-lined pans, heated by top heat, the fuel gases being in direct contact with the sulphuric acid. This process is used to a considerable extent, but from the large quantity of sulphune acid to be concentraied per ton of bleaching powder, a very material addition is made to the cost of manufacture

Other contact substances—Many substances have been the objects of proposals, some of which are inseparable from the manufacture of chlorine from metallic chlorides, that is, from HCl in the nascent state. A general investigation on the mutual action of HCl and O in the presence of certain metallic compounds (of Cu, Fe, Mn, and Cr) was made by Lamy (Bull Soc. chim 1873, 20, 2). We must refer to the original, and will only mention that copper salts were found to be much more efficient than others, and that with these the decomposition is at its maximum at about 440°

The proposals to employ ferric chloude (Thibierge, 1855, and others) or chromic oxide (Hargreaves and Robinson, 1872) have not had

any practical success

Nickel oxide was proposed by L. Mond (Eng. Pat. 8308, 1886) He passes HCl over heated NiO, when the chlorine combines with the base The product is then in the same apparatus exposed to dried and heated air, whereby NiO is reformed and Cl is given off order to increase the active surface, pumice stone is impregnated with the chloride, and after drying the mass is exposed to the action of the gases in cylinders made of earthenware or enamelled iron The gaseous HCl and air being previously heated, the retorts do not require very much additional heat from without, and therefore can be made of a large diameter is claimed for this process that it converts the HCl completely into chlorine, and that impure HCl, which is unfit for the Deacon process, is here quite suitable

De Wilde and Reychler proposed (Eng. Pat. 17272 and 17659, 1889) to employ a mixture of magnesium and manganese chlorides with magnesium sulphate. The reaction takes place in two stages.

(1)  $Mn_3O_8Mg_3+16HCl$ = $3MgCl_2+3MnCl_2+8H_2O+4Cl$ (2)  $3MgCl_2+3MnCl_3+8O=Mn_3O_8Mg_3+12Cl$ 

The process is not, as far as is known, actually worked.

(c) The electrolysis of metallic chlorides method—Recent years have seen a large development of electrolytic processes for the decomposition of metallic chlorides, chiefly those of sodium and potassium into chlorine and alkali. It was observed as early as 1800 by Cruikshank that on electrolysing a solution of common salt, caustic sodia was formed at the negative pole Berzelius, Hisinger, and Davy all worked on the same subject, but a long time elapsed before their observations were utilised in actual manufacture

The difficulties experienced in the electrolytic decomposition of alkaline chlorides on a manufacturing scale have been first the cost of the electric current which was absolutely prohibitive until the dynamo-electrical machine had been so far developed as to be a commercial reality, viz in 1872 by Gramme, and when it became possible to conduct electrolytic experiments on the large scale over long periods of time, it was soon found that there were many and serious difficulties as the corrosion of the anodes, the evolution of gas from the cathode, the diaphragms were either excessively porous or not sufficiently porous, and they disintegrated rapidly, there were excessive resistances, voltages, and the generation of heat, and there were leactions, so  $\mathbf{that}$ neither chlorine nor the alkali metal product was obtained in the expected purity or quantity

The various electrical processes suggested or tried for the decomposition of alkaline chlorides are all attempts to overcome economically these

difficulties

Theoretically a current of 1 ampere liberates

in 1 hour 1 3236 grams of chlorine.

The number of patents taken out since the year 1885 in connection with electrolytic cells for the production of chlorine, is enormous, embodying every variety of shape, design, and method of work. We shall only deal with a few representative samples, illustrating the broad classes of design which have, up to the present, been used industrially on a large scale

In describing these developments of the electrolytic processes, and their effects upon Leblanc's process, Lepsius in Berliner Berichte (1909, 2915) says, with German pride, that it is no wonder that the electrolytic process was first carried out in Germany, the richest country of the earth in salt and potash, and while he pities the fate of poor Leblanc, yet he concludes with characteristic German military imagination and arrogance, that the bitter international struggle between the old process born in France and developed in England, and its two younger rivals, is now finished after the crippling caused by the Belgian rival, The Solvay Ammonia Soda Process, because there appeared a German rival, the electrolysis of the alkali chlorides, whose victorious conquest of the chlorine market and other successes caused such annihilating wounds that the hundred-year old process was no longer able to stand

Electrolysis of Potassium and Sodium Chlorides

The cells may be roughly divided into four classes

I The cells in which the electrolyte consists of the fused salt

II. The cells in which the electrolyte is a

salt solution, and in which the cathode and anode are separated by a porous partition

III. The cells in which the electrolyte is a salt solution, and in which a moving mercury cathode is used to receive and remove the sodium produced.

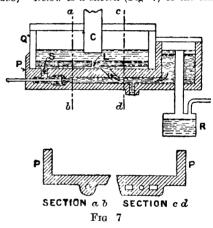

IV. The cells in which the electrolyte is a salt solution, and in which the caustic soda solution produced is only kept from mixing with the brino undergoing electrolysis by reason of the greater sp gr of the former

Class I The Cell with the Fused Electrolyte — The best known examples of this cell are the

Vautin and the Acker cell

The Vautin cell (Eng. Pat. 13568 of 1893 and 9878 of 1894) electrolysed fused NaCl or KCl, with or without the addition of fluorides or other chlorides to lower the point of fusion, over a cathode of molten lead or tin with which the sodium or potassium formed an alloy. (See paper by Vautin, J. Soc. Chem. Ind. 1894, 448.)

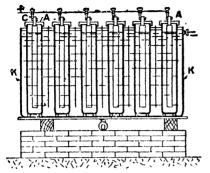

The Acker cell is designed on the same principle as the Vautin cell and makes use of the lead cathode (see Eng. Pat. 6636 and 6637 of 1898). Below is a sketch (Fig. 7) of the Aker.

cell, taken from a paper by J B Kershaw in Electrician, Oct 25, 1901. The bottom of the cell P is trough-shaped and of cast non serves as electrical connection between the main conductor and the mass of fused lead L resting on it The upper part of the cell Q is constructed of any refractory basic material not attacked by chlorine gas or fused salt anode c is of carbon and dips into the fused The channels and subsidiary vessel R are salt arrangements designed to remove and decompose the lead alloy as it becomes sufficiently saturated with sodium. The decomposition of the alloy is effected by blowing steam into it, and the heat generated by the conversion of the sodium into hydroxide is returned to the cell and assists in maintaining the necessary temperature The voltage actually taken by the Acker cell is 675, and the current efficiency 54 p.c. (Report of Commission on Science and Arts, J. Franklin Inst. 1903, 156). The Acker cell was worked at Niagara Falls on an industrial scale, from about 1900 to 1907, when the works were completely burned down and have not been rebuilt.

Class II. The Porous Draphragm Cells.—The best known of the diaphragm cells is the Griesheim cell, which has been used on a very large scale in Germany, and also in Spain, France, and Russia.

Fig. 8 represents the cell in longitudinal sectional elevation, Fig. 9 represents it in plan,

and Fig. 10 represents it in cross sectional The plate upon which the cell rests is shown by Figs. 8 and 10 to be insulated from

the ground by wooden bars, this is so that a number of such cells may be run electrically in The containing bath KK, Fig. 8, KMK,

Fig. 9, M, Fig. 10,

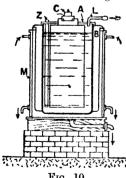

Fig. 10.

is built of sheet iron, and its two long sides are each covered with steam jacket M, the object of which is increase temperature of the electrolytes and so to reduce their electrical resistance. The negative electrical lead is attached to the iron bath as indicated the binding bу screw, lead and -

sign on the right-hand side of Fig 8 The bath is closed by a cover cut into segments and shaped so as to allow of the insertion of the five hanging iron cathode plates B, Fig. 10, and shown but not lettered in Figs. 8 and 10, and the six porous anode compartments A shown in each figure. Water is supplied to the tank K by a pipe (not shown), and by the electrolysis of the brine in the anode compartment is converted into a

caustic soda solution and hydrogen, the caustic soda solution is drawn off by the pipe under the centre of the tank shown in all the figures; the hydrogen gas is led away by a pipe not shown to gasholders for subsequent use The anode to gasholders for subsequent use compartments are composed of iron frames covered inside with cement, in the frames are set and cemented the porous diaphragms in large flat sheets These porous diaphragms were made by mixing cement, common salt and hydrochloric acid in due proportions into a paste, and then forming into the shape required: when the salt subsequently dissolves the diaphragm becomes very porous The anode compartments contain the anodes, which were first the ordinary pressed carbons, then gas retort carbons, and then carbons prepared in a special anode works, where the large pressed plates were roasted at the highest temperature of a porcelain kiln. These special anodes had a life of twelve months The Figs 8 and 10 show them passing through the covers of the anode compartments, and the external electrical Each cover also contains a connections c. long tubular earthenware basket z, Figs. 9 and 10, for the addition of solid salt and a pipe L, Fig 10, for the escape of the chlorine gas The covers on the bath, and on the anode compartments, having been made gas tight by cement, all the anode connections are electrically connected as shown in Fig. 8, all the chlorine pipes are connected into a main LL, Fig 9, and the electrical current may then be forced through the cell.

When the process has proceeded so far that the cathode liquor contains about 8 p.c caustic potash or soda and about 14 pc. of the corresponding chloride, it was found that the chlorine gas contained several per cent of carbonic acid, and as this interferes with the use of the chlorine for making bleaching powder, and as the destruction of the anodes is too costly, the process is interrupted by stopping the current and running off the cathode liquor; the cathode compartment is then refilled with fresh brine and the current restarted The cathode liquor is then evaporated in large double or triple effect vacuum evaporators until it contains 50 pc caustic alkali, during which all but a small quantity of the accompanying chloride crystallises out and is afterwards returned into the process.

The corrosion of carbon anodes led to their replacement by cast anodes of magnetic oxide of iron prepared by fusing ferric oxide in the electric arc furnace, whereby there is also a partial reduction. The anodes are difficult to prepare, but they have a good conductivity, and they last indefinitely With oxide of iron anodes there is no further trouble from carbonic acid, but the anode liquor then contains potassium chlorate which crystallises out and is removed periodically and utilised This output of chlorate can be increased at will by increasing the strength of the caustic alkali in the cathode compartment.

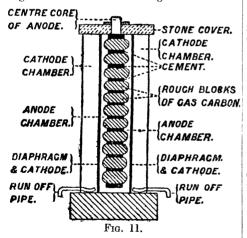

These magnetic anodes were exported by Germany to America, but when war was declared the supply was stopped and a number of attempts were made to produce them in America. Their great drawback is their extreme brittleness, but it has been found that this can be reduced to

one-half by suitable slow cooling or annealing, and that it can also be reduced to one-third by the admixture of about 5 pc of copper oxide, and by combining both modifications rods of 3 9 cm. when supported at 17 8 cm apart require a weight of 119 kg in the middle before they snap (Thompson and Atchison, Trans American Electrochemical Soc 1917, 213)

These cells in Griesheim absorbed from 1884–1892 400 h p, after which it was increased to 800 h p, and soon after to 2000 h p, by 1894 installations began to be erected elsewhere, Bitterfeld in Savony, Westeregeln, Ludwigshafen, Lamotte in France, Flix in Spain, and Slawjansk in South Russia, by 1909 the total h p, absorbed by this cell was 33,000. (Lepsius,

Ber 1909, 2895)

The Hargreaves-Bird Cell—The following illustration shows the Hargreaves-Bud cell (Eng Pat 18871 of 1892: 5197 and 18173 of 1893). The peculiarity of this cell is that the diffusion of the cathode and the anode liquids into each other through the diaphragm, which takes place in ordinary diaphragm cells, is in this cell largely counterbalanced, as far as the diffusion of the cathode liquid is concerned, by employing a very considerable hydrostatic pressure on the anode liquid This electrostatic pressure is, however, not sufficient to force any noteworthy amount of anode liquid into the cathode compartment because the diaphragm is in the ordinary sense nearly liquor tight, but it is yet sufficiently porous to allow the cation, sodium, with its electrical charge to pass through under the driving force of the electric current. The Fig. 11 is a vertical and diagrammatic cross

section of the cell It shows two thick lines marked 'Diaphragm and Cathode'; each of these consists of a sheet of iron wire gaure on to one side only of which is plastered first a layer of asbestos pulp, and then a layer of Portland cement. The frame of the cell consists of a long base shown in the figure and two uprights not shown in the figure, turning the cement sides of the two "diaphragm and cathode" plates towards each other they are so firmly pressed against either side of the base and uprights as to form a watertight cell marked 'anode chamber,' at the same time electrical contact is made

between the iron wire gauzes and the negative electric conductor. Two other sheets of thin iron are then similarly pressed against corresponding ledges provided in the base and uprights, but not shown in the figure, so as to make with the two 'diaphragm and cathode' plates two chambers marked 'cathode chamber' in the Fig Into the anode chamber is placed the anode built up of blocks of gas retort carbon on a central leaden core and also the brine to be electrolysed Into the cathode chamber no liquor as such is put, but steam is blown in, which by heating the anode cell condenses as water on the cathode and so continually converts the sodium deposited by the electric current on the wire gauze cathodes and washes the solution of caustic soda formed down to the bottom of the cathode chamber, from whence it flows by the trapped run-off As it was found that a higher officiency was obtained by passing also carbonic acid gas (the exhaust from gas engines) into the cathode chamber, the manufacture of caustic soda was abandoned and replaced by the manufacture of sodium carbonate

A paper on this cell, by Hargreaves (J. Soc. Chem Ind 1895, p 1011), states the current density as 187 amperes per square foot of diaphragm, the voltage required for the preceding current as 3.4 volts; the current efficiency as 80.3 p.c., and that the resultant soda liquor contains per 100 molecules  $\mathrm{Na}_2\mathrm{CO}_3$ , only 3.0 molecules NaCl if ordinary care is exercised, but that it is possible to reduce this amount to only 0.03 molecule. The present working is understood to give a current efficiency of about 90 p.c., and to require 4 volts per cell.

The Townsend Cell (Eng Pat 18403 of 1904) resembles the Hargreaves-Bird cell with this difference, that the cathode compartment is filled with kerosene oil which squegees the alkali as it is formed off the cathode, and thus makes it possible to produce chlorine and caustic soda in this type of cell without great loss of current efficiency Kershaw (Electrician, April 24, 1908) gives the current efficiency as 90 p c, and the voltage per cell as 47 In the Seventh International Congress, 1909, 10, 36, Backeland describes the result of 31 years' work at Niagara with 1000 kilowatts, the old cells were made for 2000 amperes, but new cells to consume four times this power will be capable of taking 6000 amperes The current density per square foot of anode surface has also been increased from 100 amperes to 144 amperes The attack on the carbon anodes requires the cleaning of the cell in about 30 days, which is a very simple matter, and the graphite anodes are so arranged that they can be repaired, and are ultimately entirely consumed. Aluminium conductors last longer than copper conductors in atmospheres where small amounts of chlorine are occasionally present. The hydrostatic pressure in the anode chamber is regulated so that with a cell using 2500 amperes, the amount of liquor passing through the diaphragm is most advantageously 24 litres per hour, which gives a soda liquor containing per litre 150 grm. NaOH and 200 grm. NaCl, and under these conditions the anode liquor contains but little hypochlorite and chlorate and consequently the chlorino has a satisfactory degree of purity.

The Finley Cell (Eng. Pat. 1716 of 1906) has a double diaphragm dividing the anode and cathode compartments. The diaphragm is very open in texture, and the brine feed for the cell is run into the centre compartment between the two diaphragms, from where it passes outwards on either side to the anode and cathode compartments. In this way, an additional obstacle, depending for its strength on the speed of feed of the brine, is interposed to prevent intermixture of the products of the electrolysis.

The diaphragms are made of asbestos 2-3 mm thick, and the compartments are also only a few millimetres thick, the diaphragms and frames are belted together in any number after the fashion of a filter piess. (Seventh International Congress of Applied Chemistry, 1909,

x. 42)

Class III. The cells in which the electrolyte is a salt solution, and in which a moving mercury cathode is used to receive and remove the sodium

produced

The mercury cathode for the preparation of alkali metals was first used by Davy, it was described in an application for a patent (Eng Pat 4349 of 1882) by Nolf It is mentioned again in Hermite's patent, 3957 of 1886 Further patents describing its use are Hermite and Dubose, Eng Pat 21959 of 1891, Greenwood,

Eng. Pat 5999 of 1891

The general principle of these cells is that the electrolysis takes place between an anode above and a cathode of mercury vertically below. The chlorine liberated naturally rises upwards and out of the solution, and the sodium or potassium freed combines with the mercury to form an amalgam. The amalgam, when sufficiently highly saturated with the alkaline metal, is replaced by fresh mercury and the amalgam itself decomposed by water, with the liberation of H<sub>2</sub> and the formation of a caustic alkaline solution

The current efficiency of the modern mercury cell is stated to be not less than 90 p c, and the

voltage required 4 3 volts

Professor Lepsius (Ber 1909, 2903) enumerates the following advantages and disadvantages of the mercury cell as compared with

the diaphragm cell -

The advantages of the mercury cell are (1) the purity of both the chlorine and the caustic alkali produced, which are very important advantages, (2) the comparatively high concentration of the caustic solution; (3) the high current efficiency.

The disadvantages of the mercury cell are:—(1) the higher voltage, 4 3 volts as against 3 5 volts in the diaphtagm cell; (2) the cost of the mercury, of which 72 tons are required for a plant utilising 6000 h p , (3) the greater cost of installation apart from the question of the mercury

The various patents taken out and cells suggested differ chiefly in the method adopted for the movement of the merculy. To Castner, however, belongs the chief credit of making the

mercury cell technically successful.

Casiner's Rocking Cell—Castner (Eng. Pat No. 16046 of 1892) employs a moving mass of meicury, connecting up the anode and cathode chamber. Patent No. 10584 of 1893 makes the movement of the mercury by a rocking motion of the cell, see Fig 12, which represents the original rocking cell A is the cell divided into

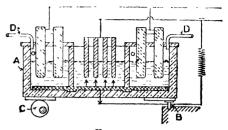

Fig. 12.

three compartments, and resting on the righthand side on adjustable kinfe edges B The lefthand side of the cell rests on an eccentric, c, tevolving on a shaft; this gives the rocking motion The two outer or anode compartments have carbon anodes and are filled with saturated bime, the centre compartment contains iron cathodes and is filled with NaOH solution A layer of mercury, about  $\frac{1}{8}$  inch thick, hes on the bottom of the cell and alternately flows from first one and then the other anode compartment into and through the cathode compartment into the other anode compartment. The chlorine liberated in the anode compartment is carried away by pipes on

Castner, in the Chemical Trade Journal, 1894, 211, stated that the results of 1 week's work on a unit of 28 working cells, arranged in two parallel series of 14, gave a yield of 930 lbs. chloring and 1120 lbs. NaOH per 24 hours, the amperes used averaging 571, and the volts 55 1 or 3 9 per cell

In 1895 the Castner Kellner Alkalı Co was formed to work this cell. Works were erected in Runcorn with 1000 h p, and other similar works were soon erected abroad, viz. at Osternicuburg near Bernburg with 1500 h p by the Deutsche-Solvay Werke, at Augsburg by Merster Lucius & Bruning, at Jemappes near Brussels with 1000 h p, at Liubimow in Russia, at Jaice in Bosma with 1300 h p, and at Niagara Falls, N America, by the Castner Electrolytic Alkalı Co in 1901 with 6000 h p. (Lepsius, Ber 1909, 2903)

in 1901 with 6000 h p (Lepsius, Ber 1909, 2903) Kellner Pressure-displacement Cell—In this cell the chlorine compartment is placed in the

Fig. 13.

centre of the cell and on either side of it is a caustic compartment, each of which is provided on its further side with a recess, DD, which forms the alternative receptacle for the mercury. In these receptacles are immersed pressure vessels open at the bottom and connected at their tops to compressed air supplies which are automatically so regulated that the mercury is forced to move continuously from side to side by compressed air.

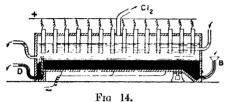

Above (Fig 13) is a sketch which shows the construction and working of the cell, taken from the Chemiker Zeitung, Oct. 30, 1909.

The anodes are platinum gauze of which I gram is made to cover four square inches, and are placed in a cement box which has proved more satisfactory than the stoneware jars Each cell contains six electrode formally used boxes, and each box holds 88 pieces of platinum gauze. The cathodes are cast iron, cast in grill shape, and the primary battery, sodium amalgam-caustic solution-iron, acts independently of the main current through the chloring cell, The current used is and also regulates itself 4000 amperes per cell

The great advantage of this cell is the highcurrent density which has resulted in consider-

able reduction of plant

The Kellner-Solvay Scoop Wheel Cell —This cell consists of two slanting troughs communi-

cating with one another at each end, in which the mercury is kept in constant circulation by a rotating scooped wheel placed between the two troughs at the one end. This cell is built; in very large units, taking up to 10,000 amperes, and it is said that a 15,000-ampere cell is well within the bounds of possibility

Fig 14 is a diagrammatic sketch of the chlorine side of the cell, B being the mercury inlet and D the outlet for the amalgam, the scooped wheel is, however, not shown, neither is the caustic

side of the cell

Whiting Cell —A cross sectional view of this cell is shown in Fig 15 The right-hand side shows in the upper portion the tement cover with its attached graphite anodes and connections being lowered into the brine cell below, which consists of a number (say five) of separate compartments

intervals of two minutes, the mercury amalgam is entirely emptied by the automatic lifting of poppet valves, which are operated by the little shaft and cams shown above the cells towards the left, and the liquid amalgam runs over the graphite plates lining the threefold zie-zae iunway shown on the left of the figure; these plates and the amalgam being immersed in water act as a primary cell and generate caustic soda solution, hydrogen and pure mercury. The mercury next reaches the scoop wheel and by arrangements not shown in the figure is lifted and flows to the right side of the figure, whence it enters each cell

The ebb and flow of the mercury in rotation is used to admit fresh brine supplies to each compartment. This complicated arrangement is made to prevent the unequal flow of mercury and the formation of sodium amalgam of excessive strength. The cell was operated at the

Oxford Paper Co., Rumford, U.S.A., and is de scribed in Trans American Electrochem. Soc., 17, 327 (1910)

The new Castner-Kellner Cell differs essentially from the Kellner-Solvay cell only in the method of conveyance of the mercury, which, in this case, is effected by means of an Archi-Taussig, Zeit. für Elektrochemie, median screw 1909, 659

Class IV The Specific Gravity Cell — The best known cell of this type is the so-called 'Glocken Cell,' patented by the Oesterroichischer Verein für Chemische und Metallurgische Produckte, and from 1901 working on a large scale at Aussig in Bohemia, Berlin, and Stassfurt

Fig 16 is a diagrammatic sketch, in which A is the anode and K the cathode, separated by the non-conducting and impervious walls D, E of the bell a The bath w is filled with salt solution, which enters at L and overflows at the pipe F The chlorine escapes at c. These walls are required to keep the ascending current of hydrogen gas arising from K quite distinct and separate from the ascending current of chlorine gas arising from A The anode and cathode are both situated in the upper parts of the electrolyte, and these parts are greatly agitated by the ascending gas bubbles-but the lower portions of the electrolyte are almost entirely stagnant and serve only as a means of conducting the electric current from the anode to the cathode. As the brine around the anode loses a portion of its chlorine by escape of the gas, and loses a corresponding portion of its sodium by electric migration of the cation Na' towards the cathode, this layer of liquid becomes continually lower in specific gravity and would ultimately lose all its dissolved salt were it

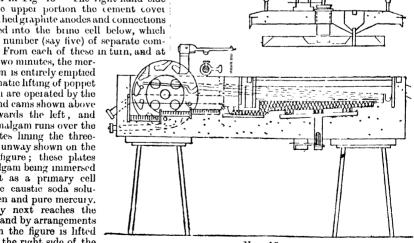

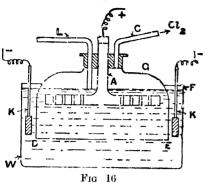

Fig 15.

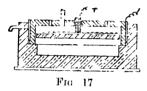

not for the constant feed of fresh brine at L: the quantity of this feed is such that it is only partly able to counterbalance the reduced On the other hand, the sodium gravity liberated on the cathode forms with the adjacent brine an intensely strong film of caustic soda

solution, which falling by its high specific gravity into the lowest part of the cell forms a

heavy layer there which is scarcely disturbed by the slow current of weak brine from the inside of the bell trickling past the edges of the bell to be partially converted into caustic soda and

hydrogen before it passes away by the exit pipe F

Figs 17, 18, and 19 are diagrams of the actual cells, Fig 17 being a cross sectional elevation, Fig 18 a

plan, and Fig 19 on the left-hand side a longitudinal sectional elevation of the bell and its attachments, and on the right-hand side a cross sectional elevation of the same. The

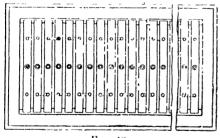

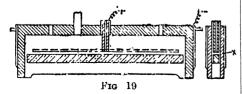

Fig. 18

outer containing vessel is seen to contain two ledges to carry the bells, of which there are a great number in each cell. The junction of the anode with its conducting stem is badly shown

in the figures. The brine supply is different from that shown in Fig 16, for, to prevent the agitation of the electrolyte by the inflow of brine, the supply pipe is made to traverse the whole

length of the anode, its two ends are closed and the brine escapes by a number of small holes along its upper side. The main portions of the cathode are best seen on the right-hand portion of Fig 19 at x. The chlorine passes from bell to bell by the connecting arms shown in Fig. 18, and then makes its exit from some particulai bell by the larger pipe shown in Figs 17 and 19, but not shown in Fig. 18. The electrical connections are indicated diagrammatically in Figs 17 and 19 only Each bell takes about 22 amperes at 4 volts (Lepsius, Ber. 1909, 2904)

Electrolysis of Zinc Chloride—The waste calcium chloride from the ammonia soda process has been utilised since 1897 by Brunner Mond and Co, of Winnington, as a source of By heating the liquor with crude chlorine zinc oxide and carbon dioxide the reaction  $CaCl_2 + ZnO + CO_2 = ZnCl_2 + CaCO_3$  takes place, or by treating it with native zinc carbonate (calamine) the reaction  $CaCl_2 + ZnCO_3 = ZnCl_2 + CaCO_3$  The filtered solution of zine chlorido is freed from its impurities (amongst which is a not inconsiderable amount of cadmium) and the resultant solution is electrolysed with carbon anodes and circular revolving cathodes that are only partially immersed, to produce chlorine gas and an exceedingly pure metallic zinc. Many of the details are due to C. Hopfner (But. Pat. 11724 of 1891, and D R P 85812 of 1895) Fuller details are given in two volumes of Monographien über angewandte Elektrochemie, namely—Die Darstellung des Zinks auf elektrolitischem Wege, Gunther, 1904, 99-180 and Die elektrochemische und elektrometallurgische Industrie Grossbritanniens, Keishaw, 1904. 108, and also in Applied Electro-Chemistry, Allmand, 1912, 286

(d) Proposals and non-important methods for the manufacture of Chlorine—Many processes have been proposed and tried for utilising the residual ammonium chloride, or the residual calcium chloride of the ammonia soda process, but with the exception of Hopfner's zinc chloride method just previously described, none are now in use Many other processes have also been tried for preparing chlorine from various sources and in various ways, but have been abandoned. Some of these old methods are enumerated below, fuller information may be obtained from Lunge's Sulphuric Acid and Alkali

1 Chlorine from ammonium chloride—The most persistent efforts for the direct manufacture of chlorine from NH<sub>4</sub>Cl were made by Mond, who took out the English patents Nos 65, 66, 1049, 3238, 8308, of 1886, 10955 and 17273 of 1887, 2100 and 2575 of 1889 Articles dealing with the Mond process are found in J Soc Chem Ind 1892, 466, 1893, 10, and 1893, 63 There was also a proposition from the Verein Chemische Fabriken of Mainz (Eng Pat 3322 of 1886)

2. Chlorine from CaCl<sub>2</sub>.—Persistent efforts for the direct recovery of the chlorine in the CaCl<sub>2</sub> produced in the ammonia stills of the ammonia-soda process were made by Solvay: Patents 77 and 171 of 1877, 838 of 1880, 7258 and 7259 of 1884; 8724 of 1885; 13389 of 1886; 18574 of 1888 Other patents: Twynam's process (Eng. Pat. 731 of 1885); Bramley's process (Eng. Pat. 8289 of 1887), Lyte and Steinhart (Eng. Pat. 21225 of 1890)

Chlorine from magnesium chloride.—Many efforts were made by Weldon to produce chlorine direct from MgCl<sub>2</sub>; his patents are: Eng Pt 565 of 1868; 967, 968, of 1881; Weldon and Péchiney, 9305, 11035, of 1884; 14653, 14654, of 1887 Detailed description of the Weldon-Péchiney experimental plant at Salmide, is given by Dewar (J. Soc. Chem Ind. 1887, 775) Other patents are Wilson (Eng. Pat 3098 of 1885), Gamble (Eng. Pat 17217 of 1889), Lyte and Tatters (Eng. Pat 17217 of 1889), Schlosing (Eng. Pat. 11821 of 1887, 11469, 11470 of 1891) (See also Eschellmann, J. Soc. Chem. Ind. 1889, 2, comp. ibid. 100)

Chlorine produced by passing HCl gas over heated peroxide of iron on manganese is the subject of a patent by H Burns (No 15448 of

1886).

Chlorine by permanganates has been the object of patents by Tilghman (1847), Condy (1866),

Tessić du Motay (1871 and 1873)

Chlorine from chromates and HCl has been proposed by MacDougal and Rawson (1848), Peligot (Ann Chim Phys. [2] 411, 267), Gentele (1861), Shanks (1858), Claus (1867), Aubertin (1873)

Chlorine by heating metallic chlorides with MnO<sub>2</sub> and H<sub>2</sub>SO<sub>4</sub> was patented by Binks in 1853

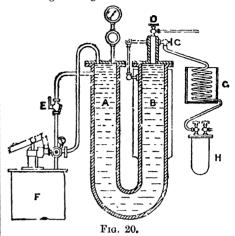

Chlorine by the assistance of nitric and or nitrates - Baggs and Simpson (1864) proposed making chlorine from aqua regia Dunlop (1847) patented the preparation of chloring along with nitious acid, by heating together common salt, sodium nitrate, and sulphuric acid, the nitious acid is absorbed by vitiol and the chlorine is passed on to bleaching-powder This process was working for many chambers years at St Rollov; it was patented again by Roberts and Dale in 1868, and a patent running on similar lines is that of J Taylor (No 13025 of 1884) Other processes employing nitrates or nitric acid, which have not had any practical success, are those of Banks (1839), Tessié du Motay (Bull Soc chim 22, 48), Schlosing (Compt. 1end 55, 284) The later The later patents are those of Donald, Eng Pat 62 of 1887, and Just, Eng Pat 14857 and 14859 of 1888, Davis, Eng Pat. 6416, 6698, and 6831 of 1890, Wallis, Eng Pat 13822 of 1892, and Krause, Eng Pat 16227 of 1894.

Chlorine Liquid — Liquid chlorine was first obtained in 1805 by Northmore — The pure gas can be condensed to a liquid at atmospheric temperature, 15°, by a pressure of six atmospheres, or at atmospheric pressure by reducing its temperature to —34° — If the gas is not pure it requires higher pressures or lower

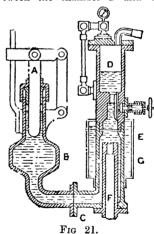

temperatures to liquefy it

The first to prepare it commercially was Knietsch of the Badische Amlin und Soda Fabrik in 1888 The English Patent 13070 of 1888 records that the ordinary metals withstand the action of chlorine gas provided the gas be dry, so that cast iron, wrought iron, steel, phosphor bronze, brass, copper, zinc and lead may be used for making apparatus for dealing with gaseous and liquid chlorine. The resistance of ordinary metals to attack was evidently not sufficient for the manufacture of a pump with moving metallic piston or plunger, for the patent describes two pumps each with a moving piston of concentrated sulphuric acid to confine

and compress the chlorine gas contained in one limb of a U-tube, while the upper part of the other limb contains another liquid like paraffin oil in which pressure is exerted either by an external pump filled with the same liquid, Fig 20, or an internal plunger A, Fig 21 In the first figure the gas valves D and C are shown

external and are actuated by hand. In the latter figure the valves are internal and are actuated by their own weight and the pressures of the gas, the inlet valve sits on the top of the pipe the outlet valve sits on the top of the pipe opening into the bottom of the chamber in To ensure that the whole of the gas is swept out of the compression chamber a small pipe with an external controlling valve is arianged between the chamber in and the compression

chamber so that on each suction stroke a portion of the acid in D enters the compression chamber along with the gas from F, and on each pressure stroke first chlorine gas and then a little sulphuric acid passes the automatic valve in the bottom of To prevent intermingling of the paraffin and acid the pump limb in Fig 21 is en-

larged in diameter at B. To prevent the possibility of gas being liquefied in the compression chambers, these are heated by an external packet as around B in Fig. 20, and as E.G in Fig. 21. The compressed gas on leaving either form of pump is liquefied in a cooler, as G in Fig. 20, and then runs into the collecting vessel in

In 1909-10 the manufacture was started in the United States of America. With minor

alterations Knietsch's process is still used though it had its difficulties. The Metallurgical and Chemical Engineering of 1916, 1, 215, states that liquid chlorine is now made almost entirely from electrolytic chlorine, and that Deacon chlorine is no good for the purpose unless it is first strengthened, as by extracting the chlorine with stannic chloride as proposed by Goldschmidt Starting with a gas supply of 97 to 98 pc purity the uncondensable blow-off gas still contains 55-65 p c chlorine, and this is absorbed in bleach chambers.

As already stated pure chlorine can be liquefied at atmospheric pressure by reducing its temperature to  $-34^{\circ}$  The Linde Co, of Germany, have introduced the process of simply cooling the chlorine gas to -45° without applying any pressure, but they are said not to liquery so high a percentage of the gas as the older process In 1911 Blucher's Modern Industrial Chemistry states that it was becoming more and more general simply to cool the chlorine gas in refrigerators so that it liquefied at normal

pressures

The liquid is supplied in steel cylinders or in ik cars holding several tons. The physical tank cars holding several tons The physical properties of the liquid were determined by Knietsch (Liebig's Ann 259, 100; the Fifth International Chemical Congress, Zeit f Comp flussige Clase, 1904, 71), and certain of them have been confirmed by Lange (Zeit f Comprimirte und flussige Gase, 1901, 39), who showed that the thermal coefficient of expansion rises steadily to 88° when its value is 0 00366, that is the same value as is given by ordinary gases, and that above that temperature the liquid expands more rapidly than the gases, he also showed that whereas liquid chlorine does not act upon non at any temperature up to 83°, yet at 96° there is a small action, for these several reasons a cylinder of chlorine filled in the ordinary way begins to become unsafe when heated to 90°

Applications of Chlorine.—It is used for the extraction of gold from its ores, and much work has been done on its use for extracting copper, lead, and zinc from mixed ores used for converting ferrocyanide into ferricyanides, manganate of soda into the permanganate, ferrous chloride into ferrie chloride, and was used for converting alumina into aluminium sodium chloride, conveiting tin into stannic chloride either from pure tin or from scrap tinned iron, after which the residual iron can be again smelted for metallic iron, this Goldschmidt process of detinning consumed large quantities of chlorine in Germany and led to the preparation of liquid chlorine in the United States of America when a plant in Chicago was installed in 1911 to treat 40,000 tons of tin scrap per year. It is used along with electrolytic hydrogen for preparing hydrochloric acid in Germany and America It is largely used for purifying drinking water, the liquefied chlorine being extremely handy for this purpose as the supply can be automatically regulated in any proportion to the amount of water passing in the mains, and a summary of the work done on gaseous chlorine as a disinfectant is given by Clayton (Journ Soc Chem Ind., 1896, 320) When used for bleaching it may be absorbed in caustic alkali to make the corresponding hypochlorite, or it may be absorbed in sodium carbonate solution to make hypochlorous acid

 $Na_2CO_3+Cl_2+H_2O=HOCl+NaHCO_3+NaCl$ which acts approximately twice as energetically as the corresponding amount of neutral hypochlorite

It is used for converting earbon disulphide into carbon tetrachloride and sulphur chloride. and for preparing the latter direct from sulphur, for converting benzene into monochlorbenzene, dichlorbenzenes, and trichlorbenzenes, acetic acid into monochloracetic acid, toluene into benzylehloude, benzylene dichloude, and benzenyl trichloride, and alcohol into chloral all these reactions the hydrochloric acid simultaneously formed is condensed in water and a very pure munatic acid is thus obtained

It is combined with acetylene to form tetrachlorethane, and from derivatives of this it is used to form pentachlorethane and tetrachlorethene, with carbon monoxide it is combined to form carbonyl chloride, with sulphur dioxide it is combined to form sulphuryl chloride (Ullmann, Chemische Industrie, 1908, 405) Other uses of chlorine are for chlorinating anthracene, anthraquinone, the cresols, benzoic acid, the xylenes, isoamylchloride (Perkin, Journ See Chem Ind 1912, 616), for the preparation of acetyl chloride, and of acetic anhydride

Many of the above uses of chlorine have been developed because of the necessity of finding new outlets for the enormous quantities of chlorine produced in recent years by the electrolytic processes for preparing caustic potash and caustic soda

The poisonous properties of chlorine gas were first used in waifare by the Germans In April, 1915, near Ypres, a German desetter in the Ypres salient gave warning of the first attempt to use poison gas in modern warfare believed him, but a week later the enemy launched his first attack with chlorine gas against our unprepared and unprotected troops. The gas was liberated from cylinders containing 40 lbs of liquid chlorine The German war of nightfulness was made to include chemical frightfulness Protection against the chlorine gas clouds was obtained by a helmet consisting of a flannel bag soaked in a solution of sodium thiosulphate and sodium carbonate, and contaming a mica window (Bevan, Journ Soc Chem Ind 1916, 651, Self, Journ Soc Chem Ind 1915, 868) Since then the Germans have used a number of gaseous chlorine compounds as poison gases, as phosgene COCI2, chloropictin CCl<sub>3</sub>(NO<sub>2</sub>), trichloromethylchloroformate ClCOOCcl<sub>3</sub>, "mustard gas" dichlorodiethyl-CICOOCCI<sub>3</sub>, "mustard gas uninotical control of the sulphide chloroacetone, chlorosulphonic acid, other, Soc Chem methylchlorosulphonate (Journ Ind. 1918, 127 R, and Tone, Metallurgical and Chemical Engineering, 1918 [2] 357). Shame to their boasted Kultur

In the following pages are described in detail the applications for the manufacture of bleaching powder, liquid chloride of lime, calcium hypochlorite crystal, potassium hypochlorite solution, sodium hypochlorite solution, sodium hypochlorate crystal, potassium chlorate, sodium chlorate and hydrochloric acid.

Chloride of lime or bleaching powder. By far the greater part of the chlorine produced on a manufacturing scale is converted into chloride of lime or bleaching powder.

In 1799 Charles Tennant took out a patent for absorbing chlorine by dry hydrate of lune, and the compound thus formed, 'bleaching powder,' was sold by the St. Rollox Works, established in the same year, at 140l. per ton.

Composition of Bleaching Powder—This substance being originally supposed to be a direct compound of chlorine and lime received its original name of chloride of lime; but in 1835 Balard propounded the theory that bleaching powder was a compound or mixture of equivalent proportions of calcium hypochlorite and chloride

mixed mechanically with a residue of calcium hydroxide In 1842 Gay-Lussac supported these views.

Subsequently Odling, Lunge, Schappi and Naef showed that CaCl, as such does not exist in bleaching powder, as it cannot be extracted by alcohol, etc, and they therefore proposed the constitution Cl Ca OCl, and the full formula for bleaching powder may then be written Ca  $\left\{ \begin{array}{c} \text{Cl} \\ \text{OCl} + \text{H}_2\text{O} \end{array} \right\}$  Free lime is always present in commercial bleaching powder because it is only guaranteed to contain 35 p c of available chlorine, and stops are taken not to let the chlorine exceed this amount essentially, bleaching powder can experimentally be made much stronger than 35 p c. So much so that any attempt to express the free lime as an essential component is evidently fallacious

Preparation of Lime for Bleaching Powder—
The lime required for the manufacture of bleaching powder must be from as pure a limestone as possible and must be well burned. Among the most suitable limes for bleaching powder is that used in Lancashire, and made by burning the Derbyshire limestone in the district round Buxton. The average composition of this limestone is:

CaCO <sub>3</sub> .				98 9
MgCO <sub>3</sub> .				0 29
$Fe_2()_3$ .				0 17
Insol. etc				0.35
$H_2O$ .	•	•	•	0 05
				00.76

The buint lime was until recently slaked by spreading it on a brick floor, sprinkling it with water and turning it over with a spade till it has completely fallen to powder, after which it is allowed to remain in a heap for 10 hours, and the slaked lime is then passed through a wire sieve of 12–18 wires to the lineal inch by the aid of rotating cylindrical sieves. The operation of hand slaking gives rise to a considerable amount of heat, steam and dust which being unconfined are very trying to the workers, who protect themselves with muzzles and goggles.

For this reason slaking apparatus have recently been introduced whereby the operation is entirely mechanical and the apparatus is entirely enclosed and properly ventilated, so

that not only are steam and dust prevented from escaping but labour is also saved.

The slaked lime as used for bleaching-powder manufacture contains about 25 p.c. H<sub>2</sub>O, and should not contain more than 2 5 p.c. CaCO<sub>3</sub>.

The Bleaching-powder Chambers.—The apparatus in which the chlorine is brought into contact with the slaked lime varies with the concentration of the chlorine gas to be treated.

With highly concentrated chlorine gas of 85-90 p c. chlorine chambers of large size are used, namely of about 6½ feet in height, so that a man can work inside them, of a width of from 10 to 20 feet and more, and up to 100 feet long. Their sides and top are usually made of about 5- or 6-lb sheet lead, fastened by external lead straps on an external timber framework, exactly like vitriol chambers.

The floor is made of large stone flags, or of coal-tar asphalt, the joint between the sides and the edge of the floor being specially protected by a skirting and asphalt poured behind it.

The chambers are fitted —with doors at each end, so as to ventilate the chamber when it is being charged or discharged (generally made of non protected by paint), with glass panes in two opposite sides or ends for observing the colour of the gas, with 'lutes' for introducing the gas, with other lutes in the roof of the chambers for the exit of the unabsorbed gases, and with some contrivance for removing the gas remaining at the end of the operation (v infia).

Sometimes the chambers are not erected on the ground-level, but upon pillars, like vitrol chambers, leaving about 10 feet of clear space from the ground. In this case the packing of the finished bleach into casks can be done by means of trap-doors in the chamber floor, with wooden hoppers attached underneath, below which the casks are placed, the bleach being pushed down into them from above by means of wooden rakes.

Sufficient slaked lime is wheeled into the chamber to make a uniform layer of 3 to 4 inches, and the piles of lime are then spread by shovel and a big wooden rake with a plain blade from which stick out below two long gauging spikes and with this the lime is very quickly spread into a perfectly even layer of the desired thickness. In order to assist absorption the surface of the lime is drilled into furrows by a take similar to that described except that the lower edge is provided with deep notches about three inches wide and the same in height; the increased rate of absorption is caused not so much by the extra surface exposed to the chlorine as by the continuous draught of gas through the ridge resulting from the gas in the furrow (chlorine) being heavier than the gas in the ridge (the residual air from the not pure chlorine). The chamber doors are then closed and the joints made gastight with lime putty or with a luting made of

tar and china clay
The 'gassing' of the chambers is done
either singly or in series, the former being the
old method

The Single-chamber Method —A small lute in the top of the chamber being opened, the gas connection is opened, and through the small windows the heavy chlorine could be seen

falling to the bottom of the chamber, and there vanishing. As the formation of the bleaching powder proceeds the gas spreads further, forms a layer all over the lime, the layer increases in thickness and presently chlorine begins to issue from the open lute, which must then be closed and the chlorine main connected to another chamber, without however shutting the gas off from the first chamber, which thus continues to receive a certain amount of chlorine. After a short time the gas inlet to the first chamber is closed, and the chamber is left to itself for 12 to 24 hours, when the gas becomes pale in colour or colourless.

It is difficult to get full-strength bleach by one operation; there is always a superficial crust which greatly hinders the penetration of the gas It is, therefore, necessary to turn the stuff over with spades, and treat again with chloime.

The opening of the chamber doors for this purpose was formerly one of the most awkward operations in an alkali works, as a nuisance was caused not only in the works but sometimes at a distance of a mile or two, and on occasion has been so intolerable as to have produced fatal effects. The matter is now under the Inspector of Alkali, &c, Works. The gas in the chamber must, before any door is opened, be tested by drawing a sample from the exit end at a height of not more than two feet above the chamber floor.

For testing the sample, several kinds of apparatus have been proposed eq that of Ballard (21st Report on Alkalı, &c, Works, 37, 22nd do 55) and of Stark (J Soc Chem. Ind. 1885, 311) Ballard's apparatus consists of a cylindrical glass jar, closed at the top by an indiarubber cork, through which the nozzle of a 4-oz enema ball (finger pump) passes, as well as an elbow tube reaching down to the The lower end of this tube is closed at the lamp, so as to leave an opening fine enough for a needle only to pass through houzontal branch of this tube is inserted in the side of the chamber at a point about 2 feet from the bottom When compressing the ball, the air is driven out by a small hole made in the nozzle just above the cork, this is now closed by the finger, and on relaxing the pressure the ball will expand, and will cause 4-oz measures—that is, 25 of a cubic foot—of chamber air to enter into the jar and bubble through the test solution contained therein This is continued till the end of the reaction is indicated by the test liquor turning blue The liquor consists of 3 485 grains of arsenious acid, dissolved in sodium carbonate and rendered neutral by sulphuric acid, to which is added 250 grains potassium iodide, 50 grains precipitated chalk, 10,000 grains water, 6-10 drops For each test 400 grains are used, ammonia adding a little starch paste at the time of using When 2½ grains of chlorine per cubic foot are present in the chamber air, ten aspirations of the chlorometer will cause a blue colour to appear; if more aspirations are needed, there is less chlorine present, and vice versa. Stark's apparatus attains the same end, not by the finger pump (which is certainly a somewhat rough instrument), but by a gas burette on the Orsat'

Another form of apparatus is Fletcher's in J. Soc. Chem. Ind. 1887, 367.

Collapsing Gas Sampler, an aspirator shaped like a concertina made with ebonite ends and indiarubber coated cloth sides, into which a measured quantity of sodium arsenite is charged It is easily carried to the chamber without fear of breakage An attached rubber tube, a short length of glass tube, both cleaned by recent washing, and a piece of soft, luting enable it to be attached air-tight to the chamber. By fully pulling the bellows open one tenth of a cubic foot of gas is drawn in, and the rubber tube being then closed by kinking, the gas is thoroughly shaken with the solution; a side opening previously closed with a finger is then opened and the gas expelled into the operator's face, it will probably not smell of chlorine, further measured quantities of gas are drawn in and shaken until the expelled gas begins to smell of chlorine.

If the test is above 2½ grains chlorine further time must be given for the chlorine to be absorbed, or it must be otherwise removed most satisfactory way of removing the chlorine is to dust into the chamber through a luted hole in the top, more or less dry slaked lime either by hand or by Brock & Minton's whizzer (Eng Pat 7199, 1886; 23 Report on Alkalı, &c., Works, 58-60) This machine, on being lowered into the hole, rests in the water of the lute and no chlorine escapes. The hopper of the machine is filled with slaked lime powder and the handle being turned the lime drops slowly towards an attached paddle which is revolving at a high speed inside the chamber, and the large air currents which it sets up in the chamber carry the lime dust to a considerable distance in the chamber, and a very energetic absorption of To reach every the chlorine begins instantly part of the chamber the machine is lifted out of the hole and carried to one or two other holes and these also dusted. In this way anything up to 2 cwt of chlorine in a chamber 100 ft long may be absorbed, and the dust settled within 3 hours

When it is proved by any of these tests that the air in the chamber contains less than 2½ grains of chlorine per cubic foot, and it is daylight, then the chamber doors may be opened

After the doors have been opened, and the chamber allowed to ventilate itself a little, the workmen wearing thick flannel muzzles may enter, and with shovels turn the bleach. The doors are then closed, litted, and the chamber gassed again as before described.

Sometimes this must be done even a third time, before the appearance of the product and the laboratory test show it to be finished. To avoid the objectionable turning of the bleach in some British works and generally in Germany and France the layers are made only two or even only one inch

The Series of Chambers Method —This method was described in Lunge's Sulphuric Acid and Alkali, 1880, as the only rational one—It was described in the Inspector under the Alkali Acts Report for 1885 as a most important improvement used in a large English works by which stronger bleach was prepared than previously possible and that without losing chlorine or causing a nuisance—It was again described by Jahne of Petrowitz, and the abstract is found in J. Soc. Chem. Ind. 1887, 367.

The series consists of at least three chambers. better four, or even more, and with the Deacon chambers, which are worked on the same method, seven chambers form a series In the series the gas always enters first into a nearly finished chamber, and the unabsorbed gas passes in succession through other chambers which are further and further removed from being finished until the whole of the chlorine is absorbed and the exit gas is accordingly 'sweet' The thickness of the layer of slaked lime must be such that the whole of it can be sufficiently chlorinated without turning. When it is considered that the first chamber has been sufficiently chlorinated the stream of strong chlorine is directed into the next following chamber and is cut off from the finished chamber. The finished chamber is, of course, full of chlorine nearly as strong as that supplied by the generators and it is absorbed by the bleaching powder only exceedingly slowly The casiest and quickest way of removing this gas is by the use of Brock and Minton's whizzer described in the 'single chamber method' When the chamber is sweetened with all the precautions previously described it may be opened, the bleach may be very carefully sampled, taking great care to take due proportions of the top and bottom layers, and the sample tested in the laboratory. The experience of the workmen generally leads to the obtaining of a satisfactory test, but should it be low the chamber may be turned or not, closed, and gassed again for a certain time, and then treated as before, and finally the bleaching powder removed The empty chamber is at once limed, closed, and put into the working series again, but now as the last chamber of the Each chamber in turn comes up to strength and is removed from the series, packed, limed and inserted again into the series, and so on indefinitely The system of gas pipes and lutes necessary for making these changes is figured in Lunge's Sulphuric Acid and Alkali, 3rd ed vol. 3, p 618, for a set of three chambers. and the same system of pipes are used for the Deacon Chambers next described

The following rules relating to bleaching powder chambers worked in either of the two preceding ways are recommended by the Chief Inspector of Alkali, &c, Works (Mr A E.

Fletcher), in his 21st Report, 12 -

I Bleaching-powder chambers should contain not less than 200 square feet of floor space for every ton of powder made in them per week If there is less space, the work, and especially the

packing, must be hurried too much

II. The chambers should be so arranged and connected together that the residual chlorine from a finished chamber may be drawn into one containing fresh lime, unless some other means be employed for absorbing it (such as Brock and Minton's plan described above) The air finally discharged into the atmosphere or into a flue or chimney must not contain more chlorine than  $2\frac{1}{2}$  grains per cubic foot.

III. No chamber should be opened when the air in it contains more than 21 grains of chlorine per cubic foot. In testing for this, the air should be drawn from a point not more than 2 teet above the chamber floor, and taken from

the draught end

IV. No chamber may be opened until the air

in it has been tested, and the result of such test entered in a book.

V. No chamber may be opened except in

daylıght.

Mechanical Chambers for absorbing Strong Chlorine Gas — Many proposals have been made for mechanical absorbing apparatus for strong chlorine, but none of them seems to have met with permanent success; sometimes the working parts are worn out after a short time, and sometimes the bleach produced in them is too weak. Of course, it cannot be said that the construction of a mechanical chlorine absorber for dry lime is an impossibility, but it must be difficult to construct unless a perfectly regular stream of chlorine gas is at command, and efficient means are employed for artificially removing the heat given off during the absorption

The absorption of weak chlorine, that is, chlorine diluted with very much nitrogen and oxygen, as it is obtained in the Deacon process, and in most of the processes proposed for dealing with calcium and magnesium chlorides, cannot be carried out in the ordinary chambers. The most efficient plants for this purpose are Deacon's shelf chambers, and Hasenclever's

mechanical chambers

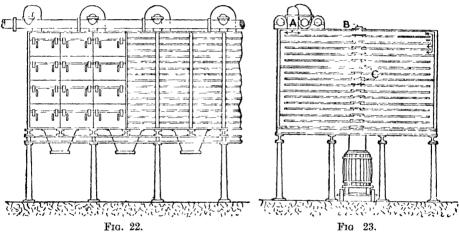

Deacon's chambers,—To expedite the late of absorption the furrowed layer of lime is reduced greatly in thickness, viz to § inch As the weak chlorine contains 90 or more p.c. of mert gases, that is, it contains per unit of chlorine nearly 200 times as much mert gas as does Weldon chlorine, the dilution of the incoming Deacon chlorine by the very large volume of air or residual gases in the Weldon chambers is unnecessary to keep down the temperature of the bleaching powder, and the layer of gas as accordingly reduced greatly in thickness, viz to about 6 inches Further, as the escaping mert gases are able to carry away the heat generated, it is unnecessary to have the large heat radiating surfaces which are provided by the Weldon chambers, and it is therefore possible to reduce the ground space occupied by placing as many as sixteen such lime and gas layers as described above over each other Chambers only 6 inches high cannot, of course, be charged with lime and discharged of their bleach by workmen entering the chamber as with the Weldon chambers, but must be operated by the workmen from outside the chambers with long-handled rakes, which, from the hygienic point of view, is a great advantage

Figs. 22 and 23 show the construction of a set of seven Deacon chambers, Fig 22 being a front elevation of 31 chambers, and Fig. 23 being a view of the broken end shown by Fig. 22; the dimensions of each chamber are 8 feet wide and 13 feet high, as shown by Fig. 22, and 21 feet long and 13 feet high, as shown by Fig 23 Each chamber is subdivided into two halves by a central partial partition, as is shown by the right-hand side of Fig. 22, but the figures do not show the gas passage which exists through the bottom of these partial partitions, nor do they indicate that the gases flow downwards in each left-hand half, and flow upwards in each right-hand half, The partitions and partial partitions chamber are made of slate or sandstone flags, and they are carried by the pillars and girders shown in

The partitions and partial partithe figures tions in turn carry the sixteen shelves to support the lime layers, and also carry the top covering shelves. The shelves are made of slate or flagstone, the bottom and top slabs only reach to each end of the chamber, all other slabs end 6 inches short of one or other end of the chamber to allow the gases from the inlet pipe to zigzag down the one half of the chamber, as shown by Fig 23, and then zigzag up again on the other half of the chamber to the outlet pipe; all the shelves have a gap of a foot in the middle of the 21-foot dimension, and these gaps are covered by easily removable boards, as shown by B and C in Fig 23. To lime the chamber the wooden covers B are removed, and the wooden slides c are pushed on one side with the exception of the two on the bottom Sufficient lime to cover one shelf with a layer nearly 1 meh thick is then dropped through the gaps from which the covers B have been removed, and falls down to the two bottom shelves. There it is spread and then furrowed by long-handled rakes from each end

of the chamber The slides c on the bottom shelf but one are then pushed over then gaps, and the lime charges for those shelves dropped and levelled as before The test of the shelves are limed similarly till all are limed, and the top gaps covered with then boards B and made gas-tight with lime or with luting The ends of gas-tight with lime or with luting the chamber are closed by hanging iron plates on the shelves, as shown on the left side of Fig. 22, the joints are made gas-tight with luting. Each of the other six chambers is limed similarly The two top cover flags of each chamber each contain a hole provided with a water lute, the left one serving as inlet, the right one as outlet to the chamber The gas supply main is shown in Fig 22, with a lute for each of the seven chambers, and the movable aim is shown in position which passes the gas into the first The exit gas from the first chamber chamber passes into the second chamber, and all following chambers in turn by movable aims, shown in Fig 22 and in Fig 23, where one arm is marked From the seventh chamber the exit gas passes by an arm into the middle or exit main

205

shown in Fig 23, whence it is sucked by a fan, and being now free from chlorine, is blown into the air, the exit main runs the whole length of the chambers, and is provided with a lute adjacent to the exit lute of each chamber When samples taken through test holes in the end covers show that the bleach is up to strength, the gas arms are changed, so that the gas supply is cut off the first chamber, and then goes to the second, and thence, as before, to the seventh The finished bleaching powder in the first chamber is discharged by removing the end doors, pushing on one side the slides c, and then pushing the bleaching powder to the centre of the chamber, where it falls through the gaps and the hopper shown in the figures into the The chamber is next relimed, cask below. and the ends closed as before described, and it is ready to become the last chamber in the series. To effect this the exit from the seventh chamber is cut off from the evit main, and instead it is joined by a gas arm to the right-hand main shown in Fig. 23, which return main carries the gas the whole length of the chambers, and by a suitable arm is connected to the inlet

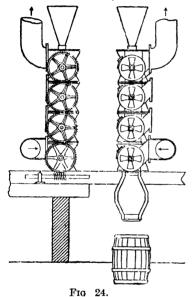

of the first chamber The exit from the first chamber is connected to the exit main Each chamber in turn is thus discharged, relimed and remserted into the cycle Such a set of chambers furnishes 4 tons of bleach per day.

Hasenclever's chambers —Another style of chamber which is particularly suitable for absorbing weak chlorine such as is produced by the Deacon process, is the mechanical chamber of Hasenclever (Eng Pat 17012, 1888), employed at Aachen, and strongly recommended by an English Commission as a thorough remedy of the difficulty arising from the contact of the workmen with the chlorine gas and the bleaching powder dust connected with the use of the Weldon chambers. To make these Hasenclever chambers suitable for use with strong chlorine they may be worked intermittently, and it has been proposed to make them suitable by mixing air with the The Figs 24 and 25 show one of the Fig. 25, in its original forms of the apparatus central portion, is an elevation, but in its upperand lower portions is a sectional elevation, and in several respects is very indistinct; Fig 24

shows on the left side an elevation of the back ends of the tubes, while on the right side it shows the front ends of the tubes with the covers removed that carry that end of the shafts. The slaked lime passes from the hopper shown in both figures into the top tube, where it is slowly worked by the blades attached to the revolving shaft towards the back end of the tube, where the first and second tubes are united by a large passage not adequately shown in Fig 25. The direction of iotation and the setting of the blades in the second tube are such that the lime is now slowly moved along the second tube towards its front end, where it drops through another large passage into the third tube, from the back of the third tube it drops again into the back of the fourth tube, and finally at the front end of the fourth tube drops into the hopper, which is closed by a sliding door. The chlorine enters at the front of the fourth tube and passes to the tubes above

by the large passages already mentioned, and the residual gases escape from the front end of the first tube as shown, to the suction fan actuating the whole Deacon plant. Fig. 25 shows four circles at the back ends of the tubes and two circles at the right ends of the tubes, and Fig 24 shows two gas passages on the middle tabes, which are antiquated, and should not have been shown By gently drawing the slide of the hopper the bleach falls direct into the cask with practically no nuisance Means are provided at the back end of the fourth tube of easily starting or stopping the shafts, and doors are provided for inspecting and, when necessary, cleaning the inside of the tubes, as shown by Fig 25, for second and third tubes, and by Fig 24 right-hand side for all four tubes Such a set of tubes makes I ton bleach per

General Remarks on the making of Bleaching Powder—Good strong bleach cannot be made

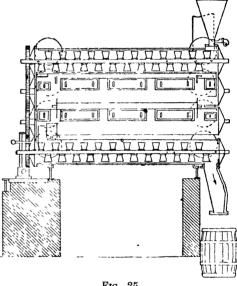

Fig. 25.

from lime that is badly burnt, slaked, or sitted, nor from chlorine that contains too much carbon dioxide or aqueous vapour or hydro-chloric acid gas, nor in very hot weather, nor if the chlorine is initially passed into the chamber so fast as to allow the temperature to rise too high It ought to consist of pretty heavy flakes, easily crushed, or a heavy but not dusty powder, which can be kneaded with the fingers into a tough paste. The laboratory test of a sample carefully taken from various parts must test at least 35 pc available chlorine, and if it is intended for export it must test still higher.

Packages.—Bleaching powder must be packed in very well-made casks, preferably made of hard wood The ends are sometimes secured by a coat of plaster of Paris. This is done in order to prevent the access of air, which quickly deteriorates the powder both by its moisture and its carbonic acid.

places; both rain and sun would quickly spoil the bleaching powder, even if placed in good casks.

Properties of Bleaching Powder. — Good bleaching powder is a nearly white powder, often mixed with lumps which, however, test as high or even higher than the powder. It has a peculiar smell, quite different from that of chlorine, and not owing to hypochlorous acid, since it is just as perceptible in alkaline solutions If it gets on to the skin a very strong odour is developed, which is highly characteristic; this odour persists even after washing the skin with soap.

In the air bleaching powder attracts moisture and carbonic acid, and gradually changes into a pasty mass. Mixed with a little water, it forms a stiff paste, with a perceptible swelling and rise of temperature; this is probably caused by the transformation of 2CaOCl<sub>2</sub> into The packages must be kept in cool, dry | Ca(OCl)2 and CaCl2, which then acts upon the

free lime to form crystals of calcium oxychloride which causes the mass to set like cement.

Bleaching powder decomposes gradually even in closely stoppered bottles or well-protected casks. The presence of light, heat, moisture, and carbonic acid greatly accelerates this change; so does shaking, e.g. in transit Hence the strength of bleach is usually only guaranteed at the place of shipment, but it ought not to lose above 2 or at most 3 p c by a few weeks' journey.

Experiments on the rate at which bleaching powder loses its available chlorine have been made by J. Pattinson, in 1874 (Chem. News, 29, 143) and 1886 (J. Soc. Chem. Ind. 587). He experimented in the first case with samples kept in loosely corked bottles, sheltered from direct sunlight, and found that these lost on an average 0.33 p.c. monthly from February to April, 0.86 from June to September, 0.28 from

November to January The greatest loss occurred in August, viz 1 4 p c per month

The keeping properties of bleaching powder depend on the quality of the line used, on the temperature conditions under which it has been made, and on its stiength. The more free calcium hydroxide is left in the bleaching powder, the more stable it is. This shows that, when bleaching powder is required for export, especially to tropical countries, it is a mistake to require a high initial test.

A few experiments made by Thummel (Arch Pharm 1834, 22, 1) prove that light has much more action on bleaching powder than exposure to air.

The following complete analyses of the samples of bleaching powder investigated by J Pattinson (v supia) may serve as an example of the best descriptions of the commercial article—

	Made of Irish limestone (from Larne)	B made of Irish limestone by another manufacturer	C made of French cliff

The small quantity of unchanged calcium hydroxide is proof for the opinion that this is merely lime mechanically protected against the action of chlorine by the bleaching compound CaOCl<sub>2</sub> previously formed

Liquid chloride of lime or Bleach liquor. This substance was first prepared in 1798 by Chas. Tennant by absorbing chlorine gas in milk of lime. Many bleach works have prepared it on quite a small scale for their own use, but it is now prepared by alkali works on

a considerable scale for use in bleach works in the not too distant neighbourhood, packed in carboys or steel tank wagons, as being more convenient than the preparation of clear solutions of bleaching powder by the bleach works.

Absorption of Chlorine by Milk of Lime -As all the processes for preparing chlorine on a commercial scale produce it at approximately atmospheric pressure, the gas has to be absorbed by the surface of the milk of lime, and because of the very small solubility of lime in water agitation of the milk of lime is an absolute necessity to keep the lime in suspension and to accelerate its solution, and to bring the lime solution to the surface, and after it has absorbed its modicum of chlorine, to quickly remove it and again saturate it with lime Various forms of agitators have been used. blades attached to horizontal shafts, or to vertical shafts, or to vertical revolving cones or cylinders, and these last are considered to be the most efficient, as besides setting up a swirl in the liquid, they also set up a very rapid flow of liquor from the bottom to the top, thus very effectually and rapidly renewing the surface of the liquor.

The containing vessels have been made of lead, or flagstone, but cast iron is now employed, as it soon becomes coated with a limey deposit

both below and above the liquor, and any action of the gas or liquor is reduced to a minimum Three or more vessels are coupled up so that the gas passes them in series. Each is filled with water and lime in the proportion of 100 gallons and 10 to 15 lbs, making a milk of 12° to 18°Tw During the absorption of the During the absorption of the chlorine the temperature rises, and the admission of the chlorine should be so regulated that the temperature does not rise above 32°, or at most 37°, and for this same reason the absorbers may be cooled by building them inside a water tank. When the sp gr of the liquor after settling clear has risen to 1 040, or the contents of available chlorine is 7 pc, the gas is passed into the next absorber as first in the series, and the first absorber is allowed to settle the considerable amount of excess lime which is absolutely essential to prevent the conversion of the hypochlorite into chlorate The clear The residual liquid is then run off into carboys lime is either augmented with some fresh lime for the next operation, or if the accumulated impurities in it are too great, it is washed to recover admixed hypochlorite, and is then run away

Dissolving Bleaching Powder to make Bleach Inquor.—When bleach inquor cannot economically be obtained from the source just described, it is always prepared by the bleaching works by extracting bleaching powder with water. To avoid a loss of available chlorine and a waste of time in settling out the insoluble matter, certain conditions have to be observed, so that it cannot form lumps inside the dissolver.

1 The best practical temperature for the water is 21° to 26°.

2 The agitation must be effected by mechanical power so as to show a strong swirl on the surface, say, with a peripheral speed on the agitator of 500 feet per minute for tanks of 5 feet to 9 feet diameter, and the lower limbs of the agitator must be not more than 1 inch from the bottom of the tank

3. The bleaching powder must be emptied a little at a time on to a 1-inch mesh sieve placed outside and above the dissolver, and the passage of the powder assisted by working it with a spade, any lumps then left are to be knocked through with the flat of the spade After completing the bath, agitation for 20 minutes is ample for all strengths of solution up to 16°Tw Further time spent on agitation is wasted, and, by beating the insoluble residue, renders subsequent settling appreciably slower

4 The run-off pipe should be at such a height as to allow 5 cubic feet of sludge per cwt of bleaching powder used per batch, for all strengths of solution up to 16°Tw Unless a sufficient space is allowed, enormous waste of time will arise in waiting for the last few inches to settle clear

5. The residual sludge consists, not of bleaching powder, but of insoluble lime suspended in bleach solution. The agitating tank should be filled again with water, and the contents agitated for 5 minutes only prior to settling, when the clear liquor of about 2°Tw. is run off to be used for making the next batch, and the washed sludge is then to be run away to waste.

When the precautions given above are followed, the loss of bleaching powder in the

washed sludge will not exceed 2 lbs. per cwt. of bleaching powder used.

Properties and Uses of Bleach Liquor -The experiments made by Lunge and Landolt (J. Soc. Dyers and Colorists, 1885, Nov. 25) with bleach liquor have shown that the action of the air is nothing like so injurious to the stability of such solutions as that of the light, which ought to be excluded by all means Solu tions kept in the dark in closed vessels, remained practically unchanged up to the 24th day, and up to the 33rd day, when the experiment was finished, the strength had only decreased from 29 58 to 29 12. Kept in open vessels in the dark, they remained unaltered up to the 12th day, on the 33rd day they had lost 330 But when kept in closed vessels in diffused daylight, the decomposition set in at once, and on the 33rd day only 8 52 remained of 33 02 originally present Solutions of chloride of magnesia behaved similarly to those of chloride of lime, those of zinc or aluminium hypochlorite, as might be expected, were much less stable

The specific gravity (at 15°) can be used to approximately determine the available chloring grams per litre in a good bleach liquor

Sp gr	1 01		5 58
1	1.02		11 41
	1 03		17.36
	104		2375
	1.05		$29\ 60$
	1.06		35.81
	1 07		42 31
	1 08		49 96
	1 09		55.18
	1 10		$61\ 50$

but such a method is utterly useless for an old solution, or one that has been partly used, or is in any other way abnormal, the only way of testing such an abnormal solution is to make a chemical test, the best of which is Penot's method, with sodium arsenite in presence of bicarbonate of soda (Lunge and Hurter's Alkali Maker's Handbook, 2nd ed 126)

The use of bleach liquor for bleaching purposes is described in Cross and Bevan's Cellulose, 2nd ed 284-294. The effect of free lime on bleaching is similar to that of free caustic soda when sodium hypochlorite is employed for bleaching

The germicidal power of bleaching-powder solution is very great, and it has been used successfully for years as a disinfectant. One part of bleaching powder will, in 2-4 hours, destroy the following bacteria: coli, typhosus, and cholera in 2000 parts of ordinary sewage

(See Schumacher, in Gesundheit-Ingenieur of Munich and Berlin, August 10, 19, 30, 1905; Sheridan Dolépine, in Medical Chronicle, May, 1894, and G. C. Clayton, in J. Soc. Chem. Ind 1896, 320)

Calcium hypochlorite crystal. The Chemische Fabrik Griesheim Elektron (D. R. P. 188524, 1906) describes the production of calcium hypochlorite as follows:—

Chlorine is introduced continuously with agitation into milk of lime until the latter is nearly saturated. The solution is then concentrated in vacuo until the calcium hypochlorite crystallises out and can be dried in vacuo. The calcium hypochlorite obtained is said to be more

stable than ordinary bleaching powder, gives a clear solution in water, and contains 80-90 p.c available chlorine.

Potassium hypochlorite solution (Chloride of potash of Eau de Javel) This liquor was first made in 1789 at the Javel Works near Paris, and was the first bleaching compound known It was then made by passing chlorine into a solution of potashes (crude potassium carbonate) in eight parts of water. This liquor is rarely made at the present time, as it has been replaced by the cheaper soda compound, which has now mostly usurped its name

Sodium hypochlorite solution (Eau de Labarraque, usually called Eau de Javel). This liquor was made by passing chlorine into a solution of sodium carbonate in 10 parts of water till the liquid began to effervesce and to bleach litmus

$$Cl_2+2Na_2CO_3+H_2O$$

=NaOCl+NaCl+2NaHCO<sub>a</sub>

any further passage of chlorine produced free hypochlorous acid and CO<sub>2</sub>

The liquors containing free HOCl keep very badly, the HOCl partly volatilising and partly losing its oxygen

Hypochlorite of soda solution is used to day as a bleaching agent for the bleaching of special fabrics, in steam laundries to whiten clothes, and as a disinfectant, and is now prepared by one of the three following methods

- 1 By the precipitation of a solution of bleaching powder by sulphate or carbonate of soda, when a solution is obtained containing about 5 p c of available chlorine, but no free HClO, and which will, therefore, keep unchanged for some time. This operation is usually conducted at the factory or the place where the solution is used.
- 2. By passing chlorine into a solution of caustic soda until nearly all the soda is chlorinated

This solution is made at alkali works, and sold at a strength of 10–15 p c. available chlorine

It has been found necessary to leave a small amount of free soda, about ‡ p c. Na<sub>2</sub>O, in order to make the solution stable, by removing all free hypochlorous acid and by removing traces of iron which would otherwise be converted into sodium ferrate, and aid the decomposition by carrying oxygen from the hypochlorite to the atmosphere A very full statement on the manufacture and stability of sodium hypochlorite solution made in this way is contained in a paper by Muspratt and Smith (J Soc Chem Ind 1898, 1096)

3 By electrolysis of brine solution Under chlorine we have discussed the electrolytic cells devised to liberate chlorine from common salt solution. In the case of the preparation of sodium hypochlorite there is no necessity when the electrolysis starts to attempt to keep the main products, chlorine and caustic soda, apart, but, on the other hand, they must be brought together. But directly the formation of hypochlorites has begun then troubles begin: (1) there is insufficient agitation to bring the caustic soda to the chlorine, and consequently chlorine escapes, and free hypochlorous

acid and chlorate are formed; (2) the hypochlorite, hypochlorous acid and the chlorate are themselves electrolysed with evolution of oxygen, and the output of hypochlorite rapidly falls to nothing, (3) the hydrogen liberated at the cathode reduces the hypochlorites already formed, and again the output coases

The following cells have been introduced (see papers by W. H. Walker in Electro-Chemical Industry, 1, 439).—

The Kellner cell consists of a stoneware vessel divided into a number of small compartments by glass plates fitting into small grooves in its sides. Those glass plates are wound with platinum-indium wire, and form bipolar electrodes. The electrolyte is circulated rapidly through the cell and through a cooling coil.

The Schuckert cell is a large stonewaie trough, separated into 8-10 compartments. In these compartments are bipolar electrodes in the making of which platinum-indium wire may or may not be used. Circulation is effected by means of the hydrogen evolved, and each cell has a cooling coil

The Haas-Octel cell consists of a rectangular box divided into small compartments by a series of vertical bipplar carbon electrodes set in grooves

From the figures given by Walker, the k w h. per ton available chlorine produced in solution can be calculated, and are given in the following table for the Kellner and Schuckeit cells. The Haas and Oettel figure is taken from a paper by Reuss before the Society of Dyers and Colorists, Feb. 1911.

Name of cell		of a stan- zed cell	K W H per ton available
	Amps	Volts	Chlorine
Kellner Schuckert . Haas and Oettel	120 100 80	110 110 110	8800 8500 8400

These cells are adapted for the production of weak solutions only of hypochlorite of soda containing 1–2 pc available chlorine, as only a partial decomposition of the NaCl is possible without an enormous fall in efficiency. The cost of salt is, therefore, high, and actually about 7 tons of salt are required per ton of available chlorine produced

Cells such as these are designed for the purpose of erection at the factory or works where the hypochlorite solution is used, and where neither bleach liquor nor bleaching powder are readily available

Full details of these and other cells are to be found in the series Monographien uber Angewandte Elektrochemie, namely, vol. 8, Engelhardt, Theoretical Constructive Description, 1903, 275; vol. 17, Abel, Theoretical Description; 1905, p. 110, vol. 38, Ebert and Nussbaum, Practical Applications, 1910, p. 367, all under the title, Hypochlorite und Elektrische Bleiche.

Uses of Sodium Hypochlorite Solutions — The uses include the bleaching of such cotton

and linen fabrics as require to have the softest possible feel, and the fullest degree of whiteness, for bleaching paper pulp; for whitening clothes in steam laundries, for disinfectant purposes Hypochlorite of soda solution possesses strong germicidal powers, which Klein estimates for a solution containing 10 p c. by weight of available chlorine at 21 times that of phenol (See Klein, Comparative Bacteriological Report on Chloros, Public Health Engineer, June 9, 1906 further data, see Schumacher, Gesundheit Ingenieur of Berlin and Munich, Aug 10, 19, 30, 1905; Clayton, J Soc Chem Ind 1896, 320) And lastly, the strong solution prepared by method 2 is used in enormous quantities by the Badisch Anilin und Soda Fabrik for the conversion of phthalimide into anthranilic acid, which last is used in the manufacture of artificial indigo (Haller, Les Industries chemique et pharmaceutiques, Exposition Universelle de 1900, Paris, vol 2, pp 128-130).

Sodium hypochlorite crystal. Until recently sodium hypochlorite in the solid form was unknown Muspratt and Smith, in 1898, however, by the systematic production of a more and more concentrated solution, produced crystals of the following composition (J Soc Chem. Ind 1898, 1100)—

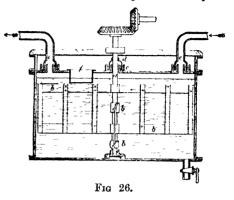

NaOCl	37 брс
NaClO <sub>a</sub>	nıl
NaCl.	37,
Water (by diff)	58 7 ,,
	-
	100 0

The crystals dissolve in their water of crystallisation at 18°-21°, and their rapidly decompose. By drying under vacuum part of the water of crystallisation is removed, and a more stable product obtained containing up to 60 p c of available chlorine with a melting-point of over 43° (see Muspratt, J. Soc Chem Ind. 1903, 592)

Magnesium, Zine, and Aluminium Hypochlorites, all of them obtained by adding the sulphates of these bases to a solution of bleaching powder, are sometimes used for special purposes because they have a more tapid action than chloride of lime. Their properties have been fully investigated by Lunge and Landolt in the above-mentioned memoir. They are never manufactured for sale, but prepared by the users themselves.

Potassium chlorate. This salt was originally made by saturating caustic potash solution with chlorine gas. Liebig proposed to saturate a thm paste of three molecules of slaked lime with one molecule of potassium chloride; there is, however, a disadvantage in that some potash is lost along with the insoluble impurities of the lime, and this is obviated by saturating milk of lime only, drawing off the claimed calcium chlorate liquor, evaporating it to the necessary concentration, adding potassium chloride equivalent to the calcium chlorate present, and cooling the solution to crystallise the potassium chlorate This manufacture was started in 1847 at St Helens, at Messrs. Muspratt's works, and was described in detail by Jurisch in 1888, Die Fabrikation von Chlorsaurem Kalı und Anderen Chloraten, and in Lunge's Sulphuric Acid and Alkalı. The absorption of chlorine by milk of

lime begins with the formation of calcium hypochlorite, as has already been described under the heading Liquid Chloride of Lime or Bleach Liquor, and that description applies here, and is supplemented by Fig 26, the sectional elevation of an absorber built up of east-iron plates

with rust cement joints, and 10 feet diameter and 5 feet 6 inches deep; the agitating shaft a with its aims b, b is carried by the foot step, and by the bearing attached to the non guder seen just below the crown wheel, but this girder does not cover the entire top of the tank or prevent access to the manhole f, as the figure suggests; the device of a cup d and a water lute c prevents any escape of chlorine through the shaft hole. The manhole is always open, so that there is no hindrance to the addition of water or lime or the removal of samples times a water-jacket surrounds the absorber to prevent too high a temperature, as described later At least three, better six, absorbers are worked in series on the chlorine, so as to absorb the whole of the chlorine supplied and to obtain an innocuous residual gas, the gas mains for this purpose are not shown in Fig 26, but they are exactly like those indicated in Figs 22 and 23.

The milk of lime is also of approximately the same strength as when making bleach liquor; it should not exceed  $16^{\circ}$  or  $17^{\circ}\text{Tw.}$ , which corresponds to 6.3 to 6.7 lbs CaO per cubic foot.

As the absorption proceeds the temperature slowly rises, and while an excess of lime still remains, the reaction is

$$2Ca(OH)_2+2Cl_2=Ca(OCl)_2+CaCl_2+2H_2O$$

and the temperature should not be allowed to rise above  $32^\circ$  or at most  $37^\circ$ . The reason for keeping the temperature to this limit is that, as the calcium hydrate goes more and more into solution, the impurities that originally accompanied it are more and more released, and become active catalysts, enabling the hypochlorite to decompose  $\text{Ca}(\text{OCl})_2 = \text{CaCl}_2 + \text{O}_2$ , and this catalytic action is the more active the higher the temperature, the principal impurities acting in this way are the iron and the manganese oxides. The evolution of the minute oxygen bubbles in the turbid liquor causes the formation of a very strong and persistent scum which partly or almost completely covering the surface of the liquor forms so effective a

separating layer between the chlorine gas and the alkaline liquid below that absorption of the gas is very greatly reduced or even entirely stopped. When absorption of the chlorine has gone a little further, so that the free ('a(OH), has been acted upon and only remains in small local particles, a series of complicated reactions occur which are not correctly understood, but may possibly be

$$2Ca(OCl)_2 + 4Cl_2 + 4H_2O = 2CaCl_2 + 8HOCl$$

i.e a small amount of free hypochlorous acid is formed which, however, has no effect on the remainder of the hypochlorite, but which when further treated with chlorine yields, it is assumed, chlorine monoxide

$$4HOCl+4Cl_2=4Cl_2O+4HCl$$

and it is assumed that it is this chlorine monoxide which oxidises the hypochlorite to chlorate  $\mathrm{Ca}(\mathrm{OCl})_2 + 4\mathrm{Cl}_2\mathrm{O} = \mathrm{Ca}(\mathrm{O_3Cl})_2 + 4\mathrm{Cl}_2$ , with regeneration of the free chlorine. The sum total of those reactions is

$$3Ca(OCI)_2 = Ca(O_3CI)_2 + 2CaCI_2$$

The last reaction is accompanied by the generation of so much heat that the temperature of the liquor rises exceedingly quickly up to 65°-70°, the scum previously mentioned disappears, as there are no longer any hypochlorites to decompose with evolution of oxygen, and as the reaction of the haud has changed from alkaline to acid the basic oxides in the scum pass into solution, the liquid smells of chlorine, and the dissolved hypochlorous acid bleaches litmus paper instantly; and lastly, the liquid generally has turned from colourless or light yellow to deep pink, due to the conversion of the manganese in the lime into a permanganate By summing the equations representing the formation of the hypochlorite and the conversion of the same into chlorate, the total reaction appears

 $6Ca(OH)_2 + 6Cl_2 = Ca(O_3Cl)_2 + 5CaCl_2 + 6H_3O_3$ which, though expressing the main end result, fails to represent any of the indispensable intermediate stages. The completion of the conversion of the hypochlorite into chlorate may be readily ascertained by adding to a sample of the cooled liquid some strong hydrochloric acid, there should be no evolution of chlorine gas. Full analysis of the liquor always shows that the molecular proportion of chloride is somewhat greater than indicated by the general equation above, namely 50, if much oxygen is evolved the figure may reach 5 8, but with very good work the figure may be 53 The operation lasts from less than 24 hours to 72 hours, according to the speed at which the chlorine can be passed so as to comply with the condition of complete absorption With reference to the possibility of increasing the speed of absorption, and so with efficient cooling reducing the catalytic decomposition of the hypochlorite a description by Lunge (Sulphuric Acid and Alkali) of the absorbing apparatus used by Messrs. Péchiney at Salindres is of considerable interest, the agitation being effected by means of a paddle wheel with horizontal and submerged axis, but each blade in turn projects through the liquid surface as the paddle revolves, and the absorption is excellent and superior to that in all other absorbers.

The finished liquor in the absorber may show, according to the quality and the quantity of the lime used, a strength of from 24 Tw up to 32°Tw, and statements have been made of strengths obtained up to 44°Tw. To obtain the subsequent separation of the potassium chlorate in a proper manner, it is concentrated by evaporation until it shows from 50°Tw. to 70°Tw, and during the evaporation there is considerable corrosion of the pans and also decomposition of the chlorate. For these reasons it would appear that more attention might be given to the direct manufacture of stronger chlorate liquors by an adaptation of the process referred to by Lunge as used by the Griesheim-Elektron Company for preparation of solid crystalline hypochlorite of calcium

The fimshed liquor in the absorber smells of chlorine and of hypochlorous acid, and these objectionable substances for the subsequent treatments may be removed by the addition of small quantities of sodium throsulphate or of tank waste

'The liquor is run from the absorber into a settling tank, whence the clear liquor is drawn through a deep siphon, and the residual mud is run into a filter press, or is diluted and washed by decantation, the washings being used for making fresh milk of lime.

The strong settled liquor is measured and tested for its content of chlorate, and the theoretical quantity of muriate of potash calculated, allowing for the approximately

5 p c. of impurities contained in it

The open boiling-down pans are made either of cast iron or preferably of wrought iron, as it does not crack, and is repairable when damaged by corrosion After charging with the settled liquor the fires are lighted and the muriate of potash is added. The boiling is continued until the hot liquor shows 70°Tw, when the boiling is stopped and the liquor allowed to settle. The mid consists of magnesia originally contained in the lime, or in the muriate of potash, then converted into chloride which, decomposing in the pans into magnesia and hydrochlonic acid, makes a very objectionable mud, and also corrodes the pan from which a sediment of ferric oxide results, the mud also contains gypsum from the original lime, and from the sulphates in the muriate of potash, to prevent this mud from burning fast to the pan it must be removed after each operation, and the soluble salts recovered by washing

The coolers for the first salts are generally made of non, since in no case can a pure product be obtained at this stage. They are best made like those used for soda crystals, with a plughole for running off the mother liquor. They ought to be numerous enough to permit of the liquor remaining in them 9 or 10 days in winter and 14 days in summer. Here the crude chlorate of potash crystallises in long accular crystals, totally unlike in general appearance the thin plates in which the same salt crystallises when pure, but in reality possessing exactly the same crystalline faces, only developed in different fashion. They are easily distinguishable from the large transparent prisms of hydrated calcium chloride which appear if the concentration has been too great. They must be broken up after draining, and the adhering mother liquor washed

off with a little water, and finally drained in a hydro extractor.

The mother liquor is a nearly saturated solution of CaCl<sub>2</sub>, with a little KCl, and with about 30 grams of KClO, per litre With bad work much more chlorate is left in the liquoi. In the very best case 10-12 pc of all chlorate manufactured is lost through this cause, usually much more (25-30 p c.). Usually it is not even attempted to recover the chlorine from these liquors by heating with hydrochloric acid—they are simply run to waste. But, with due care, the mother liquors can be quite well worked for chlorine by taking care to run the hydrochloric acid in pari passu with the liquor. Strictly speaking, it is not the chlorine of the chlorate which is recovered in this way, but chlorine produced by oxidation of the HCl added

Wylde, Hammill, and Auer (Eng Pat. 15097) describe a process for the recovery of about half the chlorate left in the mother liquor by refrigeration The process is described in detail by Hammill (J. Soc. Chem. Ind. 1889, 168), who states that the crude crystals obtained by refrigeration have a finer grain than the ordinary ciude crystals, but when thrown down from mother liquors of not over 72°Tw, are no more impure, and are as readily refined by one recrystallisation. Hammill says that on cooling to  $-12^{\circ}$  only 13 5 grams KClO<sub>3</sub> per litre remain in the liquois. This process has now been worked successfully for many years

Another process for greatly reducing the loss of chlorate in the mother liquors is that of Péchiney (cf Weldon, J Soc Chem. Ind 1882, 41). He concentrates ordinary chlorate liquor made from lime of a density of 42°Tw, up to 100°Tw (hot), and cools it down to at least 12°C., but not below 10°C Of its 5.5 mols of CaCl<sub>2</sub>, 43 are thus caused to crystallise out as CaCl2,2H2O (probably it should be 6H2O), but if the temperature were allowed to fall below 10°, calcium chlorate would crystallise as well The crystals are separated by a hydro extractor, and the mother liquor is treated with the calculated quantity of K(1, 1 there being only 1.2 CaCl2 present to I KICO,, the mother liquous cause a very much smaller loss than in the ordinary process Péchiney's process is specially suited, and was originally invented, for the manufacture of sodium chlorate (cf infra) It is evidently only possible to work it in the cold season, unless artificial cooling is employed

The crude chlorate of potash is always purified by recrystallisation ('finished') For this purpose it is redissolved in a mixture of water and of the mother liquor obtained in the finishing process, which is done in a lead-lined vessel, with the aid of steam, preferably indirect The solution is made at a full boiling heat, sometimes with the addition of very small quantity of sodium carbonate and of sodium sulphide, in order to precipitate any iron and lead present, it is made up to 25°Tw, and, after good settling and straining through canvas, the liquor is run into the coolers. These are made of iron lined with lead (wood lined with lead is not so good); they are either of a deep pattern, with wooden laths placed inside for the crystals to adhere to, or else they are made quite shallow, but covered over to prevent any too rapid cooling The crystallisation lasts from 8 to 14 days, according to the season.

The crystals are drained, washed on the drainer, and then again drained in a hydro extractor. This is imperative, since it is required that chlorate of potash should show little or no trace of chlorides, 005 pc. being a maximum sometimes stipulated. So long as there is PbCl<sub>2</sub> present, this cannot be very easily effected, but the lead can be removed in dissolving, as stated before. The mother liquors and washings are used over again till they become too impure, when they go back to the boiling-down pans. The crystals are dried on a hollow iron plate, covered with sheet lead,

and heated by steam

Chlorate of potash is either sold as 'crystals' or 'ground' For the former purpose the crystals tals, as they come from the drying plates, are sifted through a sieve with eight holes to the linear inch, or less, as the case may be. The powder is best ground while still slightly warm. The mills may be of any description, horizontal, edge runners, rollers, but the chlorate during grinding ought not to come into contact with iron, nor with any organic substance (straw, wood chips, &c.), or dangerous explosions may occur it must be sifted through a revolving sieve, made of miller's gauze, with mechanical brushes. The powder ought to be snow-white, and without any grittiness, like fine flour. The crystals ought to be thin, brilliant transparent plates, excessive drying will make them opaque. Both are usually packed in 1-cwt kegs, laid out with blue paper.

The loss of the chlorine used to amount to about 38 pc, with the new processes the losses are about 30 pc, or at least 25 p.c. The loss

of the potassium amounts to 25 p c

Magnesia Chlorate of Potash Process — The great loss of chlorate in the ordinary process has given rise to the process of Muspratt and Eschellmann, where magnesia is substituted for lime (Eng Pat 3960, 5183, and 5186 of 1883, and 1900 of 1885) A detailed description of this process has been given by Higgins (J. Soc. Chem. Ind. 1887, 248). The magnesia is obtained by burning Greek magnesite at not too high a temperature; when overburnt it is uscless for the absorption of chlorine. The MgO is very finely ground, suspended in water, and exposed to the action of chlorine in the ordinary octagons
The reaction is not so violent as with lime
The temperature of a finished octagon is usually 43°, and it never exceeds 60°. In the finished liquor the proportion of chlorate to chloride is very near to the theoretical, viz 1.5·1 or less, this constitutes an important advantage over the lime process, 7 p.c. less chloride being formed. No pink colour appears with very pure magnesia, but it does when it contains manganese. The of this liquor varies from 1.17 to 1 22. The strength

The octagon liquor is now boiled down to 75°-80°Tw, when on cooling about 50 p.c of the chloride will crystallise out as MgCl<sub>2</sub>,6H<sub>2</sub>O. The mother liquor contains il mol. chlorate to 2 8 chloride. Potassium chloride is now added to it in slight excess, and the potassium chlorate crystallised out. The mother liquors being

<sup>&</sup>lt;sup>1</sup> The intermediate formation of a calcium oxychloride, described in Péchiney's patents and Weldon's paper, has since been given up.

much less in quantity than with lime, and KClO<sub>3</sub> being less soluble in MgCl<sub>2</sub> than in CaCl<sub>2</sub>, the magnesia mother liquors contain much less chlorate than lime liquor (on an average 19 grams down to 10 grams per litre), and the yield of KClO<sub>3</sub> rises to 90 p.c. of the total.

The mother liquor is treated with HCl to destroy the chlorate, with due precautions against explosions. The still liquor is now neutralised with MgO; a solution of kieserite (MgSO<sub>4</sub>) is then run in to decompose the calcium chloride present, and the gypsum, along with iron oxide, is settled out. The liquor is with iron oxide, is settled out. now concentrated in cast-iron pots (wrought iron is acted upon too much); the iron dissolving in the liquor is oxidised to the ferric state, and is precipitated by MgO; the settled liquor is run into barrels, where it sets to a hard mass containing 47 p.c. of  $Mg(\mathfrak{A}_2)$  This magnesium chloride is sold to cotton sizers

This process would, of course, only become general if the magnesium chloride obtained as a by-product could be profitably decomposed for chlorine, as it is not saleable by itself in very large quantities, and could not compete in price with the Stassfurt article Such utilisation of magnesium chloride for the manufacture of chlorine had been intended by Weldon, who first proposed magnesia for the above purpose, and it is again mentioned in a patent of J Wilson (5975 of 1884). Twyman (4397 of 1881) proposes dolomite, under the idea that double chloride of potassium and magnesium (carnallite) will crystallise out of the mother liquor after the chlorate. (This seems quite hopeless, since the principal question is not that of saving KCl, but KClO3)

Electrolytic Chlorate of Potash Processes are the most recent In the preparation of chlorine from potassium chloride solution by the Griesheim process when using magnetite anodes the by-product formed is potassium chlorate, and it crystallises out in the anode cells and is recovered More direct methods are described under Sodium chlorate.

Uses of chlorate of potash are principally for the manufacture of lucifer matches, for pyrotechnical purposes, for tuses, for some descriptions of gunpowder, and other cases where it is a constituent of explosive materials. It is also largely employed, on account of its oxidising properties, in dyeing and calico printing, in the manufacture of alizarin, &c.

Sodium chlorate. This compound, which formerly was only a chemical curiosity, has become of technical importance, since it was found that it is much more suitable for the preparation of aniline black than potassium chlorate, owing to its greater solubility

It was at first thought that it could not be prepared from the calcium-chlorate liquor of the ordinary process, because NaClO3 is very soluble, and cannot be separated from CaCl, by crystallisation, and when a demand for it sprang up, it was made from potassium chlorate by means of hydrofluosilicic acid (cf Lunge's Alkali, 3, 320), and was sold at two or three times the price of the potassium salt

The process of Bottomley and Molesworth (Pat. 3005 of 1881) consists in treating a hot saturated solution of potassium chlorate with one of bitartrate of soda, and separating the precipitated potassium bitartrate from solution of sodium chlorate

The manufacture of chlorate of soda from calcium chlorate liquor was first carried out by Péchiney, by means of his process of removing most of the calcium chloride from the crude liquor by crystallisation. The purified liquor thus accumulated during the colder part of the year is mixed with a solution of ordinary sodium sulphate, that is saltcake, neutralised by lime before it is used, with continuous agitation, until all the calcium soluble salts have been converted into calcium sulphate, and final additions of either liquor are then made until neither is in excess. The CaSO<sub>4</sub>, which, under the proper conditions, is crystalline, is then separated from the liquor by filtration and washed in a hydro extractor The solution of sodium chlorate and sodium chloride is now concentrated by evaporation, during which most of the sodium chloride separates in the solid form and is fished out The remaining solution on cooling yields crystals of sodium chlorate, which are purified by recrystallisation. The purified sodium chlorate crystals contain no more than 0 16 pc NaCl. The mother liquors from the chlorate crystals, and the washings of the sodium chloride, go back into the process, and thus nearly all the chlorate contained in the liquor is obtained

Chlorate of soda is manufactured by the Muspiatt Chlorate Process by means of their magnesium chlorate liquor, freed from nearly half the MgCl, by evaporation and crystallisation (cf supra) To this liquor sodium carbonate is added, till all the magnesia is precipitated as a basic carbonate (magnesia alba), in order to be used over again in the process. The remaining solution of NaClO<sub>3</sub> and NaCl is concentrated by evaporation, with fishing out the NaCl, and after attaining 120°Tw, is allowed to cool down, the sodium chlorate crystallises out, and is purified in the usual manner

Manufacture of Alkaline Chlorates by Electro-The passing of an electric current through a solution of NaCl or KCl liberates Na or K at the cathode, and Cl at the anode The Na or K at once decomposes H O to form NaOH or KOH and hydrogen gas If the electrolyte is heated from 45° to 100°, and the caustic alkali is removed promptly from the cathode to the anode, the CI liberated is absorbed in the caustic alkali

produced to form chlorate There are, however, a number of secondary reactions, both at the anode and the cathode, and the electrolysis of the chloride cannot be carried to completion, because the product, the chlorate, is itself subjected to electrolysis and so destroyed Theoretically, a current of 1 ampere will produce in 1 hour 0.7627 gram KClO<sub>3</sub>, or 0.663

gram NaClO<sub>3</sub>
Gall and Montlaur, in their Eng. Pat. 4686 of 1887, describe the production of alkaline chlorates by the electrolysis of alkaline chlorides in a trough divided into two parts by a porous diaphragm The anodes are platinum-iridium sheets containing 10 p.c. of iridium; the cathodes are iron, though it is stated that nickel would be preferable. The electrolyte consists of a 25-p c solution of K(I, kept at a temperature of about 80°. The liquor from the cathode compartment containing the alkaline hydrate

there produced, is circulated through the anode compartment and combines with the chlorine liberated. A current density of 50 amperes per square decimeter is used, and a pressure of 4.5 to 5.0 volts is required. In the case of potassium chlorate, the anode liquor is run into crystallising vessels, where the KClO3 crystallises out, and the mother liquor, after resaturation with KCl, is passed back to the cathode compartment In the case of sodium chlorate the anode liquor has first to be concentrated to crystallise out the NaCl before crystallising out the NaClO<sub>3</sub>. The crystals obtained require, of course, to be refined by recrystallisation, as in the case of those produced by chemical processes

Hurter (Eng. Pat. 15396 of 1893) electrolyses KCl in a metal vessel which acts as cathode, and which has on its inner side a coating consisting of a mixture of Portland cement, salt and sand, which, after washing out the salt, yields a porous diaphragm. The anode is a sheet of platinum suspended in the centre of the Several vessels are superposed and worked in series, being kept apart by insulating rubber rings A solution of KCI containing a little caustic alkali is run into the top vessel, from which it overflows, through a glass or ebonite pipe, into the cell below. The hydrogen evolved escapes by pipes from the upper part of each compartment

Blumenburg (Eng. Pat 9129 of 1894) describes a cell with a porous diaphragm in which the anode compartment is closed and connected by a pipe with the bottom of the cathode compartment, so that the chlorine liberated at the anode passes into the liquor in the cathode compartment, and there combines with the caustic alkali produced, the tempera-ture being maintained at a temperature of about 49°. In the Ger Pat 89035, and also in the US Pat. 537179, Blumenburg passes the chlorine gases from the anode compartment into a gas holder, from which they pass to a separate combining vessel, where they are absorbed in the alkaline liquor from the cathode compartment. Chlorate is also formed as a by-product in the Griesheim cell described above, when using the oxide of iron anode

In 1899 Imhoff made a great advance in the electrolytic production of chlorate by his discovery of the action of small quantities of chromate of potash or soda in the electrolyte (US Pat 627063 of 1899) The action of the chromate is to form an insoluble film around the cathode, and so to prevent the reduction of hypochlorite and chlorate by the nascent hydrogen evolved at the cathode, and has resulted in a very marked and important improvement in the current efficiency

Details of the electrolytic chlorate processes up to 1903 were collected by J. B. C. Kershaw and published as vol. 19 of the Monographien der angewandte Elektrochemie, under the title, Die elektrolytische Chloratindustrie, 1905,

p 122

Perchlorates of Potassium, Sodium, and Ammonium. That by the electrolysis of chlorates there were formed perchlorates, was first shown in 1816 by Stadion, and in 1847 confirmed by Kolbe With the aid of such electrolytic methods the above-named perchlorates have been manufactured in Mansboe, Sweden, since 1895, in considerable quantities (Carlson, Zeit. für Elektrochemie, 6, 471), and since 1901 in Chedde, France (see Lederlin, D. R. P. 136678). The ammonium salt is used in the manufacture of explosives. Laboratory experiments are described by Foerster (Zeit. fur Elektrochemie, 4, 386) and Winteler (Chem. Zeit. 22, 90); see Kershaw, Elektrolytische Chloratindustrie, p 67.

Hydrochloric Acid. Commercial hydrochloric acid is a more or less pure solution of hydrogen

chloride HCl in water.

Hydrogen chloride is a colourless gas, of sp gr 1 2596 (air=1), and molecular weight 36 457 By weight it consists of 2 74 parts of hydrogen and 97 26 parts of chlorine 1t can be condensed into a liquid by cold and pressure. Its m p is  $-111~4^{\circ}$ , and b p.  $-83~1^{\circ}$ , and its critical constants  $+51~4^{\circ}\pm0~1^{\circ}$  and  $81~55\pm0~15$ atmospheres.

The vapour pressures can be expressed between 10° and 51 4° by the formula:

 $\log p = 1.152048 + 0.010312(t-10.2)$ 

 $-0.000019989(t-10.2)^2$ 

and between  $-24.2^{\circ}$  and  $10^{\circ}$  by the formula.  $\log p = 1\ 10106 + 0\ 013277(t + 24\ 2)$ 

 $-0.000039978(t+24.2)^{2}$ 

(Cardoso and Germann, J. Chem. Phys. 1912, 10, 517; 11, 632).

The heat of formation of a gram-molecule of

HCl is 22001 cals

Hydrogen chloride has a great affinity for water, and is greedily absorbed by it. The solution is the ordinary hydrochloric acid which, when somewhat concentrated, emits fumes of The following HCl on exposure to the air table by H Deicke shows the maximum solubility of HCl in water at varying temperatures. 1 c c dissolves at the temperature  $t^{\delta}$  from an atmosphere of pure HCl at 760 mm pressure —

The behaviour of aqueous solutions of HCl under varying conditions of temperature and pressure has been studied by Roscoe and Dittmar (Chem Soc Trans 12, 128) They found that concentrated hydrochloric acid on heating loses both gas and water, but as the proportion of HCl to H2O is higher in the vapour than in the original liquid, the residual fiquid gradually becomes weaker, until a sp gr of 1:101 and a percentage of 20 24 HCl is attained at a boiling temperature of 110°; the acid in this state distils without change, provided the atmospheric pressure is 760 mm. At a lower pressure the acid distilling unchanged is stronger, at a higher pressure it is weaker. A similar, but not identical

limit is attained when strong acid is exposed to the air at ordinary temperatures.

The following table gives the percentages of HCl in aqueous hydrochloric acid at various specific gravities and at a temperature of 15°:—

Deg. Twaddell	Spec. gravity	Percentage of	Grams HCl per litre	1 cubic foot weighs lbs	1 cubic foot con- tains lbs of HCl

Lunge and Hurter's Alkali-Maker's Handbook gives somewhat lower figures, they also give the following table for correcting the hydrometer readings for varying temperatures

# THE MANUFACTURE OF HYDROCHLORIC ACID

In former days small quantities of acid were produced by decomposing common salt with sulphuric acid in east-iron cylinders, and in order to utilise the more expensive sulphuric acid, an excess of common salt was used. The solid product left in the cylinder consisted of sodium sulphate, mixed with 20–30 pc. NaCl and was commercially known as cylinder cake. The production of hydrochloric acid from cylinders has, however, practically ceased.

Some time after the establishment of the Leblanc soda process in this country all the hydrochloric acid of commerce was obtained as a by-product of that process, at first the process produced enormously more hydrochloric acid gas than could be sold as hydrochloric acid liquor,

and some of the difficulties encountered in consequence are detailed in the following account.

New sources of hydrochloric acid arose when acctic acid began to be chlorinated by the Badische Anilin und Soda Fabrik in great quantities for the manufacture of monochloracetic acid and artificial indigo, and as one after another organic compound came to be chlorinated. Lastly, since the output of chlorine from the electrolysis of the chlorides of potassium and sodium was not sufficiently readily taken up, processes are now proposed of converting chlorine into hydrochloric acid either with the aid of hydrogen obtained in the decomposition of wood or of the hydrogen obtained at the same time as the electrolytic chlorine.

Hydrochloric Acid obtained in manufacturing Solium Sulphate (Salt Cake). When Leblanc decomposed salt in order to obtain sodium sulphate he proposed to convert the hydro-chloric acid gas evolved into ammonium chloride; but when the Leblanc soda process was introduced into this country that part of his suggestions was not carried out, and the acid gas was regarded as possessing no value, and it was simply allowed to escape into the air. This continued to be the case even after that manufacture had attained a comparatively large extension, but the damage caused to the neighbourhood by the acid gases soon brought about the intervention of local authorities and courts of law, and manufacturers were compelled to pay compensation for the damages they had done Repeated penalties compelled the alkali manufacturers to seek means for condensing the acid gas This was first successfully done in 1836 by Gossage's coke towers, but for many years after this there was still considerable damage done by escaping acid gas. The continued disregard by the old alkali manufacturers for the rights of their neighbours led in Belgium, in 1856, to a Parliamentary Commission, and in this country in 1863 to Lord Derby's Alkali Act, and the several subsequent Acts, by means of which British alkalı makers were compelled to adopt thoroughly efficient means for condensing their hydrochloric acid, and this has benefited all other manufacturing countries as well

The reports made by the inspectors under the Alkah Acts form an invaluable record of all the various steps taken for improving the condensation of hydrochloric acid, and have helped to spread a better knowledge of that process and have caused manufacturers to improve it up to the highest standard of efficiency

The Alkah Acts of 1863 made it incumbent upon those decomposing salt to allow no more than 5 pc of the hydrochloric acid to escape into the atmosphere. An additional Act of 1874 prescribed that no more than 0.2 grain of HCl might be present in a cubic foot of the gas escaping from the factory into the air. This corresponds to 0.454 gram HCl per cubic metre, or about three ten-thousandths by volume. The latter clause applies to the chimney gases as well, and not merely to the gases escaping directly from the condensing apparatus. Although these requirements were at first declared by many to be impossible of fulfilment, the actual results proved at once that

they were quite possible, and the escapes registered by the Alkalı Inspectors have averaged far below the limits assigned by the Acts. In 1885 only 2 13 pc of the total hydrochloric acid was allowed to escape, and the chimney and other gases escaping into the air contained only 0 10 grain HCl per cubic foot. No change has been made in the limit fixed in 1874, and the working of that Act remains satisfactory Compare the survey of these Acts by the Chief Inspector under these Acts in J. Soc. Chem. Ind 1892, 120.

Although the various processes and apparatus used for the manufacture of sulphate of soda produce gases differing within wide limits in temperature and concentration of HCl, an efficient condensation, i.e. practically complete absorption of the HCl in water to form a liquid acid of 1 15-1 17 sp gr. is usually obtained

acid of 1 15-1 17 sp gr. is usually obtained

The efficiency of the condensation of gaseous
HCl in water is dependent on three considerations:

l Temperature of the gas and of the liquid.

2 Concentration of HCl in the gases to be scrubbed and of the acid liquid to be produced

3 Time of contact between the gas and the liquid, and the average distance between the gaseous particles and the liquid particles, and also the thickness of the liquid layer, and on its motions internal and as a whole.

On issuing from the sulphate of soda plant the acid gases require cooling. The apparatus

used for this purpose depends on the temperature of the gases.

If the gases issue from the pot or pan of a handworked saltcake furnace, the temperature is comparatively low. In this case the cooling is usually done in a row or rows of earthenware pipes. The pipes used are often unglazed, but are rendered impervious to moisture and gas by boiling in tar In some cases the earthenware pipes are substituted by glass pipes of 12 inches diameter, made slightly taper, as shown in Fig 27. glas pipes are, of course, more liable to breakages by accident, and also through the effect of violent changes of temperature, than the earthenware pipes, but in sheltered positions they last well.

For the hotter gases issuing from the furnace of an ordinary muffle hand sulphate of soda furnace, or from the cylinders of the Hargreaves process, castron pipes are usually used to cool the gases down to a safe temperature before passing them as before into earthenware or

glass pipes The action of the hydrochloric acid gases on cast iron, when at a temperature well above condensing-point of liquid acid, is very slight.

When open furnaces, whether 'hand' or 'mechanical' (such as the Mactear furnace), are used, the acid gases are mixed with the products

Fig 27.

of combustion, and are consequently both much 45°, or even to 25°. The cooling of weak gas is hotter and more dilute. Under these conditions far more important than the cooling of strong gas

extensive series of cast-iron pipes are used for the preliminary cooling before passing the gases into the earthenware pipes for

final cooling.

The earthenware pipes used are usually 12-inch or 15-inch diameter socket pipes, the joints being made with a cement of tar and China clay. The castiron pipes vary from 12 to 20 inches in diameter, according to the quantity of gas, and the arrangement of the cooling system of pipes; they are socket pipes, the joints being made by ramming into the socket iron filings moistened with ammonium chloride solution.

The arrangement of the cooling pipes depends on the relative positions of the salt-cake furnaces and of the acid condensers and the space available

When the salt-cake furnace is a long distance from the condensers, a single direct line of pipes may be a sufficient means of cooling; where the distance apart is small the necessary amount of cooling surface is obtained by adding extra lengths of pipe that run vertically up and down and that start from a small stone eistern and return to another stone cistern for the purpose of collecting any liquid deposited

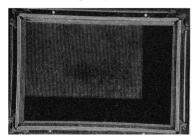

Fig. 28

The cisterns are usually made in this country of silicious sandstone found in Yorkshire, and known as 'Yorkshire flag.' The cisterns

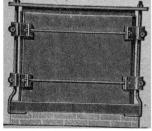

Fig. 29

of flags 4-6 inches thick, bound together by strong iron ties, and the joints made tight by thick ındıarubber cord laid in a groove between the faces of the

are composed

two stones or by a mixture of tar and fire clay, as in Fig 30 By one or more of the above arrangements of pupes and customs the acid gases are cooled to

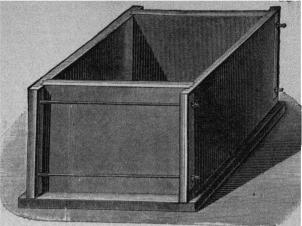

Fig. 30.

The gases next enter the apparatus where the hydrochloric acid gas is to be converted into a liquid acid of commercial strength, and that in such a manner that practically hardly

a trace of acid escapes

condensation The apparatus almost universally used are tall stone towers, packed with broken coke specially arranged, down which a stream of water is allowed to trickle. and up which the gases are caused to flow (Fig. 31) These towers were invented and patented Gossage, in 1836.

The coke tower has the merit of simplicity, and, when carefully packed, of efficiency

The comparative efficiency of various modes of treating liquids with gases has been dealt with in a series of papers by Hurter, who also gives some interesting data on cokepacked towers (J Soc Chem Ind 1885, 639; 1887, 707; and 1893, 227 and 989).

Coke towers are erections of considerable height, varying from about 40 feet to 60 feet. The hori-

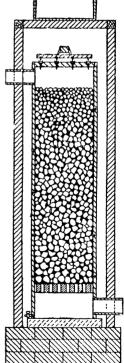

Fig. 31

zontal sectional area may vary from 25 to 180 square feet. They are provided with a grating a few feet over the bottom, on which

rests the coke which forms the 'packing' of This coke, which must be of as the tower hard a quality as possible (only the best oven-coke is applicable for this purpose), is disposed in such a way that the gas is as much as possible divided in a large number of channels (none of them being so wide that the bulk of the gas can pass up through it), and that the current of gas is constantly changed in direction. For this object long pieces of coke are laid parallel in a row, the next row is made to cross the The size of the pieces lower one, and so forth is gradually diminished from bottom to top. In order to avoid an excessive quantity of the gas passing up the side of the condenser along the wall, it is usual to place a layer of finer coke round the condenser for a few inches from the By this arrangement there is effected both a great division and constant mixture of the gases, and at the same time a suitable

Fig 32

spreading of the feeding water over a very large surface. One great advantage coke has over flints or other packings is that, owing to the roughness of its surface and its porousness, it always retains a large store of liquid, which tends to keep the working of the condensers steady under a fluctuating flow of acid gases, and to tide over difficulties occasioned by any unintentional stoppage of the liquor supply. The water (or sometimes weak acid) is fed in at the top by some contrivance assuring a uniform distribution over the whole area of the tower, and in trickling down it keeps the surfaces of the coke moist, and a very large area of contact between the gases and the liquid is thus pro-These towers are so simple to construct and so effective that of recent years there has been a growing tendency in England to do away with all cooling pipes, cisterns, wash towers, &c, and to use a couple of very large stone towers to do the whole work of cooling and condensation for two or even more salt-cake pots and furnaces. The towers are worked in series, the weak acid from the second or final tower being run down the first tower. In this way both complete absorption of the acid is assured, and the production of a strong liquid acid, i.e. one of over 1.15 sp.gr. To condense the acid from two-hand salt-cake furnaces the two towers may each be 5 feet square and 50 feet high

No difficulty is now experienced in pumping the weak acid made in the second condenser on to the top of the first condenser, either by stoneware ram pumps, chonite ram pumps,

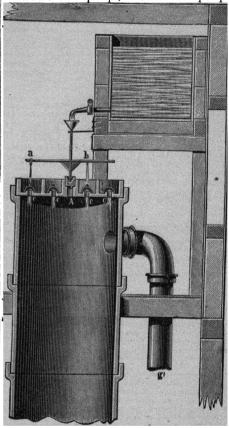

Fig 33.

stoneware acid eggs, or occasionally even yet by the Hazlehurst membrane pump, patented in 1876 The ascension pipe is usually of stoneware or ebonite, occasionally of lead

Brick towers are not to be recommended, as it is practically impossible to keep the numerous joints tight against acid oozing out. Columns of stoneware pipes cannot be made of a large area, and, therefore, are not very well adapted to large works, at least if intended for coke towers, but they do very good service at smaller works, or as supplementary to a large condensing plant of stoneware receivers. The material mostly employed for coke towers is acid proof sand-tone or, in France, volvic lava, just as

for acid tanks. The system of joining the flags together is the same as shown in Figs 28 and 29, or else as in Fig. 30, or as shown in Fig. 32, in which the flags are kept together by means of grooves worked in the stone, and without the aid of any ironwork, which is always a source of anxiety in acid condensers.

The coke towers are generally placed at a high level, and are, if necessary, put upon pillars, for the purpose of running the acid from them by gravitation either into chlorine stills, or into store cisterns for sale They must, of course, have a very secure foundation, in the construction of which not merely the great weight of the tower must be considered, but also the probability that there will be now and then leakages of acid which may make the foundation unsafe. This can be avoided by asphalting the ground in such a way that any acid running down cannot penetrate into the soil, and is conveyed to a safe distance Any damage done to the foundation, even if it amounts to much less

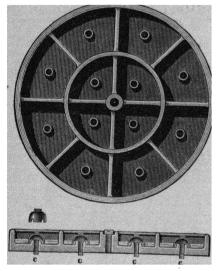

Fig. 34.

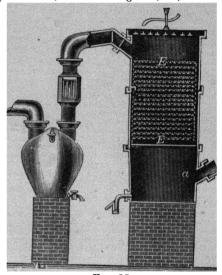

than would cause the erection to break down altogether, is extremely injurious, because it will almost unavoidably lead to the tower getting out of level, in which case the liquid will principally descend on the lower side, thus the necessary distribution of the liquid is not attained, and the action of the condenser is most injuriously affected

It has been already stated that the feeding of the towers with water or with weak acid must take place in such manner as to distribute it equally over the whole surface of the coke. Formerly this was generally done by a distributing wheel (shown in Figs 33 and 34) worked by the pressure of the feed water itself 33 ought to show two jets feeding the outer urcle of holes This causes the stream of water to reach successively every one of the holes on the top of the condenser, and thus secures a aniform distribution without depending upon the top of the tower being at a mathematical level.

Recently most manufacturers have done

away with these acid wheels, and have introduced troughs provided with a number of overflows all at the same level, feeding the same number of 'lutes' This arrangement is indicated on Fig 31. This figure represents a tower built as Fig 32, the cross-hatched outer portion representing the timber framework to support the feeding cistern

Another form of apparatus for dissolving the hydrochloric acid gas is the Lunge Rohrmann plate tower, shown in Figs 35, 36, and 37.

Fra 35.

It consists of an earthenware tower packed with a series of perforated plates E, E, the perforations being made to alternate in successive plates, so that each hole corresponds to a solid place in the plates just above and below 36 and 37 show one of the plates in detail. As is to be expected, the evidence for and against the improved packings for the condensing towers is very conflicting, and as the

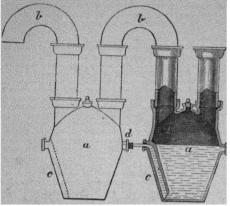

Fig. 36.

Fig 37

cost of them is naturally higher, the coke-packed tower has fully maintained its position.

In France and Germany a somewhat different system of cooling and condensation is in general use. The earthenware and glass pipes mentioned above as being used almost exclusively in this country for the cooling of the gases are more or less completely substituted by a series of earthenware Woulffe's bottles, known technically as bombonnes or touries (see Fig 38) The figure is drawn too small to show that the vessel on the right is about 1 inch higher than the vessel on the left; the liquids travel down hill from right to left, and consequently the gases are made to travel from left to right The size of the bombonnes varies from 40 to 100

gallons. They are arranged in sets of 40 up to 100, as shown in Fig 39, and, in spite of the relatively high temperature in the leading

PTG. 3N

bombonne, eventually gives a liquid acid of 1.15-1.18 sp gr They are made of the best stoneware, which is able to stand somewhat violent changes of temperature. After leaving the bombonnes, the acid gases are finally

scrubbed with water in a coke-packed tower, similar in design but usually much smaller than those used in this country The weak liquid acid produced in this tower supplies the stream of weak acid required by the bombonnes The figure does not show the means of running off the strong acid from the lowest bombonnes in the series, nor the cisterns, &c, for receiving the acid.

In the condensation of hydrochloric acid gas in water with the apparatus at present used and described above, there is little reason for difficulty in avoiding losses of HCl through in-complete absorption The difficulty more commonly experienced is to combine the complete absorption enforced by law with a high-strength liquid acid

The impurities found in commercial hydrochloric and made by the above processes are, chiefly, sulphuric acid, ferric chloride, arsenic trichloride, and either free chlorine or sulphurous acid

Sulphuric acid is the largest impurity. The hydrochloric acid condensed from the pan or pot gas is always much purer than that from the roaster gas. The quantity of sulphuric acid in

the gases from the salt-cake furnace sometimes amounts to 2 pc. and upwards; it is very troublesome in the Weldon, and fatal in the Deacon, chlorine process, and in some other

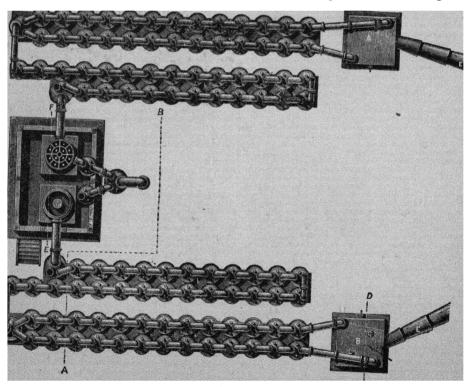

Fig 39

applications of hydrochloric acid. The suldenser or dry scrubber before condensation phuric acid in the salt-cake furnace gases can be removed to a large extent by a small confort the purification of the salt-cake furnace

gases, so as to render them suitable for the Deacon process, but the only one of these processes to achieve practical success is the Hasenclever process (Eng Pat 3393 of 1883). (See at end of Deacon Chlorme Process)

Arsenic gets into the hydrochloric acid through the sulphuric acid employed in its manufacture, the arsenic is thereby converted into AsCl<sub>3</sub>, and passes as such into the condensing apparatus. Many plans have been proposed for its removal-most frequently a treatment with sulphuretted hydrogen or with sulphides. Bettendorf (Dingl. poly J. 194, 253) precipitates the arsenic from concentrated hydrochloric acid by stannous chloride, and then distils the decanted acid. Duflos dilutes the acid to sp gr. 1:13, and digests it with strips of sheet copper at 30°C for 24 hours, and repeats this treatment with freshly scoured copper This removes all the arsenic and the free chlorine, and reduces the ferrie chloride to ferrous chloride, which remains behind on Beckurts (Fischer's Jahresb 1884, distillation 348) distils hydrochloric acid with ferrous chloride and removes the first 30 p.c. containing all the arsenic

Selenium is sometimes found in such quantities in hydrochloric acid as to be troublesome in its application (Davis, J. Soc. Chem. Ind.

1883, 157)

Hydrochloric Acid from other Sources than the Attempts have been made to Leblanc Process produce hydrochloric acid from many sources, notably from the residual liquors of the ammoniasoda process A number of suggestions have been made for the direct production of HCl. 1st, from CaCl2, 2nd, from MgCl2, 3rd, from NH Cl In this connection compare references given for the production of chlorine from these bodies earlier in the article. As far as is known, hone of the processes is used. Mond (1883) heats the ammonium chloride with so much sulphuric acid that the acid sulphate is formed and all HCl is expelled. The acid sulphate is converted by means of ammoniacal vapours into the neutral salt of commerce. O. N. Witt (1886) expels the HCl from NH<sub>4</sub>Cl by means of syrupy phosphoric acid, which forms ammonium phosphate On heating this at a higher temperature, the ammonia is driven out as well, and the phosphoric acid is regenerated Jurisch (Dingl. poly J 267, 431) has shown that this process is not placticable, because there is no material known which resists the fusing phosphoric acid, and only 63 to 86 p c. of the NH3 is recovered. Mond passes the vapour of ammonium chloride over nickel oxide, heated to at least 350°, which absorbs the HCl and allows the NH3 to pass on a certain time the process is changed by raising the temperature to 500° or 600° and decomposing the nickel chloride by steam, when HCl is driven off and NiO regenerated (Several patents taken out in 1886)

During recent years, when the chlorination of organic compounds has grown by vast strides, the hydrochloric acid gas produced when a hydrogen atom is substituted by a chlorine atom, has had to be collected and These reactions are referred to in a utilised previous page when describing the uses of chlorine. The hydrochloric acid gas is evolved HYDE

almost pure, is easily condensed, and yields an acid quite free from the usual impurities

Hydrochloric acid has also been produced by passing chlorine over wood at a temperature of 150°-350°, whereby charcoal is also formed (Bosnian Electricity Works at Jacie, D. R. P. 158086)

Lastly, hydrochloric acid has been prepared by processes inverting the practices of the last hundred years, namely, it has been prepared from its elements as a direct and definite process without the formation of by-products, or for any other reasons than its own preparation and the utilisation of the two elements formed by the electrolysis of potassium and sodium chlorides. The gases are mixed and passed over charcoal (D R. P 114219), or they are burnt together at jets (Soc Italiana di Elettro-chimica; J. Soc. Chem Ind 1915, 1142), or they are combined together by Roberts' patent (Electrochemical and Metallurgical Industry, 1910, 704), and by this last process the acid has been manufactured in Niagara since 1914.

The conveyance of hydrochloric acid mostly takes place in glass carboys of 10 or 12 gallons capacity with basket or wire hampers, sometimes in earthenware carboys of the same size, and recently hard white vitrefied earthenware jars have become available At a large French works, some years ago, tank waggons were used, carrying iron cylinders lined with ebonite.

Tank waggons have of late years come into general use, especially on the Continent consist of a waggon platform, carrying a number of stoneware jars of about 1 ton capacity each Fig. 40 shows such a waggon carrying 12

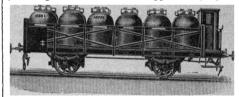

Fig. 40

jars, each of which holds I ton of acid. Specially prepared wooden tanks are also used occasionally.

The applications of hydrochloric acid solu-tion are, first and foremost, for producing chlorine by the Weldon process, for the cleaning of thin sheet iron when the same is to be coated with zinc, tin, or lead; for extracting the phosphates from bones and from bone char-for which purposes it must be quite free from sulphuric acid, for preparing zinc chloride, and zine ammonium chloride from the residual 'flux skimmings' of galvanising works, for souring goods during the process of bleaching; for neutralising the alkaline melts in the manufacture of alizarin, resorein, &c , for the manufacture of aniline hydrochloride, stannous chloride, ferric chloride, for the preparation of pure carbonic acid from limestone; in dyeing and tissue printing; and in the manufacture of many coal tar colours and intermediates, &c

ω-CHLOROACETOPHENONE v KETONES CHLOROBENZALDEHYDE v. BENZALDE- CHLOROBENZENE v. PHENYL δ-CHLOROBENZENEDISULPHONIC ACID

C<sub>6</sub>H<sub>5</sub>Cl(SO<sub>3</sub>)<sub>2</sub>H<sub>2</sub>. Formed by heating at 300° chlorobenzene with five times its volume of fuming sulphure acid containing 20 pe of sulphur trioxide Forms barium, potassium and ammonium salts, a dichloride, mp 105 5°-106° and a diamide, mp 223°-224°. The dichloride heated under pressure at 200°-210° with phosphorus pentachloride yields δ-trichlorobenzene (Olivier, Rec. trav. chim. 1918, 37, 307)

p-CHLOROBENZENE DIAZOCYANIDES v. DIAZO- COMPOUNDS

CHLOROBROM. Trade name for a mixture of equal parts of potassium bromide and chloral formamide dissolved in water.

CHLOROFORM, Trichloromethane CHCl3. Chloroform was discovered by Liebig in 1831

(Pogg. Ann 23, 242), and independently, about the same time, by Souberran (Ann Chim Phys [2] 48, 131). Its actual composition was first determined by Dumas (Ann Chim Phys [2] 56, 115) to whom is also due the name by which it is now known Chloroform is largely employed as an anæsthetic and is an important solvent, finding technical application in the manufacture of fats, rubber, resins, alkaloids, It is also a useful antiseptic

Formation -1 By the action of alkalis on chloral (Liebig, Pogg Ann 23, 442, Annalen, 1, 199; 162, 161)

CCl<sub>2</sub>CHO+NaOH-=CHCl<sub>2</sub>+HCOONa

2. By the action of water, ammonia, or alkalis on trichloracetic acid (Dumas, Annalen, 32, 101, Beckurts and Otto, Ber 14, 589)

$$CCl_3COOH + HOH = CHCl_4 + CO_2 + H_2O$$

3 By the action of bleaching powder (chlorine) on ethyl alcohol or acetone In the case of alcohol the reaction has been represented by the following equations ·

by the Contact (a) CH<sub>3</sub>CH<sub>2</sub>OH+CaOCl<sub>2</sub> = CH<sub>3</sub>CHO+H<sub>2</sub>O+CaCl<sub>2</sub>

(b) 2CH<sub>3</sub>CHO+3CaOCl<sub>2</sub> =2CCl<sub>3</sub>CHO+3Ca(OH)<sub>2</sub>

(c)  $2\text{CCl}_3\text{CHO} + \text{Ca(OH)}_2$  =  $2\text{CHCl}_3 + (\text{H COO})_2\text{Ca}$ 

According to Dott (J Soc Chem Ind 27, 271), however, the reaction is best indicated by the equation

3C<sub>2</sub>H<sub>5</sub>OH+8CaOCl

=2CHCl<sub>3</sub>+3CaCO<sub>3</sub>+CO<sub>2</sub>+H<sub>2</sub>O+5CaCl<sub>2</sub>no appreciable amount of calcium formate being found in the products of reaction

According to Feyer (Zeitsch Elektrochem 1919, 25, 115), the formation of chloroform from alcohol occurs in three stages. first, an exidation of the alcohol to aldehyde; secondly, a formation of hypochlorite, and thirdly, an interaction between the aldehyde and the hypochlorite:

(1) CH<sub>3</sub> CH<sub>2</sub> OH+HOCI

$$=$$
CH<sub>2</sub>CHO+H<sub>2</sub>O+HCl,

(n)  $OH'+Cl_2=H'+Cl'+ClO'$ ;

(III) CH<sub>3</sub> CHO+3HOCI

$$= CHCl3 + HCO2H + 2H2O,$$
(iv) H CO<sub>2</sub>H + HOCl = CO<sub>2</sub> + H<sub>2</sub>O + HCl.

Equation (1) is partly replaced by the reaction

 $CH_3 CH_2 OH + O = CH_3 CHO + H_2O$ 

expressed thus (Orndoff and Jessel, Amer. Chem. J. 10, 363):

 $\begin{array}{l} 2 {\rm CO(CH_3)_2} + 6 {\rm CaOCl_2} \\ = 2 {\rm CHCl_3} + 2 {\rm Ca(OH)_2} + 3 {\rm CaCl_2} + ({\rm CH_3COO})_2 {\rm Ca} \end{array}$ Dott (loc. cit), however, prefers the equation 2CO(CH<sub>3</sub>)<sub>2</sub>+8('aO('l<sub>2</sub>)

 $=2(H(1_3+(CH_3COO)_2Ca+2Ca(OH)_2)$ 

which agrees better with the results of experiment According to Ukita (J Chem Ind Tokyo, 1918, 21, 219) better yields are obtained by passing chlorine into ethyl alcohol until a liquid of D=1 299 is obtained. This is then added to a solution of bleaching powder and lime and distilled

Chloroform is also produced from acetic acid (Liebig), acetophenone (Orndoff and Jessel, loc cit), acetaldehyde turpentine, and ternenes (Chautaid, Jahresb 1851, 501) by the action of bleaching powder or chlorine. (V also Brit Pat 1,6094, 1917)

4 By reactions similar to the foregoing chloroform is also produced by the electrolysis of the chlorides of alkali or alkali earths in presence of alcohol, acctone, &c (Ber 1884, 17, Ref 624, see also Waser (Chem Zentr. 1910, 1, 1122), Feyer, Zeitsch Elektrochem 1919, 25, 115)

5. By the reduction of carbon tetrachloride (Geuther, Annalen, 107, 212, v also Chem Rev 1896, 88, U.S Pat 753325 (1904) and Eng Pat 13733 (1901))

6 By the action of chlorine in sunlight on methyl chloride (Regnault, Annalen, 33, 328)

7 From iodoform by the action of phosphorus pentachloride (Gautier, Bull Soc Chim. [2] 13, 127)

Manufacture - Chloroform was originally almost wholly manufactured from ethyl alcohol or methylated spirit Punfication of chloroform prepared from the latter presents rather more difficulty, but when properly carried out pure chloroform is obtained.

Of late years chloroform has been made for the most part from acetone, and although for some time a prejudice existed against the employment of chloroform made from this source for an esthetic purposes, it is now recogmsed that the product when properly prepared is in every respect equal to that obtained from alcohol.

Chloroform has been manufactured successfully in America for some years past from carbon tetrachloride by reduction with nascent hydrogen This is most efficiently brought about by mechanically agitating a mixture of the tetrachloride and finely divided non in water, a trace of acid being added to initiate the reaction (Smith, U.S. Pat 753325 (1904); see also U.S. Pat 1101025, 1914)

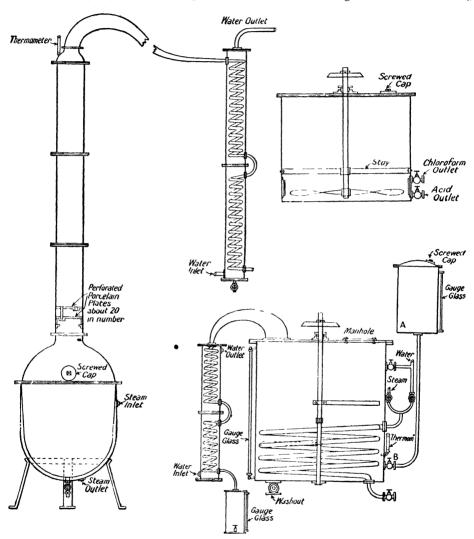

Attempts have also been made to manufacture chloroform by chlorination of the 'natural gas' (methane) produced in enormous quantities in the United States, but so far these attempts have not met with any measure of success

Electrolytic processes for the production of chloroform from alcohol and acetone have formed the subject of a number of patents, but the commercial results do not seem to have been so successful as the original experimental CH<sub>3</sub> CH<sub>2</sub> OH+O=CH<sub>3</sub> CHO+H<sub>2</sub>O work promised, and very little chloroform has In the case of acctone the reaction may be been made by this means (Schering, D. R. P.

29771 (1884), v also Zambelliti, L'Ettricita, 1899, 8, 664; Teeple, J Amer. Chem. Soc. 26, 536; and Waser (Chem. Zentr. 1910, 1, 1122)

Manufacture of Chloroform from Acctone and Bleaching-powder.—This is the process most generally employed. The method differs in minor details with the various manufacturers,

The reaction is carried out in a cast-iron tive. still of about 800 gallons capacity, which is provided with sturing gear, steam and cooling coils, and is connected with a condenser hundred gallons of water are run into the still, and 800 lbs of bleaching powder are added through a manhole, which is then securely but the following may be taken as representa-bolted down During addition of the bleaching

powder the mixture is very thoroughly stirred. (In some processes the mixing is carried out in a separate vessel, and the suspension is strained from the larger unbroken lumps of bleaching powder before being allowed to run into the still) The container (A in the diagram shown) is charged with 70 lbs. of acetone, which is then slowly run into the bottom of the still by means The introduction of the acetone of the valve B is accompanied by a rise of temperature which is not allowed to exceed 110°F., cooling being

effected if necessary by stopping the flow, of acetone and circulating cold water through the cooling coil in the still When all the acetone has been introduced the contents of the still are raised to 134°F. At this temperature At this temperature chloroform begins to distil over. The temperature is then very gradually raised to 150°F., so as to keep the chloroform steadily distilling. Towards the end of the reaction the mixture is stirred and the temperature raised until no more chloroform distils over.

The crude chloroform obtained is separated | and purified first by agitation with concentrated sulphuric acid. This operation is carried out in the vessel shown in the diagram; 1500 lbs of crude chloroform are introduced into the vessel and thoroughly stirred by means of the agitating gear shown, with 600 lbs. of sulphuric acid. The stirring is continued until a sample of the chloroform, when thoroughly shaken with pure concentrated sulphuric acid, does not impart the slightest colour to the latter. The time required for complete purification is usually about 3 hours. The chloroform is next separated from the sulphuric acid and finally distilled over lime.

The yield obtained from the above quantities averaged from over two thousand batches was 124 lbs., the highest yield in any one case being 131 lbs. Variation in yield is attributed to the varying composition of the bleaching powder, though doubtless other factors influence the result. Bleaching powder containing less than 33 p.c. of available chloring gives unsatisfactory results, while samples containing more than 35 p c. of chlorine are also often unsatisfactory The best results appear to be obtained with bleaching powder containing about 34 p.c of available chlorine.

Manufacture of Chloroform from Alcohol -This is carried out in the same plant as that used for the manufacture of chloroform from acetone A mixture of alcohol (150 lbs.) and water (3000 lbs.) is introduced into the still, bleaching powder (750 lbs) added, and the contents of the still gently heated by means of the steam Chloroform begins to distil over at a temperature of about 140°-145°F Further heating is then discontinued, the chloroform distilling off by reason of the heat generated during the reaction When the distillation begins to slacken the heating is resumed until at a temperature of 155°F the distillate consists of a mixture of alcohol and water. This mixture, which contains rather more than half the original alcohol, is used in making up the next batch, sufficient fresh alcohol being added to make up the required 150 lbs. The yield of crude chloroform from each working is about 75 lbs. Purification is effected as described above

Chloroform has also been manufactured by special processes for the purpose of producing directly chloroform sufficiently pure for anæs-Of these the most important thetic purposes

are the following .-

1 Chloroform from Chloral -It was found by Liebig, the discoverer of both compounds, that chloroform could be obtained from chloral by distillation with alkalis, and subsequent washing and drying, and this process has been utilised for the manufacture of chloroform. Upon the same reactions has been based a patent (Liebreich, Eng. Pat 15930, D R P 176063, 1904), whereby a dry mixture of chloral hydrate and alkalı can be prepared and compressed, from this product chloroform may be prepared by treatment with water. Chloroform obtained from chloral is of a high degree of purity. Like all other brands of chloroform it must, however, be preserved by the addition of a small amount of alcohol.

2. Chloroform Pictet.—This product is ob-

tained by fractionally crystallising commercial chloroform The crude chloroform is cooled to -80°, and the solid impurities are filtered off. The filtrate is then cooled to  $-82^{\circ}$ , and the liquid portion is drained off. The crystallised chloroform is then distilled at a very low temperature, and the middle fraction amounting to about 80 pc is collected as chemically pure chloroform (Pictet, Compt rend. 114, 1245, French Pat 215911, 1891, U.S. Pat. 489592, 1893). It was originally claimed that the pure chloroform obtained by this means was stable in the presence of light, and from this Schaet & Bilz (J. Soc. Chem Ind. 1893, 12, 543) deduced that it contained a small amount of alcohol which was subsequently shown to be the case.

3. Chloroform Anschutz ('Saheyhd chloroform').—Anschutz (Annalen, 273, [1] 94) observed that chloroform combined to form well crystalline compounds with the lactide condensation products obtained from o-phenol carbonic acids These compounds break up on gentle heating, giving pure chloroform The compound usually employed in the process is tetrasalicylide  $(C_6H_4 C_0)_4$  m p. 261°-262°, obtained by the action of phosphoryl chloride on This combines with 3 molecules salicylic acid of chloroform which are given up on warming The recovered salicylide can be employed again The product obtained by this process has been extensively used in Russia.

Properties — Chloroform is a heavy colourless liquid having a sweet taste and a pleasant ethereal odour It is not inflammable, but when diluted with alcohol may be made to burn and gives a smoky greenish flame. It is very slightly soluble in water (1 part in 200), but miscible with most organic solvents.

According to the most accurate determinations pure chloroform has sp gr 1 52637 at 0°/4° (Thorpe, Trans Chem Soc 37, 196), 1 52657 (Timmermans, Bull Soc belg chim 24, 244), or 1 4989 at 15°/4° (Baskerville and Hamor, J. Ind and Engin. Chem 1912, 278) According to the same authors the boiling-point is 61 2° (see also Wado and Finnemore, Trans Chem. Soc, 1904, 85, 946) Chloroform melts at -83° (Pictet) Its critical temperature is 262 9°, and critical pressure 53 8 atmos. (Kuenen & Robson)

Reactions and detection of Chloroform —The most important reaction of chloroform is the formation of an isocyanide from any primary amme when the latter is heated in presence of chloroform and alcoholic potassium hydroxide solution

### $CHCl_3+RNH_2+3KOH=R\cdot NC+3KCl+3H,O$

In practice aniline is usually employed as the reacting amine and the characteristic odour of phenylisocyanide is readily recognised. In this way one part of chloroform in 5000-6000 parts of alcohol can be detected. The reaction is also given, however, by bromoform, iodoform, chloral, trichloracetic acid, &c.; but not by ethylidene chloride. Chloroform readily reduces Fehling's solution and the reaction has been used as an indirect method of estimation.

A mixture of chloroform vapour and hydrogen when passed through a red hot tube yields hydrochloric acid This reaction also may be employed for the detection and estimation of chloroform in blood or other (non-chlorinated) liquids (Allen, Comm. Org Anlysis, vol 1 p 275)  $\alpha$  or  $\beta$  naphthol dissolved in concentrated potassium hydroxide solution when heated with a little chloroform give a blue colour which gradually becomes green and finally brown in contact with air

Anæsthetic Chloroform — The use of chloroform as an anæsthetic was first advocated by Simpson in 1848 (Edin Monthly J Med Sc 8, 415), and it is now used in very large quantities for this purpose alone Great care is necessary in its production for this purpose, since the presence of small amounts of impurities have a deleterious and often dangerous influence, and many cases of death under chloroform have been attributed to the employment of impure an esthetic the result of a considerable amount of investigation, it has now been shown fairly conclusively that pure chloroform under the influence of light, air, and moisture decomposes, more or loss rapidly according to the conditions pre-vailing, and that the products of decomposition are carbonyl chloride and hydrochloric acid, a reaction which may be represented thus

$$\begin{array}{c} \mathrm{CHCl_1\!+\!H_2O\!+\!O_2\!=\!COCl_2\!+\!HCl\!+\!H_2O_2} \\ \mathrm{CHCl_3\!+\!H_2O_2\!=\!COCl_2\!+\!HCl\!+\!H_2O} \end{array}$$

It was very early noticed that the tendency of chloroform to decompose was more marked with samples which showed a high specific gravity (1 497 to 1 50) than with those of lower density, and the greater stability of the latter was attributed to the presence in them of small amounts of alcohol It had earlier been suggested by Squibb (Amer Med Monthly, July, 1857), that the best means of preserving chloroform was the addition of a small amount of This practice has since then been alcohol recognised as sound in principle and the addition of alcohol in amounts varying from 0.6 to 1.0 p c by volume is allowed by most of the pharma-The British Pharmacopæia (1914) does not specify the amount of alcohol permissible, but defines the density at 1 483 to 1 487

Considerable diversity of opinion has been expressed with regard to the rôle played by alcohol in preventing the decomposition of chloroform, but it now appears to be fairly well established that it acts by reason of its property as a reducing agent, oxidation of alcohol taking place in pieference to that of chloroform the same time the products of oxidation appear to exert a retarding action which eventually a maximum When chloroform preserved with alcohol the decomposition of the chloroform is entirely prevented until all the alcohol is oxidised, when decomposition of the chloroform immediately commences properly stored and packed so that the action of light and air is reduced to a minimum, chloroform containing from 0.6 to 1 p.c by volume of alcohol will keep for years (Schact and Bilz, Pharm. J. 1893, 1005) The theory of the action of alcohol outlined above is due to Baskerville and Hamor (J. Ind and Chem. Eng. 1912, 368, &c), whose admirable series of papers form the most complete and recent account of the subject of this article Their theory is supported by the fact that a large

number of organic substances soluble in chloro form will inhibit the decomposition of the latter by light and air, and that all such compounds are reducing substances and act solely on account of their capacity for oxidation. That such compounds are not used in practice is merely on account of the special suitability of alcohol for the purpose

The various pharmacopeas also insist on certain tests for the absence of impurities, other than alcohol, which might possibly be present in chloroform through careless manufacture of storage. The details of the tests vary in different countries, but may be generally indicated as follows—

(1) The odour test.—This is usually carried out by evaporating a quantity of chloroform (10–50 c c.) to small bulk, and then allowing the residue to evaporate on a piece of filter paper At no stage of the evaporation should there be any appreciable foreign odour, eg of fusel oil, higher alcohols, or chlorimated derivatives of alcohol or acetone

(2) Residue—There should be no weighable residue after evaporation of 50 to 100 e.e. of chloroform

(3) Sulphuric acid test.—This consists in shaking chloroform (usually 20 c c) with pure concentrated sulphuric acid (usually 15 c c) for a short time and then allowing the mixture to stand. The two layers are required to remain colourless or practically so over a period of time which varies with the different pharmacopenas. The object of the test is to detect the presence of organic impurities which should have been removed in the process of manufacture.

A more delicate variation of this test has been suggested by Langgaard (Therap Monatsh May, 1902) Concentrated sulphuric acid and chloroform are mixed in the proportions required by the German Pharmacopæia and then four or five drops of formalin (40 p c solution) added and the mixture well shaken No coloration should develop on standing The German Pharmacopæia requires the solution to remain colourless for forty-eight hours According to Budde (Veröffentlichungen aus dem Gebiete des Militar-Sanitatswesens, 1913, 6, 113), however, the sensitiveness of the reaction increases with the amount of alcohol present

(4) Acidity —Water shaken with chloroform and separated should remain neutral to litmus

(5) Chlorine—The aqueous layer after shaking chloroform with water should give no reaction when shaken with a 10 pc solution of cadmium rodide and a few drops of starch solution

nodide and a few drops of starch solution
(b) Hydrochloric and—The aqueous layer obtained as above should not give more than a very slight opalescence with a solution of silver nitrate (Cf Analyst, 1919, 407)

(7) Decomposition products—Two c c of the sulphuric acid solution obtained as in test (3) when diluted with 5 c c of water should remain nearly colourless and have no unpleasant odour When further diluted with 10 c c of water the solution should remain colourless and on addition of a little silver nitrate should not give more than a slightly diminished transparency

For the last three tests Budde (loc. cit) proposes to substitute one, namely, a reaction with benzidine, which it is claimed is simpler and at the same time more sensitive. A little

pure benzidme is dissolved in about 10 c c of chloroform. The solution should remain per feetly bright when kept in the dark, out of contact with air for 24 hours. In the presence of chlorinated products or of carbonyl chloride an opalescence or floculent precipitate is produced. If chloral is present, a faint red coloration develops at first and changes to bluish-red after a time

## Other possible Constituents of Anæsthetic Chloroform

Ethyl chloride - Chloroform manufactured from alcohol was at one time considered, for anæsthetic purposes, superior to that obtained from acetone Wade and Finnemore (1904, 85, 938) showed that chloroform prepared from alcohol contained a small quantity (approx 0.05 p.c.) of ethyl chloride, and to this they attributed its superior qualities. According to them pure chloroform prepared from acetone, and to which a small proportion of ethyl chloride was added, was alone clinically equal to that obtained from alcohol Baskerville and Hamor (lor cit p 574), however, state that American anæsthetists have found chloroform from acetone when properly purified to be fully as reliable as They therefore look chloroform from alcohol upon ethyl chloride as an impurity of anæsthetic chloroform which although perhaps not objectionable, has no special value Since the boiling-point of chloroform is lowered to the extent of about 2° by the presence of 0.1 pc of ethyl chloride (Wade & Finnemore, loc cit) its presence is easily detected by fractionation

Acetaldehyde—For the detection of this impurity in chloroform Baskerville and Hamor suggest the following—10 c c of chloroform are shaken with 5 drops of Nessler's solution U.S.P. and allowed to stand for five minutes Anæsthetic chloroform should show no precipitate or colouration under these conditions

For the detection of acetaldehyde chloroform is in practice often tested by allowing to stand over solid KOH. For this purpose the KOH should contain at least 80 p.c. KOH and be free from water, otherwise oxidation of alcohol may take place and a positive reaction be obtained

Acetone —An esthetic chloroform should give a negative result when tested as follows. To 10 c.c. of chloroform are added 5 drops of 0.5 p.c. solution of sodium introprusside and 2 c.c. of ammonia (D=0.925) and the mixture allowed to stand for five minutes in the cold If acetone is present to the extent of 0.2 p.c. an amethyst colour is produced. By saturating the mixture with ammonium sulphate the colour is produced in the presence of 0.1 p.c. of acetone

Carbonyl chloride, which is only likely to be present in badly preserved or stored an esthetic chloroform, may often be detected by its nauseous colour. The following test is also quite satisfactory. To 15 c c of chloroform in a dry glass-stoppered cylinder of 25 c c capacity is added sufficient clear solution of barium hydroxide (0 5 p c.) to completely fill the tube, which is then kept in the dark for 3 hours. In the presence of carbonyl chloride a film of barium carbonate is produced at the junction of the liquids.

Carbonyl chloride is also readily detected by the benzidine test (Budde, *loc cit*), which gives a positive reaction with one part in twenty thousand (1 20,000). The impurities of commercial chloroform may include chloral alcoholate and similar chloral compounds. These may be estimated by treating the chloroform with N/10 alkali and titrating the excess. Pure chloroform is not affected by alkali of this strength. Aldehydic and similar compounds are detected by means of Nessler's reagent, which gives with impure chloroform a red-brown deposit readily changing to greenish black. Pure chloroform gives no such reaction (Enz. Apoth. Zeit. 1913, 28, 672. Analyst, 1913, 497)

Chloroform is comparatively unstable under the influence of ultra-violet radiation (Kailan,

Monatsh 1917, 38, 537)

Detection and Estimation of Alcohol in Chloroform -For the detection of alcohol in chloroform the iodoform reaction provides a very delicate test which, however, is not specific It is best carried out by shaking the chloroform with sulphuric acid, separating and diluting the sulphuric acid layer. This is then distilled and the reaction carried out on the first portions of the distillate To 10 c c of the distillate 6 drops of a 10 p c solution of potassium hydroxide is added, the mixture warmed to about 50°, and then drop by drop a solution of iodine in potassium iodide until a brown colour is produced The solution is then carefully decolourised by addition of potassium hydroxide On standing crystals of iodoform separate

For the estimation of alcohol the density of the chloroform forms an approximate guide provided the chloroform is otherwise pure, but for more exact determinations the method of Nicloux (Bull Soc chim [3] 35, 330, 1906) as modified by Béhal and François (J. Pharm. Chim. [6] 5, 417) is recommended. The alcohol is removed from the chloroform by agitation with sulphuric acid, the latter is diluted and gently The distillate is boiled with sulphurie acid and potassium dichromate solution containing 16 97 grams per litre is added until a green (not greenish yellow) tint is obtained Each 2 cc of solution equals 0.01 gram of absolute alcohol If the solution contains more than 2 p c of alcohol it must be diluted and the estimation repeated A similar modification has been suggested by Budde (loc cit)

1-CHLORO - 8 - NAPHTHOL - 3 6 - DISUL - PHONIC ACID

is prepared by dissolving 1-amino-8-naphthol-3 6-disulphonic acid in a cooled solution of sodium carbonate, carefully acidifying with hydrochloric acid and diazotising with the theoretical amount of sodium nitrite. The separated diazo-compound is warmed with hydrochloric acid and cuprous chloride, the copper removed by sulphuretted hydrogen, and the filtered solution saturated with common salt when the acid sodium salt of the chloroacid is precipitated (Cassella & Co, D R P. 79055). The chloro-acid is also formed by treating 1 8-naphthylene-diamine-3: 6-disulphonic acid with sodium nitrite in acid solution and acting on the azimino-compound with copper paste (Badische Anilin und Soda Fabrik, D R. P. 147852).

CHLOROPHENINE ORANGE v Azo-

CHLOROPHENINE YELLOW v. PRIMULINE AND ITS DERIVATIVES.

CHLORORUBINE v MADDER.

CHLOROXYLONINE C<sub>22</sub>H<sub>23</sub>O<sub>7</sub>N, an alkaloud ccurring in East Indian satinwood (Chloroxylon Inveteria (DC.)). It crystallises from alcohol in olourless prisms, m.p. 182°-183°, [a]<sup>18</sup>-9° 18′, a chloroform, is soluble in excess of ammonia olution, and is neutral to htmus. The salts are rystalline and dissociate in water; aurichloride 3'HCl'AuCl<sub>3</sub> groups of reddish-yellow needles, a.p. 70°. Chloroxylonine contains four 'OMe out no hydroxyl groups (Auld, Chem. Soc. 'rans. 1909, 95, 964). It produces dermantis when applied to the skin and is the cause of the dermatitis sometimes experienced by atinwood workers (Cash, Brit. Med. J. 1911, 9ct. 7; and Bull. Imp. Inst. 1911, 9, 351).

CHLORPICRIN (truchtoron tromethane) CCl<sub>3</sub> VO<sub>2</sub> is prepared by distilling nitro-compounds in particular, pierie acid) with bleaching-powder olutions (Stenhouse, Ann. 1848, 66, 241), by one heating of chloroform with fuming nitric cid (Mills, Ann. 1871, 160, 117), or by the ction of chlorine on nitranilic acid (Levy,

edlicka, Ann 1888, 249, 86)

In Hofmann's method of preparation 45 parts f fresh bleaching powder are made into a paste 7th water and mixed with a saturated solution 4 5 parts of pieric acid in water at 30° As soon s the very violent reaction is finished, the chloronerm is distilled over (Ann. 1866, 139, 111)

Chlorpierin is a mobile liquid which boils at 11 9°C and possesses a specific gravity 1 69225 0/4°) Thorpo. On heating it slightly decomposes nto carbonyl chloride and introsyl chloride Cl<sub>3</sub> NO<sub>2</sub>=COCl<sub>2</sub>+NOCl) (Gardner and Fox, them. Soc. Trans 1919, 1188). On strong coolng it solidifies and then melts at -69 2°C apour acts as a strong irritant to the eyes and aucous membrane For thermal expansion, see 'horpe, Chem. Soc. Trans 1880, 37, 198 eduction with iron and acetic acid it yields vethylamine A similar bromo-nitro-methane is nown. It melts at 10°C, boils at 127° (118 am), and is converted by the action of potassium yanide in cold alcoholic solution into the ipotassium salt of 1122 tetranitroethane Scholl, Ber. 1898, 31, 642, *ibid*. 1902, 35, 4292)

CHLORYL. Syn. for ethyl chloride used as n anæsthetic

CHOCOLATE is a mixture of cacao paste 7th sugar and flavouring matter The paste s prepared from fermented cacao beans (the nfermented kinds being unsuitable for chocoite making) in the manner described under The sugar, which constitutes 50 p c or nore of the mixture, consists usually of white rystals (although the lower-grade coloured ugars may be used for the cheaper chocolates), round to the finest powder and completely ried before admixture with the cacao paste. most common flavouring substance is anilla, but other spices, as cardamoms, cinnaion, cloves, mace, and nutmeg, or the essential ils extracted from them, also artificial flavourags such as vanillin, are frequently employed 'eru balsam and gum benzoin are sometimes sed for a similar purpose. The flavourings are

introduced either in alcoholic solution or incorporated with sugar moistened with a little oil

It is essential that during admixture the paste should be kept in a liquid condition, and to this end the mixing machines are heated to a temperature slightly above the melting-point of cacao butter, say from 35° to 40°, and the added sugar may be pieviously warmed with advantage to obviate a fall in temperature of the liquid cacao paste.

The various characters of French, Spanish, Swiss, and other chocolates depend upon the nature and proportions of the different ingredients used. A number of recipes for the preparation of some of the principal types of

chocolate are given in Zipperer, 156

In addition to sugar, various farmaceous substances are frequently employed in the cheaper forms of chocolate, as wheat and potato flour, rice, arrowroot and dextrin, and oceasionally bailey, oats, 1ye, and chestnut flour. In special cases where sugar is inadmissible, as in chocolate intended for use by diabetic sub jects, the sugar is replaced by saccharin  $(q \ v)$ It is then usual, in order to give the necessary 'body' to the chocolate, to add some form of meal or flour (preferably leguminous), and pea, bean, or linseed meal are prefeired for this Nut chocolate is made by adding nuts, purpose either ground or whole, to the chocolate paste; and milk chocolate by incorporating with it 'milk powder,' i e milk deprived of its moisture and fat The usual composition of milk chocolate, by the best makers, is approximately 10 p c cacao, 25 p c cacao butter, 40 p c sugar, and 25 p c. dued milk The above-mentioned forms of chocolate, after being ground into a more or less homogeneous mass, are placed in moulds to form bars, blocks, cakes, and numerous fancy shapes

An immense variety of fancy preparations of chocolate consist, however, merely of a chocolate envelope containing other substances, as biscuits, creams, dried fruits, nuts, fruit jelly, liqueurs, &c, and in some cases, medicinal preparations, as chocolate-coated pills. The most important of these fancy preparations are the chocolate creams

The so-called 'cream' is made either from powdered loaf sugar heated until it melts, or a mixture of this with glucose, with or without various colouring and flavouring materials. While in a liquid state, it is poured into moulds of the desired shape, made in starch flour on a table, which can be kept cool and which can be agitated by mechanical means On cooling, the creams set into a stiff granular mass, when they are either dipped into a liquid chocolate paste, or the latter is poured over them by hand and spread uniformly by means of the rocking table. The process of covering, as well as most of the other processes in the manufacture of chocolate, are now generally effected by means of ingenious and complicated machinery

An extra amount (about 15 p c ) of cacao butter (or substitute) is added to the chocolate intended for covering purposes, to keep the latter in a sufficiently plastic condition during the process of cooling and to give smoothness to the finished article. The latter, whether in the form of plain chocolate or chocolate confections, should be quickly cooled, and attention to temperature is important throughout all the various operations.

The adulterants commonly used in chocolate are similar to those mentioned under Cocoa,

the most important being the replacement of the cacao butter by other fats and oils (as coco-nut fat, illipé butter, &c), the addition of various farinaceous substances, including dextrin, and the admixture of finely ground cocoa shells (Zipperer, Die Shokoladen Fabrikationen, Vilhers et Collin, Traité des Substances Alimentaires)

CHOCOLATE FATS. Under this name, the writer comprises those vegetable fats which are used in the manufacture of chocolate as cacao butter substitutes. The natural chocolate fat is cacao butter, and best chocolates contain cacao butter only 'Cheap' chocolates are made,' to a larger or smaller extent, if not entirely, with substitutes. At first, animal fats were used, but as they impair an unpleasant flavour ('animal flavour') to the chocolate, at present fats of vegetable origin only are employed, such as coco-nut stearine and palm-nut stearine. During recent years, attempts have been made to produce chocolate fats from Boineo tallow, dika fat, and similar vegetable fats. J. L.

CHOLEIC ACID v. Cholic Acid CHOLESTEROL C<sub>27</sub>H<sub>49</sub>O Discovered by Conradi in gall-stones in 1775 Occurs in all vertebrates and throughout the whole of the animal kingdom with the exception of certain groups of the invertebrata in which it is replaced by closely related substances (Dorée, Biochem J 1909, 4, 72) It is found in bile, blood, the brain, and generally in all animal tissues, being closely associated with the lipins and fat present in the various organs Biliary calculi are composed almost entirely of cholesterol Its most abundant source is, however, wool grease

It may be obtained from animal tissues by the following method the tissue is minced, dried in an oven at 100° and the dried material ground to a powder in a coffee mill and extracted in a Soxhlet apparatus with ether for 9 hours After distilling off the other, the residue is saponified with alcoholic potash. The alcohol is The alcohol is distilled off and the cholesterol separated from the soaps and glycerol by extraction with ether The tendency of the ether and soap solutions to form emulsions makes the extraction difficult and various methods have been introduced to Thus Ritter recomovercome this difficulty mends that the soap residue be mixed with sodium chloride and water, evaporated to dryness and the resultant mass, after drying in an oven at 80°, extracted in a Soxhlet apparatus for 9 hours Kossel and Obermuller (Zeit physiol Chem 1890, 14, 599) recommend saponification of the ethereal solution of fat with an alcoholic solution of sodium ethylate at ordinary temperature. After a short time a compact mass of soaps separates which is easily filterable, the cholesterol being present in the alcohol-ether filtrate By this method wool grease, which is only saponified with difficulty, is completely decomposed in 24 hours at ordinary temperature After filtering off the soap and washing the precipitate with ether, the filtrate is well washed with water, the ethereal solution dried with CaCl2, and the ether distilled off, leaving a residue of cholesterol. It may also be separated from the fatty acids in wool grease by distillation with superheated steam or by direct heating (Mayer, Eng. Pat. 20639; J. Soc. Chem. Ind. 1894, 162).

Cholesterol crystallises from ether or chloroform in silky needles, m.p. 148 4 to 150.8 (corr.). From aqueous alcohol (90 pc.) it crystallises in characteristic plates with one molecule of water of crystallisation. Insoluble in water, sparingly soluble in cold, easily in boiling alcohol (9 parts alcohol, sp.gr. 0.87), and in chloroform, ether, carbon disulphide, less soluble in acetone, petroleum, benzene, and glacial acetic. Soluble in fats, fatty acids and in solutions of bile salts. Sp.gr. 1.046; it is optically active; in ether solution (a) = -31 12, in CHCl<sub>3</sub> (a) = -36 61. It sublimes unchanged at 200°, but is decomposed at higher temperatures, hydrogen being evolved at 300° to 320°. In a vacuum it can be distilled unchanged

Constitution—Cholesterol is an unsaturated secondary alcohol, possessing a complicated terpene-like structure which has not yet been completely elucidated. It has, however, been possible to establish in the molecule the presence of (1) a secondary alcohol group in a reduced ring, (2) a terminal vinyl group, and (3) an isoamyl group. Our present knowledge is best represented by the formula

$$\begin{array}{c} \operatorname{CH}_3 \\ \operatorname{CH}_3 \\ \operatorname{CH} \end{array} \\ \operatorname{CH}_2 \operatorname{CH}_2 \operatorname{CH}_2 \operatorname{CH}_2 \operatorname{CH}_{17} \\ \\ \operatorname{CH} \\ \operatorname{CH}_3 \\ \operatorname{CH} \\ \operatorname{CH}_4 \\ \operatorname{CH}_4 \\ \operatorname{CHM}_6 - \operatorname{CH} = \operatorname{CH}_5 \\ \end{array}$$

By applying various reagents under different conditions, a large number of oxidation products have been obtained (Mauthner and Suida, M 24, 489; Windaus, 25 paper in Berichte, 1903 to 1917, Diels and Abderhalden, Ber 1903, 3177, 1904, 3092, 1906, 885, 1371), the formula arrived at for cholesterol being based Oxidation of the secondary on these results alcohol group gives the corresponding ketone, cholestenone, mp 78°, the latter compound has also been obtained by direct oxidation of cholesterol with copper oxide at 300°, more conveniently by oxidising cholesteryl-di-bromide with chromic acid in acetic solution at 70°, and subsequently removing bromine by zine and acetic acid (Windaus, Ber 1906, 518) Cold chromic acid or potassium hypobromite solution oxidises the secondary alcohol to the ketone group and at the same time the vinyl group is oxidised and a new ring formed, the diketone, oxycholestenone is the resulting product

By the addition of two hydrogen atoms to oxycholestenone, cholestanedione, m p 170°-171°, is produced Fuming nitric acid reacts with cholesterol forming a nitro-compound which is reduced to cholestanonol, in.p 140° (Windaus, Ber 1903, 3752, 1917, 133), the latter being oxidised by chromic acid to cholestanedione The relation of these substances to each other is shown by the following formulæ:

Further oxidation of these products has resulted in the isolation of a number of carboxylic acids, respectively mono, di, tri, and tetrabasic, some containing the same as, and some a smaller number of carbon atoms than cholesterol in their molecules

The following compounds have been recognised among the products of the oxidation of cholesterol by nitric acid dinitroisopiopane and acetic, succinic, methylsuccinic and  $\alpha$ methylglutaric acids, acetone, hydroxyisobutyme acid, methylisohexyl ketone, and octane all of which substances may be regarded as derived from an isooctyl side chain in cholesterol On this assumption cholesterol may be represented by the formula

The action of ozone has been investigated by Dorée & Gardner, Molman and by Harries If the above constitution be accepted, only 4 atoms of oxygen should be taken up by the cholesterol molecule, an ozonide containing 7 atoms of oxygen has, however, also been isolated. The balance of chemical evidence being against the presence of two double bonds in the molecule, Dorée and Gaidner regard the addition of the three extra atoms of oxygen, which are only slowly taken up, as probably due to the opening of a bridged ring in the molecule

From the first of the above formulæ, only one dihydro derivative of cholesterol should be expected, several have been described, none of which appears to be identical with coprosterin, the dihydro cholesterol occurring in the intestines The 8 cholestanol, mp 142°, obtained by reducing cholesterol with platinum and hydrogen represents probably the true dihydro derivative (Willstatter & Mayer, Bei 1908, 2199)

Cholesteryl Esters — The cholesteryl esters of the lower fatty acids are prepared by heating cholesterol with the anhydrides of the acids, those of the higher fatty acids by boiling chole sterol with the acid and removing the water formed (Jaeger, Rec. trav. chim. 1907, 311) M p acetate, 114°, propionate, 98° These substances on melting form anisotropic liquids, many of the esters having 3 stable liquid phases. The benzoate melts at 146° to a turbed liquid which examined with the polariscope shows definite crystal structure and at 178° passes to a clear liquid. The laurate is an instance of a compound which can be heated several degrees above its melting-point without melting.

Detection and Estimation —The thin rhombic

plates of cholesterol obtained from 90 p.c. alcohol are very characteristic. • Under the

microscope they often show notched angles and exhibit a curious overlapping arrangement A number of colour reactions have been described of which the following are the most useful. Salkowski's test A small amount of cholesterol is dissolved in 2 c c chloroform and shaken with an equivalent amount of cone H<sub>2</sub>SO<sub>4</sub>, the chloroform first becomes bloodred, then cherry-red, and finally purple, which lasts for several days, poured into a basin, it becomes successively blue, green, and yellow owing to absorption of water The H<sub>2</sub>SO<sub>4</sub> layer is strongly fluorescent

Burchardt-Liebermann Test — Dissolve a little cholesterol in 2 e e chloroform, add 20 drops of acetic anhydride and 1 drop cone  $H_2SO_4^-$  a violet-pink colour appears. This test is also violet-pink colour appears

given by resinic acids Estimation -In animal tissues, the choles-

terol may be estimated in the residue from the ether extract by converting to the acetate by boiling with acetic anhydride. The acetate is washed with water till free from acetic acid, and a weighed amount saponified with a known volume of alcoholic potash. The residual potash is titrated with standard acid and the The residual amount of potash equivalent to the cholesterol thus determined. The iodine value will also give information The most satisfactory method is that in which the cholesterol is precipitated and weighed as its insoluble compound with digi-Ransom, in 1901, found that the hamolytic power of saponin is prevented by the addition of cholesterol Windaws investigated the reaction (Bei 1909, 238) and found that digitonin formed an insoluble compound with cholesterol m alcoholic solution A 1 pc solution of digitonin in 96 p.c. alcohol is added to the ether-alcohol solution of fat, and after standing for some hours the precipitate is collected on a Gooch filter, washed with alcohol and ether, dued at 100° and weighed The precipitate contains 25 pc cholesterol The filtrate is concentrated and after the addition of water extracted with ether, the excess of digitomin remains in the weak alcoholic liquid, and the cholesteryl esters in the ethereal layer. solvent is distilled off and the residue saponified with hot alcoholic potash The cholesterol is then extracted with ether or petroleum and precipitated with digitonin as above described In this way the free and combined cholesterol are separately estimated Various modifications of this method have been introduced, thus Prescher recommends that after saponification, the soap should be decomposed with hydrochloric acid, CHCl<sub>3</sub> added, and the CHCl<sub>4</sub> solution of the fatty acids separated, filtered, and treated with the I pc digitonin solution at 50°, the liquid being stirred during the precipitation (Zeitsch Nahr. Genussm. 1917, 481). In fats where adulteration with vegetable fats may have taken place, it is important to discriminate between phytosterol and cholesterol, for this, the acetates or di-bromides must be prepared, and their melting-points examined Marcusson and Schilling recommend the following method (Chem Zeit 1913, 1001), 50 grams fat are shaken for 15 minutes in a separating funnel with 20 c c 1 p c. alcoholic solution of digitonin. The bottom layer of oil is run off; the alcoholic upper layer containing the flocculent precipitate

of digitonide is shaken with 50 to 100 c.c. ether. The ppt. is washed with ether, dried, powdered and again washed. It is then heated with 1.5 c c. acetic anhydride in a test tube for half an hour. On cooling cholesterol and phytosterol acctates crystallise out. The acctates are re-crystallised and their mps. determined. Cholesteryl acctate melts at 114°, phytosterol acctate at 128°. They may also be separated by crystallising their di-bromides from ether and glacial acetic (Windaus, Chem Zeit 1906, 1011) A mixture of 4 grams cholesterol and 4 grs. phytosterol was dissolved in 80 cc ether and 80 c c 5 p c bromine in glacial acetic solution added After standing for 1 hour at 0°, the ppt is washed with 40c c glacial acetic acid, and with 40 c c 50 p c acetic acid, the washings being added to the filtrate, and a further ppt added to the original ppt, which is then washed with water and dried. The ppt contains the cholesterol bromide, the filtrate the phytosterol compound The ppt is heated with 100 c c glacial acetic acid and 5 grs. zinc dust for 2 hours, the excess of zinc filtered off, and a large quantity of water added A precipitate forms which is boiled for 2 hours with 100 c c. alcoholic potash, and the cholesterol then precipitated by the cautious addition of water. The phytosterol is obtained by similarly treating the solution of the phytosterol brounde

Cholesterol is found in commerce under the name of lanolin and is used mainly for medicinal purposes, and, owing to the ease with which it is absorbed by the skin, as a substitute for vaseline or lard in the composition of plasters, ointments and salves It has also been employed in the manufacture of cosmetics and pomades, and for softening leather Lanolin is obtained from wool oil, which contains about 70 pc of cholesterol and 30 pc fatty acids, by saponification by means of caustic soda, whereby an emulsion is obtained which on dilution with water gives so-called wool-milk On treating in a centrifugal machine impure lanolin separates out as a cream and may be precipitated by lime. The purified product is afterwards kneaded with 30 p.c. of water, in which state it is found in commerce and forms the 'Hydrous Wool Fat' of the B.P. Anhydrous lanolin absorbs about 100 p c of water, does not become rancid, and is antiseptic

Isocholesterol is an alcohol isomeric with cholesterol which occurs only in woolgrease, m p 137-138°,  $\alpha_D = +60$  The mixture of cholesterol and isocholesterol is heated for 30 hours in a sealed tube with four times its weight of benzoic acid. The benzoates are insoluble in boiling rectified spirit and are separated by crystallising from ether Cholesteryl benzoate crystallises in shining plates, its isomer as a light powder, mp 190°-191° Isocholesterol may also be separated from cholesterol by means of oxalic acid, cholesterol forms a crystalline compound with oxalic acid, and the isocholesterol can be estimated in the filtrate as benzoate (Madinaveitia & Gonzalea, Anal Fis Quim. 1916, 398). Isocholesterol gives no colour reaction with chloroform and sulphuric acid, but like cholesterol gives a pale yellow substance when heated with a drop of concentrated HNO<sub>3</sub> and a deep yellowish red colour on the addition I. S M. of ammonia (Schiff's reaction).

CHOLESTROPHAN v. PARABANIC ACID CHOLIC ACID C24H40O5. Occurs in bile, chiefly in combination with taurin and glycocoll as taurocholic and glycocholic acids. Free cholic acid, probably derived from these complex

acids, occurs in small quantity in the intestinal

contents, in the fæces and in the bile.

Preparation -Cholic acid and the closely related isomeric choleic and desoxycholeic acids (C24H40O4) are prepared from bile after first treating it with alkali to decompose the compounds with glycocoll and taurin Five kg ox bile are boiled for 30 hours with 1 kg 30 pc. NaOH solution under a reflux condenser, 5 litres of water added and the mixture precipitated with hydrochloric acid at 50°. The precipitate is well rubbed up with water to remove hydrochloric acid and dried on a waterbath (Bondi and Muller, Zeitsch physiol. Chem. 47, 501) The residue consists of a mixture of choice acid with choice and desoxycholeic acids, which may be separated in various ways, depending on (a) the sparing solubility of the barrum salt of choleic acid, this being pre-cipitated when barrum chloride solution is added to a solution of the ammonium salts of the mixed acids: and (b) the relative insolubility of cholic acid in alcohol Langheld (Ber. 1908, 378) recommends the following method The crude dried acids are shaken with twice their weight of alcohol and the remaining cholic acid twice recrystallised from absolute alcohol Excess of soda is added to the mother liquor, and the reaction mass warmed on the waterbath; a nearly quantitative separation of sodium cholate takes place This is filtered whilst hot, washed with boiling alcohol and recrystallised The mother liquors are concentrated in racuô and cooled the sodium salts of the fatty acids present now separate The remaining acids are regenerated from the salts and esternfied with 02 pc. alcoholic H(I. The esters are boiled with much ligroin which dissolves 4 pc On saponifying the ligioin-insoluble esters with alcoholic potash, a further separation of cholic acid as sodium salt takes place. The residue is extracted with boiling benzene and ether, and then recrystallised from ethyl acetate. It consists of the two isomeric desoxycholeic acids the existence of which has been described by Mylius and by Vahlen By fractionation from ethyl acetato these were obtained as substances melting respectively at 172° and 187°. The latter appears to be identical with the choleic acid obtained by Mylius (Ber 1886, 369 and 2000, 1887, 683 and 1968)

Properties - Cholic acid is a monobasic acid containing two primary and one secondary alcohol groups. It crystallises from aqueous ether or from dilute acetic acid with 1 molecule of water, from alcohol with one molecule of alcohol: it loses both water and alcohol at 120°. It is soluble in acetone and acetic acid, almost insoluble in cold water, more soluble in hot Its solubility in cold 70 pc alcohol (1 m 75)is 1 in 20 Specific rotation:  $a_D=37\,0$  (Vahlen, Zeitsch physiol. Chem 21, 265). It behaves to bromine and potassium permanganate as a saturated substance, but forms an ozonide on treatment with ozone, suggesting the presence of an unsaturated cyclic substance (Langheld, Ber. 1908, 1023; von Furth and Ishihara,

Brochem. Zeitsch. 43, 323). A large number of oxidation products have been obtained (Pregl. Zeitsch physiol Chem 1910, 167). On distilling under 12 mm. pressure, a heavy oil passes oil passes at 200° to 300°, solidifying to the triply unsaturated cholatrienecarboxylic acid  $\rm C_{24}H_{34}O_{2}$ , mp 163°. This acid gives the fluorescence with  $\rm H_2SO_4$  characteristic of cholic acid, but this property is lost on reducing it with hydrogen and palladium black (Wieland and Woil, Zeitsch physiol Chem 80, 287)

Colour Reactions—(1) Choice acid dissolves in conc. H<sub>2</sub>SO<sub>4</sub> with a reddish yellow colour showing a characteristic green fluorescence. (2) Pettenkofer's Test. An aqueous solution gives a red colour with a small amount of cane sugar on addition of conc. H<sub>2</sub>SO<sub>4</sub> or H<sub>3</sub>PO<sub>4</sub>. (3) Myllius' iodine leaction (Zeitsch physiol Chem 1887, 306). To 0.04 gr. m. 1 c. c. alcohol, add in the cold. 2 c. c. N/10 iodine solution and slowly dilute with water; the mixture suddenly solidifies to a paste of crystals which appear intensely blue by transmitted light. This test differentiates choice from choleic and desoxycholeic acids.

Compounds u th Glycocoll and Taurin.—Both choice and choice acids occur in combination with glycocoll and taurin forming the important bile-acids. In man the ratio glycocholate taurocholate varies from 5-1 to 10-1. Taurin is present in the bile of most mammals, reptiles, birds and fishes. Glycocholate is absent in the bile of the polar bear, dog, goose, and in certain fishes. Choice acid is formed in the liver and there combined with taurin and glycocoll It is probable that it is derived from the choicesterol of the red blood corpuscles.

The physical properties of these acids play an exceedingly important part in the digestive processes. They act as solvents for lipins and fat and so increase the velocity of resorption of the fatty acids in the intestine, and act as

activators to certain enzymes

Glycocholic Acut C<sub>16</sub>H<sub>43</sub>O<sub>6</sub>N occurs in quantity in bile, especially in that of herbivora It is extracted from fresh bile by saturating with other and decomposing with from 3 to 4 p c cone, HCl; on standing a crystalline paste of glycocholic acid separates. The bile may also be dried on the water-bath and extracted with 90 p c alcohol. After distilling off the alcohol the residue is taken up with water, neutralised with milk of lime and filtered. On acutifying with sulphuric acid the acid separates. It is easily soluble in acetone and acetic acid, soluble with difficulty in ether and insoluble in chloroform and benzene. According to Knoop, it crystallises with 1½ mol. water of crystallisation and melts at 138°

Taurocholic Acid C<sub>26</sub>H<sub>46</sub>NSO<sub>7</sub>. This is the chief constituent of dog's bile. Alcohol is added to dog's bile and the filtered liquid concentrated to dryness on the water-bath. The residue is dissolved in alcohol, precipitated with ether and dissolved in water. Ferric chloride solution is added to the neutral solution until further addition produces no precipitate. After removing the iron, the filtrate is evaporated to dryness. The sodium salt is rubbed up with alcohol containing 2–3 p.c. hydrochloric acid; after filtering off sodium chloride ether is gradually added until crystallisation sets in. •

Properties — Soluble in water, alcohol, ethyl acetate, insoluble in ether and chloroform. The crystals are obtained anhydrous on drying invacuô. It melts with decomposition, the mp gradually changing from 100° to 180°. It precipitates protein from solution.

1. S. M

CHOLÎNE AND RELATED SUBSTANCES. Choline, timethyl-\beta-hydroxyethyl-ammonium hydroxide, CH2(OH) CH2 N(CH3)3OH, is formed by the hydrolysis of lecithin and hence probably occurs in all living cells, its isolation from animal or vegetable tissues has been recorded very many times, but has no special significance, for even when not originally present in the free state, some is generally formed from phosphatides during the process of isolation Kauffmann (Zeitsch physiol Chem. 1911, 74, 175) has shown, however, that if perfectly fresh ox brain is worked up rapidly, with precautions, hydrolysis may be avoided and then no choline is obtained The best natural source is crude lecithin Hard egg-yolk is extracted with ether and then with alcohol, the extracts are mixed and evaporated and the residue is boiled for one hour with 50 parts of cold saturated baryta solution After removal of the baryta and evaporation, the residue is extracted with absolute alcohol and to the solution alcoholic mercuric chloride or platinic chloride is added (Compare D R P 193449, Moruzzi, Zeitsch Physiol Chem 1908, 55, 352; MacLean, ibid. 55, 360) The mercurichloride is decomposed by hydrogen sulphide, the platinichloride by calculated quantity  $\mathbf{of}$ potassium chloride, in either case the choline chloride is extracted by absolute alcohol from the residue after evaporation Most other natural sources yield very little (seeds and animal viscera something like 0.02 p.c.). The isolation of choline (and betaine) from vegetable sources has been described by Schulze (Zeitsch. physiol Chem. 1909, The aqueous plant extract is purified with lead acetate, and then, after removal of the lead and evaporation, the residue is extracted with absolute alcohol. Choline and betaine are precipitated with alcoholic mercuric chloride After reconversion into the chlorides and evaporation, cold absolute alcohol dissolves choline chloride, and leaves betaine chloride behind

Cholme is best prepared synthetically. Gaseous trimethylamine is made to act (a) on ethylene oxide (Wurtz, Compt rend 1867, 65, 1015, 'névrine'=cholme), (b) on ethylene dibromide; the resulting trimethylamino-bromethylium bromide is best converted into choline by heating with water (Kruger and Bergell, Ber 1903, 36, 2901), (c) on ethylene chlorohydrin (Renshaw, J Amer Chem Societ (a) 1910, 32, 128) Cholme is also obtained (d) by methylating amino-ethyl alcohol (see below and Trier, Zeitsch physiol. Chem 1912, 80, 409). Of these methods (c) is the best, rather more than one equivalent of trimethylamine gas is passed mto ethylene chlorohydrin in a tube cooled to —12° to —20°, which is subsequently heated to 80°–90°. The yield is almost quantitative.

The estimation of choline (and betaine) has been worked out by Stanck (Zeitsch. physiol Chem 1905, 46, 280; 1906, 47, 83, 48, 334), and depends on the precipitation in sodium bicarbonate solution of choline periodide, by

a concentrated solution of iodine in potassium iodide. The weak base betaine is similarly precipitated from the filtrate after acidification. quantities of choline may be estimated physiologically after conversion into the acetyl derivative (see below, also Guggenheim and Loffler, Biochem. Zeitsch 1916, 74, 208; Fuhner, ibid. 1916, 77, 408)

Qualitatively choline is recognised as the dichroitic crystalline periodide (Florence's test for semen; Bocanus, Zeitsch physiol. Chem. 1901, 34, 339, Rosenheim, J. Physiol. 1905-6, 33, 220), and by conversion into other salts. The mercuri-chloride C<sub>5</sub>H<sub>14</sub>ONCl,6HgCl<sub>2</sub>,H<sub>2</sub>O, crossed hexagonal prisms, mp 249°-251° dissolves in about 50 parts of water at room temperature, but in alcoholic solution the limit of precipitation is given as 1 2,000,000. The platinichloride  $(C_5H_{14}(N))_2PtCl_6$  dissolves in 5 82 parts of water at 21° and is dimorphous, the conversion of the regular isotropic form into the anisotropic monoclinic one is the surest means of detecting choline without analysis (Kauff-mann and Voilander, Ber 1910, 43, 2735). The auruchloride dissolves in 75 parts of water at 21° and in hot alcohol. Neither this nor the platimehloride has a characteristic melting-The free base is a syrup, many of the salts are deliquescent (for details see Gulewitsch, Zeitsch physiol, Chem. 1898, 24, 513) soluble non-deliquescent salts, see Ger Pats Nos. 290523 and 290740 (Chem. Soc. Abstr. 1916, 1 468 and 548) The physiological action of choline is in general antagonistic to that of atropine, and not very intense, intravenous injection lowers the blood pressure (e.g. Mendel, Underhill and Renshaw, J. Pharm exp. Therap. 1912, 3, 649) Esterification of the alcoholic hydroxyl enormously increases the activity Acetylcholine is 100,000 times as depressent as choline (Hunt and Taveau, US Hyg Lab. Bull No 73, and physiological estimation above) Acetylcholine occurs in ergot  $(q \ v)$ , but is very readily hydrolysed and is absent from most extracts. The nitrous acid ester, long regarded as 'synthetic, or pseudo-muscarme, is formed by the action of concentrated nitric acid on choline The demonstration by Ewins (Biochem J. 1914, 8, 209) that the reaction product is not an aldehyde, as was commonly supposed, explains the differences in physiological action between it and muscarine from Amanita muscaria, the Fly This natural product requires further investigation, for it is apparently not identical with betaine aldehyde as was supposed by its discoverers. The alkaloid sinapin in black mustard seeds is the choline ester of sinapic acid Many other choline esters and related derivatives have been prepared by Hunt and Taveau (Lc), Menge (J Biol Chem. 1911, 10, 399, and U.S. Hyg Lab Bull No 96), Ewins (Biochem J. 1914, 8, 366), and by Fourneau and Page (Bull See chim 1914 [iv] 15, 544) latter, in connection with the physiological action of snake venom, found that palmityl and stearyl choline are strongly hamolytic

Other bases related to choline are neurine or vinyltrimethyl ammonium hydroxide

# CH<sub>2</sub> CH·N(CH<sub>3</sub>)<sub>3</sub>OH

formed from choline by putiefaction and with a similar physiological action but 10-

20 times as toxic Amino cthylalcohol or hydroxy ethylamine ('colamine') CH2OH CH2NH2 was obtained by Thudichum in 1884 by the hydrolysis of the brain phosphatide kephalin, in which it entirely replaces choline It has been more recently recognised in other phosphatides, Trier (Zeitsch physiol Chem. 1913, 86, 1, 141, 153, 407) For a full account of choline and allied substances, see Barger, The Simpler Natural Bases, Longmans, 1914

CHOLINE ESTERS v MUSCARINE and ERGOT CHONDRIN. A substance allied to and much resembling gelatin Obtained by boiling cartilage with water When dried it is a hard, horny substance which softens to a jelly in cold water, and is entirely dissolved by boiling water It is precipitated from its aqueous solution by nearly all acids, in excess of certain of which it redissolves, and by alum, lead acetate, copper and iron sulphates, and mercuric and mercurous These reactions are said to distinguish nitrates it from gelatin.

By Morochowitz, chondin is regarded as a mixture of gelatin, mucin, and salts (v Glue)

CHROMITE or Chrome-iron-ore A member of the spinel group of minerals, consisting essentially of ferrous oxide and chromic oxide FeO  $\text{Cr}_2 \vec{O}_3$ , or  $\text{Fe}(\vec{r}_2 O_4)$ , analogous to the aluminates. The ferrous oxide is, however, often partly replaced by magnesia, and the chromic oxide by alumina, so that there is a passage to chrome-spinel or picotite; on the other hand, with a replacement of chromic oxide by ferric oxide, there may be a transition to magnetite (Fe<sub>3</sub>O<sub>4</sub> or FeFe<sub>2</sub>O<sub>4</sub>) All these minerals are cubic in crystallisation and belong to the same isomorphous group—the spinel group. The actual amount of chromic oxide varies considerably, as shown by the following analyses, the ordinary ore, as mined, contains on an average 45 p c Cr<sub>2</sub>O<sub>3</sub> .-

	Cr <sub>2</sub> O <sub>2</sub>	$Al_2O_3$	Fe <sub>2</sub> O <sub>3</sub>	FeO	MgO

In general appearance, chrome-iron-ore is very like magnetite, but it is readily distinguished from this by the dark-brown colour of its streak CHROMIUM 233

or powder, and by the fact that it is only slightly, if at all, magnetic Sp gr about 45 Crystals are of rare occurrence, the mineral being usually found as grains disseminated in basic rocks of igneous origin, especially those rich in olivine (viz the peridotites) Sometimes these grains are segregated into nodular masses of considerable size and with a granular to compact texture Rocks of this kind, when subjected to weathering processes, become hydrated and altered into serpentine, and for this reason most of the workable deposits of chrome-non-ore are in serpentine rocks. With the denudation and breaking down of these tocks, the heavy grains of the chemically resisting chromite collect in the beds of streams and rivers, and some of the deposits worked in the Ural Mountains are of this nature

Chromite is the only commercial source of chromium and its compounds It is used for the preparation of the oxides and chromates employed as pigments, and in dyeing, calicoprinting and tanning, in the manufacture of chrome-steel and feriochrome, and for chromebricks and furnace linings. It is mined in European and Asiatic Turkey, Greece, the Ural Mountains, New Caledonia, India, Baluchistan, Rhodesia, Quebec, California and Oregon, and formerly, to a considerable extent, at Bare Hills, near Baltimore in Maryland, and in Lancaster co in Pennsylvania Quarries were, at one time, worked on Unst, one of the Shetland Isles (Special Reports on the Mineral Resources of Great Butain, vol v Mem Geol Survey, 1916)

On the Califorman deposits, see J. S. Diller, Mineral Resources of the United States, U.S. Geol Survey, for 1915, 1916, those of Canada, see F. Cirkel, Dept. of Mines, Canada, No. 29, 1909, and those of Rhodesia, A. E. V. Zealley, Trans. Geol. Soc. S. Africa, 1914, xvii. 60

LJS CHROMIUM. (Fr Chrome; Ger Chrom) Symbol Cr At wt 520 Chromium occurs principally as chrome-non-ore, or chromite (qv) Found largely in Rhodesia, New Caledonia, Russia, Greece, Asiatic Turkey, and India Chromite deposits are also worked to a small extent in Bosnia-Herzegovina, Japan, California, Oregon, Transvaal, and Newfoundland principal producers in 1913 were New Caledonia 62,000 tons, Rhodesia 63,000 tons, Russia 21,000, these countries furnishing about 90 pc of the world's total As sesquioxide C12O3, it is found in small quantities in chrome ochre, generally mixed with clay and associated with chromite, in France and Siberia As lead chromate it occurs in crocoisite and malanchioite PbCrO4, and as a basic lead chromate in the rare mineral phænicite 3PbO 2CiO3. It is usually present in the form of *chromite* in meteorites, but rarely to the extent of more than 1 pc. The rarely to the extent of more than 1 pc greenish colour of the emerald, verd-antique marble, serpentine, sapphire, and many other minerals, is due to the presence of chromium sesquioxide.

Preparation.—Metallic chromium may be prepared by several methods Deville produced it in combination with a small quantity of carbon, in ingots weighing as much as 100 grams, by the ignition of a mixture of chromium sesquioxide and sugar in a lime

crucible, at the highest temperature of a blast furnace

Wohler (Annalen, 111, 230) prepared chromum by fusing a mixture of the violet chromium scsquichloride with twice its weight of zine under a layer of equal parts of potassium and sodium chlorides. The mixture of zine and chromium so produced was treated with dilute nitric acid to remove the zine, and the chromium remained as a light-greenish powder consisting of minute octahedra belonging to the quadratic system (Bolley), of sp. gr. 6-81 according to Wohler, 7-3 according to Bunsen

Chromium may be prepared by the electrolysis of its salts, but the purity and condition of the deposit vary greatly with current strength and solution concentration. A bright deposit, capable of receiving a polish, can be obtained by the use of a hot 25 p c acid solution of chromic chloride, with a current density of about 40–50 amperes per square foot. As in the case of nickel, the deposits have a strong tendency to peel (Cowper Coles, Chem. News, 81, 16).

It is most easily obtained in small quantities by heating equivalent parts of chromic oxide (or mixture of the oxide and anhydride) with aluminium powder. When started, the heat of the reaction causes it to continue and a fused mass of chromium of a high degree of purity is obtained (Goldschmidt, Annalen, 301, 19)

In large quantities it is best prepared by heating the oxide with carbon in the electric furnace. The crude metal thus obtained always contains carbules, of which three definite compounds appear to exist. Cr<sub>3</sub>C<sub>2</sub>, Cr<sub>4</sub>C, and Cr<sub>5</sub>C<sub>2</sub>. It may be refined by further heating in the electric furnace on a bed of lime mixed with chromic oxide. The refined metal crystallises in cubes or octahedra and still contains about 1.5 p.c. carbon. By further refining, however, with a double oxide of chromium and calcium, the pure metal is obtained (Moissan, The Electric Furnace).

Pure chromium is a steel-grey metal, slightly harder than glass, the carbides, however, are harder than quartz, so that a metal with between 1 5 and 3 p e carbon can only be cut and polished by diamond dust Its density is 6 92, and it oxidises superficially in moist air, the meltingpoint is probably above 2000° (1510°, Johnston, J. Ind. Eng. Chem. 1917, 9, 873). The pure finely divided metal burns rapidly when heated in the blowpipe flame, and a pyrophonic powder may be prepared by distillation of chromium amalgam in vacuó (v in/ra) It also unites with nitrogen when heated in nitrogen or ammonia, forming a very stable nitride Ciude chromium does not burn until heated to above It combines with sulphur vapour at 700°, and when heated to redness in hydrogen chloride, forms chromous chloride Electrolytic chromium occludes 250 times its volume of Aqueous hydrochloric acid acts hydrogen slowly on the metal, but the action is accelerated if the chromium is made the anode in electrolytic hydrochloric acid Heating with sulphuric acid causes evolution of sulphur dioxide, concentrated nitric acid and aqua regia have no As in the case of iron, active and passive action varieties of chromium exist; in general, the metal is rendered passive by oxidising solutions, whilst

234 CHROMIUM.

hydrogen ions make it active. In the electromotive series, the active chromium immediately follows zinc, the mactive metal is near platinum. The cause of the passive state is usually ascribed to the existence of a superficial film of oxide, but

this view has been disputed

Chromium carbide boils at 2270° C., and the vapour consists entirely of chromium. Between 2050° and 2250° the fused mass remains constant in composition and corresponds with  ${\rm Cr_3C_2}$  Below 2050° down to 1875° graphite and the carbide  ${\rm Cr_3C_2}$  exist side by side as solid phases  ${\rm Cr_6C_2}$  is also shown to exist (Zeitsch. Elec. Chem 18, 24–157)

Alloys. Various alloys of chromium have been prepared, chiefly by means of the electric furnace, by the 'thermit' method, or by the

mixture of the molten metals

Molten zinc dissolves but little chromium, a hard and brittle alloy has been obtained in the form of hexagonal lamellæ Aluminium and chromium mixtures, containing between 5 and 55 pc chromium, separate into two liquid layers, and probably contain a compound, Cr<sub>3</sub>Al The alloys with a low percentage of chromium are brittle, one containing 13 pc chromium can be powdered in a mortar.

Alloys with antimony are brittle, and compounds represented by SbCr and Sb<sub>2</sub>Cr are known Chromium alloys with copper with difficulty, but an alloy can be obtained by stirring in copper oxide into a molten alloy of aluminium and chromium (Moissan) The liquid metals are miscible only to a small

Cobalt and chromium are miscible in all proportions, both in the liquid and the solid states, and yield a mixture of minimum melting-point 1320° with 47 pc Cr Homogeneous alloys, containing above 30 p.c Cr, when cooled, separate

into two sets of crystals, distinguishable by electrolytic etching.

extent

Nickel chromium alloys with less than 90 p c

nickel are non-magnetic

Silver and chromium, although partially miscible in the liquid state, form no solid solution Molten cadmium does not dissolve any chromium. Molten mixtures of lead and chromium, containing more than 27 pc lead, separate into this mixture and pure lead

Chromium also forms silicides and bondes in the electric furnace, of the former, compounds represented by SiCr<sub>3</sub>, SiCr<sub>2</sub>, Si<sub>2</sub>Cr<sub>3</sub>, and Si<sub>3</sub>Cr, have been described. They are very hard— SiCr<sub>2</sub> is harder than corundum—and are not attacked by ordinary acids, though attacked readily by hydrofluoric acid and by aqua regia. The bordes Cr<sub>3</sub>B<sub>2</sub> and CrB are metallic looking crystalline solids, not attacked even by a mixture of aqua regia and hydrofluoric acid The compound CrB is stated to be weakly magnetic The phosphide CrP, obtained from the metal and copper phosphide, forms dull-grey crystals, sp.gr. 571, which burn in oxygen, forming chromium phosphate, but are unattacked by all acids except a mixture of hydrofluoric acid and aqua regia

By electrolysis of a strongly acid solution of chromic chloride, using a platinum anode and a merculy cathode, an amalgam Hg<sub>3</sub>Cr is obtained, soft and brilliant, and altering but slightly in air. By pressure, a harder amalgam

HgCr as obtained, which alters in air more rapidly. By distillation in vacuó, both lose mercury and yield pyrophoric chromium (v. supra). An amalgam may also be obtained by the action of sodium amalgam on a chromium salt.

With *iron* the alloys of chromium are of great interest. The presence of chromium in iron or steel produces a much finer texture, greater hardness, tenacity, and elasticity, and greater smoothness of fracture. Chromium cannot be used to replace carbon in steel, as has

been asserted (Boussingault)

When crystalline, the tendency of these alloys is to produce needles instead of plates, as in the case of manganese. Chromium lowers the Ar<sub>3</sub> point eventually causing its disappearance, whilst it raises the Ar<sub>2</sub> point of the steel, the proportion of chromium required being less the higher the carbon, eg with 0.2 pc. carbon 5 p c chromium is required Hence chiomium steels are self-hardening (i e. air-hardening). Steels containing 15 p c chromium have been used for tools and have to be cast to shape With 05 pc chromium and 05 pc carbon the steel is used for well bits and just and has no equal in the hardened state. With 1 pc chromium and high carbon the steel is used in bearing balls, cones, roller bearings and crushing machinery. These low chromium steels when well annealed can be machined Its principal use is in conjunction with other alloy steels, especially nickel steels, to which it imparts greater toughness and hardness As such it is used extensively in automobile parts, and when used in armour plates they are case-hardened and quenched. Chrome steel is also used in the manufacture of special kinds of files The alloy is usually prepared of the requisite composition by the addition of a definite amount of 'ferrochrome,' containing from 40 to 85 p c chromium to the molten steel. Ferrochrome was formerly prepared from 11ch chrome-1ron ores in blast furnaces by the use of coke and hot highpressure blast, or in crucibles. In 1890 the manufacture was commenced in the electric furnace and has gradually superseded the other methods. In the reduction of chromium from chromite to form ferrochiome, the iron being reduced, reduction of chromic oxide begins about 1185° (' Thirty parts of pure carbon are theoretically necessary for every 100 parts of non and chromium reduced On the basis of the double carbide Fc<sub>1</sub>C,Cr<sub>2</sub>C<sub>2</sub> being formed in reduction of the chromite the following reaction occurs:

 $\begin{array}{l} 9 \mathrm{FeO}, 9 \mathrm{Cr_2O_3} + 50 \mathrm{C} \\ = [2 (\mathrm{Fe_3C}, 3 \mathrm{Cr_3C_2}) + 3 \mathrm{Fe}] + 36 \mathrm{CO} \end{array}$ 

The ferrochrome resulting would contain theoretically 10 4 pc carbon, 31 4 p.c. iron, and 58 2 pc chromium. The ore has to be finely ground and is then mixed with anthracite coal in the proportion of 37 parts of carbon to 100 parts of ore which forms the above alloy and charged into the furnace. The power consumption in a 750 kilowatt furnace of the Alby carbide type at Kapperaen, Norway, was 3.0 kw. hours per pound, or 0.68 kw. year per, short ton for 5 pc carbon and 65 pc chromium ferrochrome. The percentage of carbon in the ferrochrome cannot be kept low by regulating the coal

CHROMIUM.

235

charged into the furnace, but decarburisation can be effected with an oxide slag of iron or chromium after tapping the slag from the first reduction. (Amer. Electrochem. Soc. 1913, 176.)

The addition of chromium decreases the magnetic properties, but all alloys, to 80 p.c. chromium, are magnetic. The magnetic property of chromium is not increased by cooling in solid hydrogen (Compt rend. 150, 687). A carbide of chromium and tungsten of great hardness and of sp gr 8.41, has been produced in the electric furnace, and to it the special properties of chrome tungsten steels are probably due. These latter (as well as chrome molybdenum steels), containing up to 3 p.c. chromium and 16 p c tungsten, are used for the manufacture of machine tools. Cobalt is frequently added to both classes of tool steel.

Detection of Chromium. When heated strongly, all compounds of chromium impart a green colour to a borax bead in both the reducing and oxidising flames On ignition with potassium nitrate, all chromium compounds produce a yellow colour, due to the presence of potassium chromate. If this is dissolved in water, the addition of a solution of lead acctate produces a precipitate of chrome yellow similar oxidation occurs when chromium compounds are fused with sodium peroxide, or when solutions of chromium salts are boiled with sodium peroxide. A delicate test for a soluble chromate is to add excess of hydrogen peroxide to a little of the solution in a test tube and shake up with a few cc of ether, a blue colouration indicates chromium (See under Perchromic

Solutions of chromic salts of salts of sesquioxide of chromium have an acid reaction With caustic alkalis they produce a green precipitate of hydrated oxide partially soluble in excess of the reagent, but reprecipitated on boiling the solution. With carbonates, a green precipitate is produced, likewise soluble in excess.

Chromates (in which the chromium exists as an acid) are usually strongly coloured. Soluble chromates are reduced, when warmed with sulphuric acid and a reducing agent such as alcohol, with the production of a green colour. The chromium is then present as a base, and may be precipitated, as already mentioned. When heated with hydrochloric acid, they are partially reduced, with evolution of chlorine and formation of chromium chloride and chloride of the metal present as chromate, together with the formation of chromyl chloride CrO<sub>2</sub>Cl<sub>2</sub>

Solutions of chromates containing no free acid except acetic acid give a yellow precipitate with a salt of lead, a red precipitate with silver nitrate, and a yellow precipitate with a salt of barium

Estimation —When present as a base, chromium is usually estimated as sesquioxide  $Cr_2O_3$ . For this purpose, the solution is heated nearly to boiling, ammonia solution added in slight excess, and the temperature maintained until the liquid is perfectly colourless, indicating that the hydroxide, which is slightly soluble in excess of ammonia, is completely precipitated. The precipitate is well washed by decantation and transferred to a filter, washed thoroughly with hot water, dried, and ignited. The oxide produced

contains 68.63 p.c. of chromium The precipita. tion is not complete in presence of organic matter, and when a glass vessel is used, the precipitate always contains a small percentage of silica Chromium, when present as a chromate, cannot be estimated directly by that method quires to be first reduced to a base For this purpose, hydrochloric acid and a small quantity of alcohol are added, and the solution heated until the odour of alcohol is dispelled chromium may then be precipitated as above For the direct estimation of chromium in chromates, the precipitation with lead acetate is most satisfactory The solution is mixed with sodium acetate and acidified strongly with acetic A solution of normal lead acetate is then added, and the precipitate of PbCiO<sub>4</sub> is collected on a weighed filter, washed, dried at 100°, and weighed It contains 16 19 p c of chromium, or 31 06 pc of chromic anhydride CrO<sub>3</sub> Or the precipitate may be dissolved in well-cooled dilute hydrochloric acid (1 of HCl to 3H<sub>2</sub>O) potassium iodide added and the liberated iodine titrated with N/10 sodium thiosulphate. The following scheme may be adopted for the estimation of chromium in chrome iron ore A few grams of the carefully sampled mineral are ground in an agate mortar and passed through a fine muslin The dust so produced is further ground in small portions until all grittiness, on passing a little between the fingers, has disappeared and the ore cakes as an impalpable powder round the About 0 5 gram of the powder is weighed into a platinum crucible of about 50 c c capacity, covered with twelve times its weight of recently fused hydrogen potassium sulphate (potassium bisulphate), and gently heated to just fuse the After keeping at this temperature for 15 or 20 minutes, the heat is gradually increased until the crucible bottom becomes red hot. The fused mass should not be allowed to rise above half-way up the crucible The mixture soon fuses quietly, and evolves dense fumes of sulphuric acid, the heat is gradually increased to bright redness In about half an hour, 6 parts of powdered anhydrous sodium carbonate are added and the mixture again fused for an hour at a red heat, 6 parts of nitre being added in small portions. The temperature is then raised to a full red heat for about 20 minutes, the crucible cooled and transferred to a porcelain basin where the mass is boiled out with water The solution is filtered, and the residue washed with hot water until the filtrate comes through The filter and its contents are dired, the precipitate detached and placed with that still remaining in the basin, the filter paper burned, and the ash also added. To ascertain if the fusion has been satisfactory, this residue is digested with moderately strong hydrochloric acid, when the whole should dissolve Any insoluble black residue indicates either imperfect grinding or insufficient fusion It must be collected on a filter, dried, and the whole ignited in a crucible and treated with potassium bisulphate, &c, as in the first instance. The aqueous extract, after fusion, is mixed with the main solu-To the liquid, a few grams of ammonium nitrate are added, and the whole evaporated to dryness, taken up with water, and filtered from the alumina, silica, &c., into a porcelain basin. An excess of sulphurous acid solution is then 236 CHROM1UM

added, and the solution heated until that gas is nearly expelled. The chromate, having thus become reduced to chromium sulphate, a slight excess of ammona is added, and the solution boiled until colourless. The precipitated chromium hydroxide is washed by decantation with hot water, transferred to the filter, and washed The use of the suction with hot water six times pump is of great assistance in this operation. The precipitate and filter are then diied, transferred to a weighed platinum crucible, and heated sently until the paper is charred. The crucible gently until the paper is charred. The crucible lid is then placed at the edge of the crucible so that the flame may reverberate into the crucible, and the whole ignited strongly for 10 or 15 The weighed precipitate should show no yellowish colour on treatment with a few drops of water, if such a colour is produced it indicates imperfect washing of the precipitate The oxide contains 68 63 p c from alkalı salts of chromium

The oxidation may also be effected by means of sodium peroxide, and the chromate produced, instead of being reduced to chromic oxide, may be estimated as chromic acid volumetrically. For this, various methods are available, eg(1) boiling with standard assenious oxide and estimating the excess by standard rodine, (2) adding potassium rodide and titrating rodine liberated by standard throsulphate; (3) adding standard ferrous ammonium sulphate solution and titrating excess with standard potassium dichromate

A speedy and accurate method for the estimation of chromium in ferrochrome or chromite, is the following 1 part of the ore is finely powdered, as described above, and fused with a mixture of 5 parts of sodium peroxide and 8 parts of caustic soda in a silver crucible The aqueous extract is filtered and again similarly treated, three or four such fusions are necessary to dissolve all the ore, when the only residue is a little silver extracted from the crucible The filtrate is acidified with sulphuric acid, boiled for 40 minutes and diluted to a known volume aliquot part is then titrated with potassium iodide and standard sodium thiosulphate

Chromates may also be readily estimated in acid solution by hydrazine sulphate, whereby nutrogen is liberated, 100 c c of nitrogen at N.T P. being equivalent to 0.59576 gram Ci

#### COMPOUNDS OF CHROMIUM.

Chromium forms a number of oxides, of these, chromous oxide ('r(), and chromic oxide or chromium sesquioxide Cr<sub>2</sub>O<sub>3</sub>, are definite basic oxides, yielding with acids salts in which chromium is present as a divalent or trivalent cation, forming the chromous and the chromic salts. Chromic oxide can also combine with bases to form salts, the chromites, of the type MCrO<sub>2</sub>, in which the chromium is present in the monovalent anion CrO'2. Chromic anhydride CrO3 is an acid anhydride forming, with bases, salts of the type M<sub>2</sub>CrO<sub>4</sub>, the chromates, or M<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>, the dichromates, in which the chromium exists as the divalent anion CrO"4 or Cr2O"7 Other oxides have been prepared and are usually regarded as compounds of the basic and acid oxides, e.g. Cr<sub>2</sub>O<sub>3</sub> CrO<sub>3</sub>=chromic chromate. The chromous salts are of no industrial importance at present.

The salts of chromium are coloured shades of

violet or green; all solutions of violet chromium salts show similar absorption towards light, spectrum due therefore to the chromium ion in solutions of green complex salts the absorption band and limit of complete absorption are both shifted towards the red end of the spectrum.

Chromous oxide, CrO, is most conveniently prepared by the action of dilute nitric acid on chronium amalgam which dissolves the mercury leaving chromous oxide as a black powder.

Chromous salts. Traube & Goodson (Ber. 1916, 1679) have prepared chromous salts by the electrolytic reduction of the corresponding chromic salts as a cathode of pure lead. The most favourable conditions for the reduction of violet chromic salts are in moderately acid concentrated solutions with a current density of 2.5 amps per square decimetre. The more common green salts can be used in more concentrated solutions, but require a greater density of current.

Chromous salts are gradually oxidised in acid solution with the liberation of hydrogen, thus  $2 {\rm CrO} + {\rm H_2O} = {\rm Cr_2O_3} + {\rm H_2}$ . They are on this account able to reduce compounds with double or triple linkings in the presence of water. Acetylene is thus reduced to ethylene, but not to ethane. Nitrous oxide in the presence of alkali hydroxide is reduced to integen. Nitric acid and hydroxylamme are reduced quantitatively to ammonia (Ber 1916, 1692). Chromous salts from stable double compounds with hydrazine salts and may be precipitated from chromous acetate dissolved in air free water, covered with petroleum ether. Chromous di-hydrazine chloride  ${\rm CrCl}_22{\rm N}_2{\rm H}_4$  is a blue-coloured powder sparingly soluble in water.

Chromic oxide, Chromium sesquioxide  $({\rm Gr}_2{\rm O}_3, {\rm This})$  compound is produced by the oxidation of metallic chromium and by ignition of chromic hydroxide, chromic anhydride, and ceitain chomates

Wohler prepared this oxide in fine, small rhombohedral crystals by passing the vapour of chromyl dichloride through a tube heated to redness. The crystals are isomorphous with corundum and of equal hardness, their sp gi is 5.21. Crystalline chromic oxide is also obtained when a mixture of potassium dichromate and sodium chloride is heated to redness (Ditte, Compt. rend. 134, 336). The finest coloured amorphous chromate Hg<sub>2</sub>CrO<sub>4</sub> in a covered crucible, mercury and oxygen escape, and the oxide remains as a green powder. For the preparation of this substance on the large scale, a great number of methods are recommended

Boil a solution of potassium dichromate with half its weight of flowers of sulphur so long as the green hydroxide is precipitated. The addition of a little potash solution, by forming potassium sulphide, accelerates the decomposition. The precipitate is filtered from the solution containing potassium sulphate, and washed. The sulphur retained in the precipitate may be removed by heating. Instead of performing the reaction in the wet way, the mixture may be ignified in a crucible, and the resultant mass digested with water (Lassaigne, Ann. Chim. Phys. [3] 14, 299). Wohler (Pogg. Ann. 10, 46) heats a mixture of potassium

dichromate with its own weight of ammonium chloride and a small quantity of sodium carbonate, and purifies the residue by washing

According to Barian (Rev Scient. 20, 425), a very pure colour, suitable for colouring fine porcelain, is produced by igniting in a crucible a mixture of 4 parts of potassium chromate and 1 part of starch. The mass is washed free from potassium carbonate and re-ignited

Chromic sesquioxide is a green pigment of great permanence. It is not acted upon by chlorine or sulphur gases or by an intense heat It melts at 1990°, and crystallises on cooling

Chromium hydroxide  $(r_4(OH)_5O_2, 10H_2O)$  or  $(r_4(OH)_{10}O, 9H_2O)$  (Jovischitsch Heid Chim Acta, 1920, 3, 46) absorbs carbon dioxide from the atmosphere until saturation limit is reached. The compound appears to be  $(CO_3(Cr(OH)_6)_2, 8H_2O)$  or  $(Cr_2(OH)_5O)$   $(CO_1OH_2O)$  (Jovischitsch) It can be dried at (100)0 without losing  $(CO_2)$ 0, which is, however, liberated by acids (Compt. red. 158, 782)

Hydrogen and carbon monoxide are without action, but it is reduced to the metallic state on heating with carbon at a temperature of 1185°

or higher.

This oxide is largely used under the names chrome green (mixtures of chrome yellow and Prussian blue are also frequently called chrome greens and must not be confounded with the true chrome green), and ultramaine green for imparting a green colour to glass, porcelain, &c It is used for producing the chrome red glaze in ceramic ware, as a pigment, in oil and water colours and in printing, and as a mordant in calico-printing and dyeing. Certain hydrated oxides are also used under various names, their colours are, generally speaking, brighter than that of the anhydrous oxide, but they usually contain small quantities of other substances besides the oxide and water

Guignet's Green; Pennettier's Green, Emerald Green; Veridian Cr4O3(OH)6 This pigment appears to be identical with that formerly manufactured in secret by Pennettier According to Guignet's method, 3 parts of bone acid and I part of potassium dichromate are heated to dull redness in a reverberatory furnace mass swells up, evolves oxygen, and becomes of a fine green colour; it contains the borates of potassium and chromium, or a double borate of those two metals. It is boiled with water, whereby the borate of chromium is decomposed into boric acid and hydrated chromium sesquioxide, potassium borate also remaining in solu-tion. The precipitate is well washed, dried, and finely ground. It usually contains boric acid even after thorough washing. The washings and mother liquors are evaporated for the recovery of the boric acid.

According to the Chem. Zeit 9, 851, the process now used on the large scale is as follows: The boric acid is first purified by solution in how water, treated with animal charcoal, and recrystallised. The crystals are dried in a centrifugal machine. The mother liquor may be employed three or four times for recrystallisation of fresh portions of acid, but becomes then too impure for further use. Eight parts of potassium dichromate and 3 parts of purified boric acid are ground into a stiff paste with water, and the mixture in charges of about 1 cwt. is heated

to dull redness for about 4 hours in a reverberatory furnace. The fused mass is thrown into water, and washed repeatedly by decantation, the pigment is ground while wet, again washed, filtered, and dried. The first two washings contain considerable quantities of potassium borate, which is recovered by evaporating in leaden pans, adding hydrochloric acid and allowing the boric acid formed to crystallise. The mother liquor is further evaporated and crystallised. The crystals are redissolved, the lead (from the pans) precipitated by hydrogen sulphide, and the filtrate recrystallised. In this manner, from 70 to 75 p.c. of the boric acid is recovered.

Guignet's green is the most permanent green pigment known, it is unacted upon by light of concentrated boiling alkalis; it is not affected by acids in the cold, but hot hydrochloric acid slowly dissolves it. When heated to 200° it becomes anhydrous. It is a fine green pigment largely used for the same purposes as the dangerous arsenical greens. It possesses good covering power, and can be mixed with other pigments without alteration. When mixed with lead chromate, it is employed for the pioduction of a pale-green colour in landscape painting.

Other chrome greens are obtained by the use These always contain of sodium phosphate some phosphoric acid They are, however, not as brilliant as the oxide chrome greens. Various methods of preparation are employed Arnaudon dissolves ammonium phosphate with slight evcess of potassium dichiomate in a little boiling water, evaporates until mass solidities on cooling, heats at 80° and later at 200°, washes with hot water, dries and powders Another method consists in boiling a solution of 10 lbs potassium dichromate with 18 lbs sodium phosphate, adding 10 lbs. sodium thiosulphate and a little hydrochloric acid, and boiling until precipitation is complete. precipitate is washed, ground, and dried

According to Bong (Ber 29, 201), a blue pigment, retaining its colour at high temperatures, suitable for colouring porcelain, &c, is produced by igniting strongly, in the air, an intimate mixture of 5 parts borie acid, 15 parts alumina, 20 parts magnesium carbonate, and 2 parts

barium chormate

Chromyl dichloride CrO<sub>2</sub>Cl<sub>2</sub>. Mossan (Compt. rend 98, 1581) prepared chromyl chloride by treating dry chiomic anhydride with hydrochloric acid gas It forms at the ordinary temperature but the action is accelerated by heating It may also be made by distilling potassium bichromate (3 parts), common salt (3 parts) with sulphuric acid (9 parts) in an atmosphere of carbon-dioxide. The corresponding bromide and iodide cannot be made by this method, but the fluoride can, the formula for the latter being CrO<sub>2</sub>F<sub>2</sub> (Gazz chim ital 16, 218) Perkin (Chem Soc Trans 1907, 191) found that the best way of preparing this compound is to dissolve chromic anhydride (50 grams) in strong hydrochloric acid (170 c c) to which is added 100 cc of strong sulphuric acid, 20 cc at a Chromyl chloride sinks as a red liquid and may be separated in a tap funnel. B p at 760 mm. is  $116^{\circ}63^{\circ}$  m p.  $-96^{\circ}5^{\circ}$ ,  $\pm 0.5^{\circ}$ . It is a deep red liquid resembling bromme,  $D_4^{-47}$  2 0528–2 0515,  $D_4^{\circ}$  1 9591–1 9582,  $D_4^{25}$  1 9124–1 9113.

Its vapour is not dissociated at 181° C heated in a closed tube to  $180^{\circ}$ – $190^{\circ}$  trichromyl chloride (CrO<sub>2</sub>)<sub>3</sub>Cl<sub>2</sub> is formed. It is a black non-crystalline powder deliquescing in air Chromyl dichloride combines with phosphorus trichloride in carbon tetrachloride solution to

form CrOCLPOCL

Chromic chloride CrCl3 or Cr2Cl6. anhydrous chloride is obtained by heating a mixture of carbon and chromium sesquioxide in a current of chlorine It can be also conveniently prepared by Burion's method (Compt rend. 148, 170) by passing the vapour of sulphur chloride, b p. 137-90, over the oxide gradually raised to a red heat It forms pale-violet scales of sp.gr 3 03; it is almost insoluble in water, but dissolves readily, being transformed to the green variety (v. infra), if only a minute trace of chromous chloride (1 in 20,000) is present Chromic chloride may be prepared in solution by dissolving the hydroxide in hydrochloric acid It forms two isomorphous hexahydrated salts (CrCl<sub>3</sub>,6H<sub>2</sub>O), one blue and the other green, and also a tetrahydrate and a decahydrate The also a tetrahydrate and a decahydrate blue hexahydrate, when dissolved in water, appears to give the ions  $[Cr(OH_2)_6]'''$  and 3Cl', all the chlorine being precipitated by silver nitrate; the green salt, however, at first forms the ions  $[Cr(OH_2)_4Cl_2,2II_2O]$  and Cl', only  $\frac{1}{3}$  its chlorine being immediately precipitated (Weiner and Gubser, Ber 1901, 34, 1579). In calico-printing a neutral solution of chromic chloride, prepared from potassium dichromate, is frequently used The following method is recommended by De Karrur Dissolve 9 lbs. of potassium dichromate in 5 gallons of boiling water Prepare also a solution of 9 to 11 lbs. of white arsenic in 24 gallons of boiling water, and mix, with constant stirring, with the solution of dichromate greenish precipitate of chromic hydroxide soon separates, it is cooled, filtered, and washed with boiling water The precipitate is added in portions to a solution of hydrochloric acid (diluted until it no longer fumes), with constant stirring, until a portion remains undissolved solution of soda is then added and well mixed. until the hydroxide begins to precipitate dark-green solution, being thus neutralised, is evaporated to 46°B and is ready for use A basic chloride CrCl(OH), is also employed as a mordant for silk and cotton

Chromic fluoride CrF<sub>3</sub>,4H<sub>2</sub>O. This product is used in the printing and dyeing of woollen goods. It is a fine crystalline green powder, very soluble in water It has a corroding action on glass, and is therefore best kept in lead or wooden vessels It may be used as a mordant with both vegetable and animal fabrics, and is often employed in the place of acetate or nitrate of chromium for printing, and in general gives Alizarın dyes, corulein, gallein, finer results &c, and logwood extracts, are fixed as perfectly as with acetate of chromium. One advantage in using it is that it is solid. It has no injurious effect on the pile, and is often used in place of chromates where the oxidising action of these is injurious, especially with wools. Chromium silicofluoride, prepared by dissolving the oxide in hydrofluosilicic acid, has also been used in dyeing and printing in place of the fluoride, and is stated to give better results.

Chromium nitrate. By dissolving strongly

heated chromic oxide in hot concentrated nitric acid of D. 14 a solution is obtained from which the hydrate  $\text{Cr}_{\lambda}(\text{NO}_3)_{\bullet}, 15\text{H}_3\text{O}$  crystallises on cooling in the form of dark brown prisms  $[a \cdot b \cdot c = 1 \cdot 4250 \cdot 1 : 1 \cdot 1158, \beta = 93^{\circ} \cdot 10']$  In contact with dry air the crystals lose 6H2O with the formation of the grey coloured hydrate

Cr<sub>2</sub>(NO<sub>3</sub>)<sub>8</sub>,9H<sub>2</sub>O (Monatsh. 33, 9).

Chromium phosphate, formed by mixing cold solutions of chromic alum and disodium hydrogen phosphate, is a violet amorphous solid, which in contact with water becomes crystalline and has the composition CrPO4,6H2O. On boiling with water it is converted into the green crystalline hydrate ('rPO4,4H2O On further heating it loses two molecules and is converted into the dihydrate. When heated to low redness the phosphate becomes anhydrous and forms a black powder (Joseph & Rae, Chem. Soc Trans 1917, 111, 196).

Chromium phosphides. When finely divided chromium, prepared from amalgam, is heated with red phosphorus in a scaled exhausted tube the phosphide  ${\rm Cr_2P_3}$  is obtained. This on heating in hydrogen to  $440^\circ$  is converted to CrP. Both phosphides are grey and insoluble in acids

Chromium arsenides. When finely divided chromium is heated with an excess of arsenic in a sealed exhausted tube, the product powdered and again heated, the grey arsenide Cr<sub>2</sub>As<sub>3</sub>, D<sub>4</sub><sup>22</sup> 6 2 is obtained When heated in hydrogen at 480°-500° a second arsenide CrAs is obtained Both compounds are insoluble in acids

ds (Zertsch anorg Chem 86, 291)
Chromium sulphates. These are prepared by the solution of the hydroxide in sulphuric It yields a bluish-violet solution, which, on boiling, becomes green. The experiments of Recoura have shown that numbers of compounds of different constitution exist both in the violet and green varieties, but they are not of commercial interest. (f Colson, Compt. rend. 1907, 144, 79, 206, Sénéchal, ibid 1914, 159, 243 The double sulphates of chromium and potassium, sodium and ammonium, are, however, of These are known as chrome alums, importance they crystallise in fine octahedral crystals containing 24 molecules of water isomorphous with those of ordinary alum, and of corresponding composition.

Potassium chrome alum, Chrome alum Cr<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>·K<sub>2</sub>SO<sub>4</sub>,24H<sub>2</sub>O

This substance may be prepared by mixing solutions of chromic sulphate and potassium sulphate in molecular proportions, or more conveniently by the reduction of potassium dichromate in sulphuric acid solution

The best method is to add 5 parts of strong sulphuric acid to a solution of 3 parts potassium dichromate in 30 parts of water with the addition of a reducing agent, preferably a current of sulphur dioxide.

 $\begin{array}{l} {\rm K_2Cr_2O_7 + H_2SO_4 + 3SO_2 + 24H_2O} \\ {\rm = K_2SO_4 \cdot Cr_2(SO_4)_3, 24H_2O + H_2O} \end{array}$ 

When the sulphur dioxide is substituted by other reducing agents, such as alcohol, a larger quantity of sulphuric acid is required.

Chrome alum is obtained in large quantities as a by-product from the oxidation of organic substances by a mixture of potassium dichromate and sulphuric acid, as in the oxidation of anthracene to alizarin, in the manufacture of aniline violet, &c.

Pure crystallisable violet chrome alum is prepared by the electrolysis of a solution of potassium dichromate mixed with sulphuric acid. The liquor is circulated in the cathode compartment which is separated from the anode by a porous vessel. The cathode is preferably of carbon. Dilute sulphuric acid is circulated in the anode compartment and the anode may be copper with copper turnings to utilise the SO<sub>3</sub> ions. (Inter Cong. 1912.)

It crystallises in fine dark-purple octahedra, especially in presence of excess of acid, is soluble in 7 parts of cold water, forming a reddish-blue solution, which, when heated to about 70°, becomes green. It returns to its original colour

after standing some weeks

When heated to 25°-30°, the crystals lose half their water and become hlac-coloured, at 100° a further quantity of water escapes and the crystals turn green, at 350° they become anhydrous, but are still soluble in water; at a temperature slightly above 350° they become greenish-yellow, insoluble in water (Lowe), and only slowly soluble in acids. The green salt only contains \(\frac{1}{2}\) of the SO<sub>4</sub> as an acid ion, and is probably a sulphate of a sulphochromyl hydroxide—For these compounds, reference should be made to the extensive researches of Recoura (Ann Chim Phys [7], 4, 494)

Chrome alum is used in dyeing, calico print-

ing, and tanning

Sodium chromealum Na<sub>2</sub>SO<sub>4</sub> Cr<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>,24 H<sub>2</sub>O corresponds to the potassium salt, but is more soluble in water

### Ammonium chrome alum

is prepared like the preceding alums. It is less soluble in water than potassium chrome alum. It melts at  $100^{\circ}$ 

Chromium chlorate  $\operatorname{Cr}_2(\operatorname{ClO}_3)_3$  is used to some extent in calico printing (Despierres and others, Dingl poly J 228, 260-263), and for increasing the permanence of aniline black may be prepared by the addition of a solution of potassium chlorate to chiome alum or by the addition of barium chlorate to a solution of chromium sulphate, the barium sulphate being precipitated According to Lauber and Weinreb (Dingl poly J 257, 290), it is best prepared by the following process: Dissolve 60 parts of chrome alum in 80 parts (by weight) of hot water; add 20 parts of soda dissolved in 60 parts of water, and wash the precipitated hy-Redissolve the precipitate in 10 parts of cold sulphuric acid of 66°B, filter if necessary and add 22 parts of potassium chlorate dissolved in 50 parts of water The solution is evaporated slightly and the potassium sulphate crystallised out; the more soluble chromium chlorate remains in solution. When heated at 100° it gives off quantities of chlorine and forms a yellow-red liquid containing chromic acid and other compounds.

Chromium perchlorate is obtained by dissolving the hydroxide in perchloric acid and evaporating the solution. It forms short green deliquescent needles and is very soluble in alcohol (Bull. Soc. chim. 1913, 103). Two

perchlorates are known [Cr(H<sub>2</sub>O)<sub>6</sub>](ClO<sub>4</sub>)<sub>3</sub> and [Cr(H<sub>2</sub>O)<sub>6</sub>](ClO<sub>4</sub>)<sub>3</sub>,3H<sub>2</sub>O Both salts are green No sodium-chromi-perchlorate exists,

Chromic anhydride, Chromic acid Cr()3 This important oxide is best prepared by the decomposition of a chromate by sulphuric acid. A cold saturated solution of potassium chromate is added to from 1 to 11 parts of concentrated sulphuric acid, with constant stirring. On cooling, if the acid used be strong enough, crimson crystals of chromic anhydride separate, if necessary, the solution is evaporated until the crystals are formed on cooling. The liquid is poured off and the crystals drained on porous tiles or pressed between porous plates They may be recrystallised by dissolving in water and evapo-The excess of sulphure acid rating to a syrup may be removed by the cautious addition of barium chromate to the solution of the crystals, or the crystals may be gently fused, when the heavier oxide sinks to the bottom of the vessel and the sulphuric acid above slowly evaporates. The mother liquors from the chromic anhydride are used for a fresh preparation until the percentage of potassium sulphate becomes excessive, they are then precipitated by the addition of lead acetate with the production of a light-coloured 'chrome yellow' containing much lead sulphate

According to Zettnow (Pogg Ann 143, 468), the largest yield is obtained as follows: 300 grams of potassium dichromate are dissolved in 500 c c of water, and 400 c c of strong sulphure acid are added. The mixture is allowed to stand for 10 or 12 hours, the solution decanted from the deposited crystals of potassium sulphate, and heated to 80° or 90°, 150 c c of sulphuric acid are then added, followed by sufficient water to redissolve the chromic anhydride at first deposited, and the solution evaporated until the The mixture oxide commences to crystallise is allowed to stand for 12 hours, decanted from the crystals, and evaporated with the production of a second and third crop of crystals. The crystals are drained, introduced into a crucible, mixed thoroughly with 50 cc of nitric acid of not less than 1 46 sp gr (weaker acid would dissolve the crystals) and drained for some hours The operation is repeated if necessary e c of nitric acid. The whole of the on a tile with 25 e.e. of nitric acid sulphuric acid and sulphate having been thus removed, the crystals are heated on a sand-bath and the nitric acid evaporated, or they may be heated to 80° in a current of air In this manner, Zettnow obtained from 85 to 90 pc of the

theoretical yield of pure dry chromic anhydride Duvilliers (Compt rend 75, 711) prepares this oxide by dissolving 100 parts of barium chromate in 100 parts of water and 140 parts of nitric acid of sp gr 1 38 (40°B.) and heating the solution until it becomes red 200 parts of water are then added, and the whole boiled for 10 minutes; cooled, and the barium nitrate allowed to crystallise out The solution is decanted, evaporated to the bulk occupied by the original amount of acid used, and a further crop of crystals of barium nitrate removed The solution, which contains only about I part of barium nitrate for 200 parts of the anhydride, is evaporated nearly to dryness, a little water added, and the evaporation repeated until all the nitric acid is driven off. The anhydride is then crystallised out and dried as usual.

240 CHROMIUM.

Barium chromate is digested for some time with about half the amount of dilute sulphuric acid required for complete precipitation, with the production of chromic anhydride and barium dichromate and precipitation of barium sulphate. Sufficient sulphuric acid is then added to just precipitate the barium, and the solution, which only contains chromic anhydride, is decanted from the precipitate and the solution evaporated (Meissner). According to C Watts, the barium chromate is best treated with excess of strong intre acid, the precipitated chromic oxide filtered through asbestos, and the intricacid driven off by heat

Chromic anhydride is a powerfully acid substance crystallising in scarlet rhombic prismatic needles of sp gr 2 788 (Zettnow). They melt at 193° without decomposition, and the melted mass exhibits supercooling; at higher temperatures oxygen is evolved together with red vapours.

probably CrO.

When heated to 250° they decompose into chromium chromate (°rO<sub>3</sub>·(°r<sub>2</sub>O<sub>3</sub>(=3CrO<sub>2</sub>, also known as chromium dioxide) with evolution of oxygen Above that temperature, the whole is converted into chromium sesquioxide. The perfectly dry anhydride, when heated to 120° in vacuo, slowly volatilises and condenses in red needles (Arctowski) By the action of light on a solution of this oxide, oxygen is evolved and chromium chromate precipitated as a brown powder

Chromic anhydride is very soluble in water 100 parts of water, at 26°, dissolve 62 parts of the oxide. The aqueous solution contains  $\mathrm{Cr}_2\mathrm{O}_7$ "ions, with a small proportion of  $\mathrm{Cr}\mathrm{O}_4$ " ions These ions are capable of transformation by the action of acids or alkalis, as indicated by the equations:

(1) 
$$Cr_2O_7'' + 2HO' \ge 2CrO'' + H_2O$$
  
(2)  $2CrO_4'' + 2H \ge Cr_2O_7'' + H_2O$ 

Datta & Dhar (J Amer Chem Soc 1916, 38, 1303), from a study of the molecular solution volumes and molecular refractivities of chromic acid, potassium chromate and potassium dichromate, conclude that the formula of chromic acid is  $\rm H_2Cr_2O_7$  and not  $\rm H_2Cr_2O_7$ .

It dissolves in acetic acid or ether without decomposition, is almost insoluble in sulphuric acid of 177 sp gr, but dissolves in stronger or weaker acid, is insoluble in nitric acid of sp gr 146

Chromic anhydride is a powerful oxidising agent. Warm anhydrous alcohol inflames when dropped upon it, and even dry ammonia gas is oxidised with production of water and nitrogen Addition of oxalic acid is said to increase its oxidising power. The solution in water, sulphuric acid, or acetic acid, is largely used as an oxidising agent in organic work In most of these oxidations, precautions must be taken to moderate the velocity of the reaction acetic acid is used as the solvent, the substance to be oxidised is usually dissolved in the same solvent and the oxidising solution slowly added, the temperature being kept sufficiently low, i e seldom above 100° Chromic acid, as an oxidising agent, has the advantage that the close of the reaction is frequently indicated by a pure green colour in place of the brownish colour.

It has the property of producing a permanent yellow colour with silk or wool, but not

with cotton. The chromium in such material may be converted into lead chromate upon the fibre or turther dyed by logwood, &c Chromic anhydride usually contains sulphuric acid and sulphates or nitrates, Moissan found 24 pc. of sulphuric acid in samples of the commercial article.

Chromates. All chromates are prepared, directly or indirectly, by the action of oxidising agents upon chrome iron ore or chromite FeO Cr<sub>2</sub>O<sub>3</sub>. This important mineral is widely distributed and extensively mined. Large deposits are found in New Caledonia, containing sometimes 5 pc of chromium sesquioxide in a form soluble in acid, probably as chrome ochre

Chromite belongs to the spinel group of minerals. It is isomorphous with magnetic iron ore FeO Fe<sub>2</sub>O<sub>3</sub>, and may be considered as that substance in which the sesquioxide of iron is replaced by sesquioxide of chromium. A portion of the chromium is usually replaced by aluminium, and some of the iron by magnesium, though this is sometimes absent. The composition of chromite varies extremely, an ore, containing 50 p.c. of the sesquioxide, is of very good quality. Of seven samples from varying localities analysed by Clouet, the chromium sesquioxide present averaged. 44 p.c. For analyses v. Chromite.

Chromite is black or brownish-black, and infusible before the blowpipe. It will scratch glass, but is itself scratched by a good steel kinfe.

A scheme for the analysis of chromite has been given under the estimation of chromium

The chief use of chromite is as a refractory lining in steel or copper furnaces. Smaller amounts are employed in the manufacture of chrome-steel alloys and of chromium compounds

Potassium chromates. Both the normal and acid chromates are of importance in the arts. The acid or dichromate, containing the larger proportions of the active constituent CrO<sub>3</sub>, is generally prepared on the large scale.

A great number of processes have been adopted for the treatment of chromite for this purpose, they all depend upon the oxidation of the chromium sesquioxide into chromic anhydride

The ore is heated to redness and plunged into cold water to facilitate the powdering, stamped, ground in a mill, and finely sifted

In former times, the ore was mixed with about two-fifths of its weight of potassium nitrate and ignited on the bed of a reverberatory furnace, the oxygen required for the oxidation of the sesquioxide into the anhydride and the potassium for its conversion into potassium chromate, being both provided by the nitrate A great saving was introduced by the substitution of atmospheric oxygen as the oxidising agent in place of the nitre, the potassium being supplied by potassium carbonate or, as proposed by Watt, by potassium sulphate The latter salt is largely used where, as in Russia, the demand for potassium sulphate is small, and hence this salt, produced during the later conversion of the chromate to dichromate, is used to replace some of the potassium carbonate. The mass, however, was very liable to fuse and the heavy particles of chromite to sink through the liquid and escape the action of the blast This difficulty was overcome by Stromeyer, who introduced lime into the mixture, thus rendering the mass porous and non-fusible and much increasing the rapidity and completeness of the action.

Tilghmann (Patent 1847) makes use of felspar as the source of alkalı. For this purpose, I part of chrome ore is mixed with 4 parts of felspar and 4 parts of lime or 7 parts of chalk. The mixture is heated to bright redness, but not to fusion, in a reverberatory furnace for about 20 hours, with constant stirring. The chromate thus produced is removed as described later.

The ore may also be mixed with potassium chloride, and heated to whiteness with frequent stirring while a current of superheated steam is passed over the mass; the iron is stated to pass away almost entirely as chloride (Swindells,

Chem. Gazz 1851, 419).

Jacquelain (Ann. Chim. Phys [3] 21, 478) prefers to produce calcium chromate in the furnace and to convert it subsequently into the required chromate by double decomposition. He thus avoids the loss of alkali always experienced in the ordinary process. The ore is finely powdered, preferably levigated and diled before use, mixed ultimately with chalk in the required proportions, and heated to bright redness on the bed of a reverberatory furnace for 9 or 10 hours, with occasional stirring (at least once an hour). The product is ground in a mill, suspended in hot water, and treated with sulphune acid until slightly acid, calcium dichromate is thus produced A little chalk is stirred into the solution to precipitate the iron as oxide, and a solution of potassium carbonate or other salt, according to the chromate icquired, is added. The calcium is thus precipitated as carbonate and the dichromate required remains in solution The solution may also be used directly for the production of chrome yellow, &c.

According to Booth's method (Pat 1852, Dingl poly J 131, 137), the ore is mixed with one-fifth of its weight of charcoal or coal and ignited in a reverberatory furnace like that used for puddling iron, out of contact with the air The product is thrown into vats, and the reduced iron dissolved out by dilute sulphune acid, the residue being treated in the usual manner for the production of chromates The weight of oil of vitual used, amounts to about two-thirds that of the ore It is stated that the value of the ferrous sulphate obtained repays the extra labour

involved

Atcherley (Hoffman's Ber u Entw. Chem. Ind [1] 725) gives a description of the manufacture of potassium dichromate as usually practised on the large scale, of which the followıng ıs an abstract

The ore is stamped, ground in a mill, and passed through a sieve of 80 meshes to the

Potash lye is prepared by soaking 7 cwts. of burned limestone (containing but little silica and magnesia) in a solution of 21 p.c. of potassium carbonate free from chloride (which would hinder the crystallisation of the product), dried, ignited,

and powdered

It is then mixed with 41 cwts of the ore, and spread in a layer 2 inches deep upon the previously heated bed of a reverberatory furnace, at the end nearest the fire. The furnace is about 9 feet long and 6 feet broad. The heat is maintained at bright redness, and the mixture turned over every 15 minutes; in about 2 hours it is gradually pushed towards the farther end

of the furnace, and its place supplied by a fresh charge. The operation is completed in about 4 hours, when the mass is greenish-yellow and contains chromates of potassium and calcium, lime, potassium silicate, and ferric oxide It is broken into coarse powder and lixiviated in wooden pans, placed steplike one above another, with a hot solution of potassium sulphate, which converts the calcium chromate into potassium chromate with precipitation of calcium sulphate. The liquid is allowed to run from one vat to another, until at last a saturated solution of potassium chromate is produced This is run into a depositing vat lined with lead and treated with sufficient sulphuric acid and water to convert the normal salt into the dichromate, and the solution cooled.

As the solution of normal chromate was saturated and contained about 1 part of salt in 2 parts of solution, the dichromate solution formed is supersaturated, that salt requiring nearly five times as much water for solution as the normal chromate, about three-quarters of the total amount in solution is thus deposited on cooling. The crystals are redissolved in sufficient water to form a solution of 1:120 sp gr. and crystallised in deep non pans at a temperature of 21°.

The production of chromates is said to be rendered easier by the addition of oxygencarriers, such as manganates or oxides of copper or iron (D R P 163814). A method dependent on this, in which ferric oxide obtained by heating pyrites is used, is the following: 240 parts chiome non ore of 50 p.c., 170 parts sodium carbonate, and 150 parts ferric oxide, with, if desired, 50 to 80 parts lime, are intimately mixed, roasted, and lixiviated. The residue contains all the original ferric oxide and may be used over again. The solution is concentrated and treated as usual The action of the ferric oxide is regarded as due to the production of an alkaline feirite which becomes converted to the chromate and ferric oxide (J. Soc. Chem. Ind. 1895, 865)

Chromates are also produced by mixing finely divided chrome iron ore with alkaline carbonates and roasting in an oxidising atmosphere in a revolving furnace at a temperature sufficient to keep the mass fluid (National Electrolytic ('o New York, J Soc Chem Ind. 1908)

Potassium chromate K2C1O4 is prepared, as already described, from chrome ore It may be produced by adding potassium hydroxide to a solution of the dichromate. It crystallises in anhydrous yellow rhombic prisms isomorphous with those of potassium sulphate, sp gr 2 71 (Kopp) 100 parts of water dissolve of potassium chromate

105.8° being the boiling-point of the saturated The solution has a fine yellow colour of great tinctorial power; a distinct yellow tinge is imparted by 1 part in 100,000 parts of water. It is insoluble in alcohol and ether, and is very poisonous, producing a condition resembling diabetes when administered by mouth or subcutaneously It also produces slow-healing sores, especially among workers in chromate factories. For these, a sodium bisulphite wash is efficacious. Such workers should pay attention to constant washing of face, nose, and hands, and packers are advised to wear respirators

When heated, it reddens and fuses without decomposition; heated with reducing agents, such as sulphur, it is reduced to chromium sesquioxide. The addition of an acid, even carbonic acid, determines the decomposition into potassium dichromate, as is indicated in the previous equations, and it is evident further that, even when excess of acid is present, the solution still contains CrO47 ions. The equations also indicate that a solution of potassium chromate possesses an alkaline reaction.

Owing to the much smaller solubility of the dichromate (4.64 parts at 0°), when the chromate is crystallised some dichromate also separates

It forms double salts with the chromates of

the alkaline earths and lead

Potassium chromate is not largely used, the dichromate, on account of its greater richness in chromic acid, being generally preferred. The general uses and oxidising properties, however, described under potassium dichromate, also

apply to the normal chromate

Potassium dichromate, generally known as Bichromate, or 'Bichrome,' K<sub>2</sub>(1<sub>2</sub>O<sub>7</sub>. This important salt is prepared in large quantities by the methods already described. It may be made electrolytically by the use of a solution of potassium hydroxide, a cathode of porous copper oxide, and an anode of ferrochrome (50 pc), which has an E M F. of 2 volts ferric oxide is also formed and precipitated (Lorenz, Zeitschanoig. Chem 1896, 12, 396). Considerably over 10,000 tons are annually produced in Great Britain.

It crystallises in anhydrous, fine, red, square tables, derived from triclinic prisms, of sp gr 2 692, and of intensely metallic, bitter taste. They melt at about  $400^{\circ}$  (Tilden and Shenstone), and resolidify on cooling without change. At bright redness, decomposition ensues, and the normal chromate and chromic sesquioxide result. Other chromates of composition,  $K_2Cr_4O_{10}$  and  $K_2Cr_4O_{11}$ , appear to exist in equilibrium with the solution with certain limits of concentration.

100 parts of water dissolve at 0°, 4 64 parts, at 30°, 18·13 parts, at 60°, 45·44 parts and at 104 8°, 108 2 parts, 104 8° being the boiling-point of the saturated solution (Koppel and

Blumenthal, lc)

Potassium dichromate is used in the preparation of all chrome pigments, of 'discharge' for Turkey red, &c, for the production of a large variety of colours in calico printing and dyeing, in the manufacture of safety matches, &c. In solution with sulphuric acid, it is used as a bleaching agent for tallow, palm oil, &c; in the oxidation of anthracene to alizarin, and in the manufacture of aniline violet and in many other organic oxidations. It is also used for tanning leather (v. Leather).

When mixed with organic substances it is reduced on exposure to light; gelatine under such circumstances is rendered insoluble. This reaction is taken advantage of in the 'Carbon' process of photography. The gelatine is mixed with a pigment of any colour,

and the paper carrying this film is sensitised by floating on a solution of potassium dichiomate On exposure under a negative, the gelatine in those portions exposed to the light becomes insoluble, and retains the pigment, while the portions protected by the darker parts of the negative are almost unacted upon, and may be dissolved in warm water. In this manner, photographs of any desired colour, and of great beauty and permanence, may be pro-Contact of the chromated gelatine with the reduced silver of an ordinary biomide print has a similar effect, and bromide photographs may hence be copied by squeezing into contact with a sensitised pigmented gelatine After a few minutes' contact, the pigmented paper is developed like a carbon print The bromide has become bleached and reduced to silver, but can be redeveloped. The insoluble gelatine does not absorb water, but will take oil, which may be mixed with any desired pigment, and this forms the basis of the cil and bromoil processes Gum. mixed with dichromate, is also made insoluble by exposure to light, and this is made use of in photography in the gum dichromate process (v PHOTOGRAPHY).

Sodium chromates. The normal chromate Na<sub>2</sub>(r<sub>2</sub>O<sub>4</sub>, 10H<sub>2</sub>O and the dichromate Na<sub>2</sub>(r<sub>2</sub>O<sub>7</sub>, 2H<sub>2</sub>O are prepared by methods corresponding to those used for the potassium salts. According to Nic. Walberg (Dingl. poly. J. 259, 188), they are prepared on the large scale as follows: 6 parts of powdered chrome ore (44 p.c. (1<sub>2</sub>O<sub>3</sub>) are mixed with 3 parts soda ash (92 p.c. Na<sub>2</sub>CO<sub>3</sub>) and 3 parts of chalk, and heated in charges of 1 ton in a reverberatory furnace for 8 hours. The mass is himited to produce a solution of 45°B, boiled down to 52°B, and allowed to crystallise in leaden pans. The crystals are first dired by a centifugal machine, and finally heated to 30° m. a drying chamber, where they crumble to a yellow anhydrous powder containing about 96 p.e. of the normal chromate

For the production of dichromate, these crystals are dissolved to a solution of 40°B and treated with sufficient chamber acid to determine the conversion into the dichromate, the right point being found by potassium iodide and starch paper Sufficient neutral sodium chromate is then added to bring the percentage of CrO, to about 72.5. The liquor is cooled in lead tanks about 72 5 to 1°, artificially if necessary, and the sodium The liquor is drained sulphate crystallised out off, filtered if necessary, and evaporated to dryoff, filtered it necessary, and the result of the ness in an iron pot, with constant stirring. The ness in an iron pot, while still hot. If the amount of CrO, be allowed to exceed 72 5 p c, the product is damp and cannot be stored in wooden casks An analysis of this substance showed CrO<sub>3</sub>, 72 3, Na<sub>2</sub>O, 26·20, SO<sub>3</sub>,

Newer methods of manufacture are the treatment of the monochromate with ammonia, followed by carbonation and deposition of sodium bicarbonate, the use of caustic alkali in the place of alkali carbonate; and the employment of only half the necessary sodium carbonate required to decompose the ore, the remainder being replaced by sodium sulphate, formed in the later stages of manufacture (Ulm, Chem. Zeit. 1914, 38, 670; J. Soc. Chem. Ind. 1914, 33, 947).

CHROMIUM.

Normal sodium chromate forms fine large fflorescent crystals of the composition

### Na,CrO4,10H2O

somorphous with Glauber s salt Unlike potasium chromate, it is less soluble than the hehromate, it is, however, more soluble than iotassium chiomate, 100 parts of water at 30° hs solving  $87\ 36$  parts of sodium chromate

Other hydrates with 6 and 4 mols of H,O re known. Their transition temperatures have peen suggested as convenient fixed points in hermometry (Richards & Kelley, J Amer

Jhem Soc 1911, 33, 847)

Sodium dichromate Na<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>,2H<sub>2</sub>O crystalises in thin, six-sided prisms with bevelled edges of a fine hyacmth-red colour, and is very oluble in water, 100 parts of water at 30° dis-olving 197 6 parts of the salt—It is hence more han 10 times as soluble as potassium dichromate which frequently makes its use preferable to that of the potassium salt

Ammonium chromate and dichromate are prepared by mixing in proper proportions solutions of ammonia and of chromic acid chromate, on heating, yields nitrogen, water, and chromic oxide, and forms a convenient method for the preparation of nitrogen free from argon

Lead chromates. The neutral lead chromate PbCrO<sub>4</sub> is best produced by the action of a solution of lead acetate on a solution of a chromate Thus produced, it is of a fine lemonyellow colour, insoluble in water and dilute acids When heated at 250°, it becomes reddishbrown, at a higher temperature it fuses, and finally evolves oxygen with the formation of chromic sesquioxide and a basic lead chromate On account of this evolution of oxygen on heating, this substance is frequently used in organic analysis.

Lead chromate is soluble in cold lime water or caustic alkali, but is unattacked by hot lime water For this reason, in immersing calico coloured with chrome yellow in lime water, for the production of an orange colour, care should

be taken that the solution is hot

When heated with caustic alkali, a portion of the chromic oxide is removed, with the production of a basic lead chromate of colour

varying from orange to vermilion

The normal chromate is largely used as a pigment, and for calico printing, and is the essential constituent of various chrome pigments as Chrome yellow, Paris yellow, Leipsic yellow The name Cologne yellow was originally given to chrome yellow containing a mixture of lead chromate and lead sulphate, but the latter compound is usually present in pale yellows known commercially as 'puie' chrome yellows Chrome yellows. The finest chrome yellow

is produced by precipitation, the lead acetate used should not be basic, or the product will be of an orange colour; the solution should be dilute, and the lead salt should be in excess, the presence of excess of chromate is liable to 'tuin' the yellow-ie to produce an orange tinge The substances used should be comparatively

For the lighter yellows, the solution of chromate is mixed with an appropriate quantity of sulphuric acid, Glauber's salts or alum (American chrome yellow), before precipitation;

the latter yields good colours but considerable care is required in the precipitation. The lead chromate is thus precipitated, together with any desired amount of sulphate, and the colour correspondingly lowered. For cheaper chromes, the colour is toned down by the admixture of kaolin, barytes, gypsum or whiting, the finely powdered solid being ground with water and well mixed with water in the tank into which the precipitating liquids are iun (vide infia) Bouthron Chatard gives the composition of ordinary Cologne yellow as CaSO<sub>4</sub>, 60 pc, PbSO<sub>4</sub>, 15 p c , PbCrO<sub>4</sub>, 25 p c.

Biot and Delisse first precipitate lead sulphate from a solution of the acetate, and digest 3 parts of the washed precipitate with 1 part of normal potassium chromate dissolved in hot The chromate is thus wholly converted into chrome yellow, mixed or perhaps combined with the lead sulphate, and a 'Cologne yellow' of good colour is produced. The colour is said to be equal to that obtained when double the ing power is, however, stated to be inferior to

that of the precipitated yellow

Milbauer & Kohn (Zeitsch, physikal Chem 1916, 91, 410) show that the feaction PbSO<sub>4</sub>  $+K_2SO_4 \rightleftharpoons PbCrO_4 + K_2SO_4$  proceeds practieally completely in the direction of left to right From determination of the stability it is shown that the solid phase PbSO4 cannot exist in the presence of K,C1O4K,SO4,PbC1O4, and that the existence of double salts is unlikely general results show that the manufacture of chrome yellows can be carried out from lead sulphate and that various shades can be obtained by varying conditions, temperature, concen-It follows also that an excess tration and time of lead acetate should be used in the manufacture since this will secure the absence of K, CrO, which would otherwise rapidly convert the lead sulphate necessary for the particular shade into chromate

Liebig uses for this purpose the lead sulphate obtained in dye works, &c, as a by-product The pigment, on account of the basic character of the sulphate, is of an orange colour

Anthon substitutes lead chloride for sulphate, treating 100 parts of freshly precipitated chloride with 27 parts of dichromate.

The method usually adopted for production of chrome vellow is the following The two precipitating solutions are placed separately in wooden tanks, and heated by steam pipes The solutions are either filtered or allowed to settle in the tanks and drawn off from above. They are run together into the precipitating tank, which contains about 200 gallons chrome yellow is allowed to settle and the clear liquid drawn off, more water is added, the whole thoroughly stirred and the process is repeated three or four times. The pigment is then put in a filter press and dried at as low a temperature as possible

According to the Textile Colourist, the preparation of chrome yellow is as follows. For the preparation of the lead acetate, four wooden tubs, 3 feet in diameter and 11 feet high, are arranged one above another, so that the liquid may pass downwards from one to the other. They are filled with granulated lead, and strong wood vinegar poured on the uppermost; after 244 CHROMIUM

remaining there for a few minutes, it is run into the second, third, and fourth for an equal time. The surface of the lead is thus thoroughly acted upon, and becomes heated and oxidised by the air. The vinegar is then passed through a second time, remaining in each tub for an hour, on leaving the fourth tub, a saturated solution of acetate is produced.

Bichrome is dissolved in 10 or 12 parts of water in steam-cased copper pans, and sufficient acetate added to just precipitate the chromate completely. The precipitate is settled, washed by decantation, filtered, and dried slowly on boards The filtration should be performed as rapidly as possible, because the pigment swells considerably while drying, and this should take place on the boards

By mixing some lead chromate with the lead acetate solution, a dark lemon colour is produced, and by the addition of caustic potash to the precipitate, a much redder pigment may be obtained

The chrome yellows, by mixture with Prussian blue, form greens known as 'Brunswick greens' and also as 'chrome greens' (not the true chrome green, vide supra) These are valuable and cheap pigments, but not as stable as the corresponding zinc greens (vide infra)

By removal of some of the acid from normal lead chromate, a basic lead chromate of a deep red colour is obtained, PbO PbCiO4, which is the base of a number of chrome reds. Between these and the various yellows a large number of shades of chrome orange may be obtained chrome reds are known by a variety of names, e g Austrian cinnabar, Persian red, Chinese red, Victoria red, Derby red, American vermilion, &c

The pigment is usually prepared by boiling chrome yellow with caustic alkali or by boiling together the lead salt, potassium dichromate, and an alkalı One such method is-20 parts of white lead are mixed into a fine paste with water, 10 parts of potassium dichromate and 3 of caustic soda, are dissolved in a little water, added, and the whole boiled until the desired colour is obtained It is then washed and driea

Runge mixes 45 parts of litharge, 6 parts of salt, and 50 parts of water, the mass becomes white, and swells considerably, more water is added to prevent it from hardening. In three or four days, the whole has been converted into lead oxychloride, a solution of 15 parts of potassium dichromate is then poured on, and the mass well stirred and washed A corresponding process is used with carbonate of lead, the colour produced being preferable to that when chloride, sulphate, or oxide of lead are used

For the production of a fine 'Persian red,' Prinvolt digests 25 parts of lead carbonate in a cold solution of 10 parts of potassium chromate for 2 days. A red crystalline precipitate of basic lead chromate is thus produced, while potassium bicarbonate remains in solution The mixture is boiled for half an hour, whereby a portion of the red precipitate becomes decomposed, with the formation of normal lead chromate and of potassium chromate, turning a violet-red colour. This is filtered off, washed, and digested with one part of sulphuric acid dissolved in 100 parts of water, with the production of 'Persian red.'

For the production of a fine vermilion pig-

ment, Liebig and Wohler's method may be used A mixture of equal parts of potassium and sodium nitrates is just heated to fusion, and chrome yellow, in small fragments, is dropped in, ebullition takes place, and the mass becomes black The heating should be continued until ebullition ceases. The chrome yellow has thus become converted into basic lead chromate and potassium chromate. If the temperature used be too high, the product becomes brown and is spoiled. The supernatant yellow liquid is poured from the heavy basic lead salt, which is then well washed in water. The washings should be poured off as quickly as possible, or the action is liable to be reversed and the normal chromate reproduced in part, with a corresponding reduction of colour.

The colour of the varieties of chrome red is due principally to the size of the crystals, those pigments of which the crystals are largest being

of the most intense colour.

For the production of chrome orange, the chrome vellow is boiled with lime or alkalı (in smaller quantity than that used for production of chrome red), until the shade required results. The cheaper chrome orange pigments, as in the case of the yellows, contain admixed kaolin,

gypsum, &c
The lead chromates all possess good covering power and brightness of colour; they are durable, but blacken under the action of sulphuretted hydrogen. They mix well with other pigments, but should not be used with

sulphides

Calcium chromate CaCrO4,4H2O is largely produced in the manufacture of chromates from chrome non ore It is soluble in water and It becomes anhydrous at 200°, and is then almost insoluble in water

Barium chromate Ba('rO4 is a canary-yellow powder, known as Yellow ultramarine or Lemon yellow It is produced by the addition of a chromate to a solution of a salt of banum.

Barium chiomate is insoluble in water and acetic acid, soluble in hydrochloric and nitric On treatment with a boiling solution of chromium anhydride, it dissolves, and crystallises on cooling as a yellowish-red powder, consisting of the dichromate BaCr<sub>2</sub>O<sub>7</sub>, 2H<sub>2</sub>O.

Both barium and calcium chromates have been employed as pigments, but are now little used on account of their lack of brightness and

covering power

Bismuth chromates. The addition of potassium dichromate to a neutral solution of bismuth nitiate gives a yellow flocculent precipitate, 3B12O3 2CrO3, soluble in acids (Lowe) heating, it becomes partly decomposed and turns greenish. From an acid solution of bismuth nitrate, the precipitate formed consists of Bi<sub>2</sub>O<sub>3</sub>·2CrO<sub>3</sub> (Lowe, Muir), and is quite insoluble in water. Bismuth chromate is used as a pigment and in calico printing

Zinc chromate, Zinc yellow, or Buttercup yellow ZnCrO4, is a beautiful, stable, yellow pigment, produced by the addition of hot neutral solution of zinc sulphate to potassium chromate, or by adding a cream of zinc oxide in water to a boiling solution of potassium dichromate.

Zinc chromate can be obtained in various tints and has a good colour. Though not equal to chrome yellow in covering power or body, it

has the advantage of not blackening by exposure to sulphides. It is largely used for mixing with Prussian blue to form the zinc greens, which are more stable and faster to light

than the corresponding chrome greens.

Perchromic acid. On adding hydrogen peroxide to an aqueous solution of chromic acid. or to an aqueous solution of a chromate acidified with sulphuric acid, a deep blue colouration is produced, which on shaking the solution with ether passes into that liquid. The colour of this substance is so intense that it constitutes a delicate test for both chromic acid and hydrogen peroxide. It is extremely unstable, evolves oxygen, and is gradually transformed into chromium trioxide. It has been regarded as Cr<sub>2</sub>O<sub>7</sub>xH<sub>2</sub>O (Barreswil), CrO<sub>4</sub>3H<sub>2</sub>O (Fairley), CrO<sub>3</sub>,H<sub>2</sub>O<sub>2</sub> (Moissan), and 2HCrO<sub>4</sub>,H<sub>2</sub>O<sub>2</sub> (Berthelot) By adding pyridine, quinoline, and other organic bases to the ethereal solution of the blue compound, Wiede obtained salts of blue salts (NH<sub>4</sub>)C<sub>1</sub>O<sub>5</sub>,H<sub>2</sub>O<sub>2</sub> and KCrO<sub>5</sub>,H<sub>2</sub>O<sub>2</sub> According to Riesenfeld (Ber 1905, 38, 4068, 1908, 41, 2826, 1911, 44, 147), these salts are acid salts of perchromic acid H3C1O8, of the type MH<sub>2</sub>CrO<sub>s</sub>, corresponding with the red per-chromates. Pure perchromic acid H<sub>3</sub>CrO<sub>s</sub>,2H<sub>2</sub>O may be obtained by the interaction of chromic trioxide and 97 pc hydrogen peroxide in methyl ether solution at -30°.

$$2CrO_3 + 7H_2O_2 = 2H_3CrO_8 + 4H_2O$$

After the reaction is complete, the blue solution is poured off, dried with phosphoric oxide, and evaporated in vacuo at -30° It forms a dark blue crystalline mass, which decomposes at above -30°. The water is regarded as water of constitution, since the blue colour is only produced in presence of water The red perchromates are considered as the anhydro salts of the blue perchromic acid (Riesenfeld and Mau, Ber. 1914, 47, 548)

Esters of chromic acid have been prepared by Wienhaus (Ber 1914, 47, 332) by shaking a tertiary alcohol, dissolved in light petroleum or carbon tetrachloride with an excess of solid chromium trioxide. The ester remains dissolved or suspended in the solvent, from which

it can be obtained by evaporation

### CHROMAMMONIUM COMPOUNDS AND DERIVATIVES

Salts of chromium readily combine with ammonia or substituted ammonias, to form complex compounds in which the chromium atom may be combined with six molecules of ammonia, as, for example, in hexamine chromium chloride  $[Cr(NH_3)_6]Cl_3$ . According to Werner's theory, the chlorine of this compound is united by primary valencies, whereas the ammonia is co-ordinated with the chromium atom by supplementary valencies (Ber 40, 20) The ammonia may be substituted by acid groups, the valency and character of the complex radical being determined by the acid and basic radicals in the molecule, as will be evident from the following description of some of the simpler compounds.

Hexamine chromium salts (luteo salts), e g. the nitrate [Cr(NH<sub>3</sub>)<sub>6</sub>](NO<sub>3</sub>)<sub>3</sub>, are prepared by treating the corresponding purpureo salts with

ammonia in cold concentrated solution (Jorgensen, J. pr. Chem. 23, 229; Mills, Phil. Mag.

[4] 35, 245)

Pentamine chromium salts (purpureo salts) Jorgensen (J. pr Chem 2, 20, 105) prepared the chloride [CrCl(NH<sub>3</sub>), ]Cl<sub>2</sub> by reducing violet chromic chloride in a stream of pure dry hydrogen at a red heat, and adding to it a solution of NH<sub>4</sub>Cl in strong ammonia. Air was passed through, HCl added, and the mixture boiled. when a carmine coloured powder is precipitated. It crystallises in octahedra, sp gr 1 687, dissolves in 154 parts of water at 16°. Representing the compound Cl<sub>2</sub>Cr<sub>2</sub>(NH<sub>3</sub>)<sub>10</sub>Cl<sub>4</sub>, Jorgensen found that only 4 atoms of chlorine are precipitated by silver nitrate, which confirms Werner's formula above given.

Triamine chromium salts. These compounds have been investigated by Werner (Ber 1910, 43, 2286), who uses triamine chromium tetroxide in their preparation To a well-cooled solution of 30 grams of chromic acid in 300 c c of water are added 300 c c of pyridine. After remaining half an hour m a freezing mixture, 750 c c 3 p c  $H_2O_2$  are added. The precipitated pyridine perchromate is collected, washed, and added to 90 c c of well-cooled 25 p c ammonia The precipitated triamine chromium tetroxide is collected after 10 minutes and washed with water, alcohol, and ether

Trichlorotriamine chromium  $[(NH_3)_3CrCl_3]$ results when triamine chronium tetroxide is added to cold concentrated hydrochloric acid A blush-grey precipitate is formed, and the filtrate from this deposits the compound after standing two days, in dark blue crystals with a greenish tinge The triaquo derivative

 $[\mathrm{Cr}(\mathrm{OH_2})_3(\mathrm{NH_3})_3]\mathrm{Cl_3}$ 

is obtained by treating one gram of the dichloroaquotriamine chromium chloride (contained in the grey precipitate above mentioned) with 8 c c of water covered with 5 c c of pyridine The resulting solution is filtered, and the hydroxoiodide precipitated by the addition of solid potassium iodide The chloride is obtained from this by triturating with hydrochloric It forms brownish-red hygroscopic crysaeid tals The corresponding bromine compounds have been prepared

The diamine chromium compounds were among the earliest known of these complexes Morland (Chem Soc Trans 13, 252) obtained a compound by the action of K2Cr2O7 on fused KCNS, which was subsequently examined by Reinecke (Annalen, 126, 113) and by Norden-skill (Zeitsch anorg Chem 1, 126), who prepared it by heating NH4CNS to incipient fusion and dropping in one-third of its weight of (NH<sub>4</sub>)<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>. The compound

 $[Cr(NH_3)_2(SCN)_4]NH_4$ 

is known as Reinecke's salt, and according to Werner is the ammonium salt of tetrathiocyanodiamine chromite, the complex molecule having an acidcharacter and being mono-valent It forms small red crystals fairly stable towards acids The potassium salt is obtained by adding KCl to its solution, and the acid [Cr(NH<sub>3</sub>)<sub>2</sub>(SCN)<sub>4</sub>]H by decomposing the barium salt with sulphuric acid. It commences to decompose at 80°. Werner and Klein (Ber. 35, 277), by oxidation of 'Reinecke's salt' with bromine, completely 246 CHROMIUM.

climinated the four thiocyano groups with the formation of dibromodiaquodiamino chromic

bromide  $[(NH_3)_2(\operatorname{Br}_2(H_2O))_2|\operatorname{Br}.$ 

The last member of the series in which all the ammonia groups are replaced by acid radicals may be represented by the salt [Cr(CN<sub>6</sub>)]K<sub>3</sub> potassium chromcyanide or hexacyanochromite It is obtained in light yellow monoclinic crystals by adding a solution of chromic acetate to a boiling solution of potassium

CHROMOCYANINES v OXAZINE COLOURING MATTERS.

CHROMOFORM. Trade name for an orangered crystalline powder formed by the union of dichromic acid and hexamethylenetetiamine (C<sub>6</sub>H<sub>1,</sub>N<sub>4</sub>CH<sub>1</sub>), Cr<sub>2</sub>O<sub>7</sub> Slightly soluble in alcohol and cold water, readily soluble in hot water. The aqueous solution on boiling, or by treatment with acids or alkalis, evolves formaldehyde

CHROMOGEN AND CHROMOPHORE v.COLOUR AND CHEMICAL CONSTITUTION

CHROMOMETERS v COLORIMETERS

CHROMONE. Colouring matters derived from chromone or pheno  $\gamma$ -pyrone (1), the analogue of coumarın (2)

or pheno α-pyrone, have not as yet been found in nature, though an hydroxy chromone (1) analogous to daphnetin (2) will no doubt possess dyeing properties and yield a yellow shade on aluminium mordant

Chromone is specially interesting owing to the isolation of the 3 hydroxy-chromonol

by Schall and Dialle (Ber 1881, 21, 3009) as one of the products of the alkaline oxidation of brazilein Benzo γ-pyrone derivatives were first synthesised by v Kostanecki (Bei. 1900, 1998), but the synthesis of chromone itself is due to Ruhemann and Stapleton (Chem. Soc. Trans 1900, 1179) When phenoxyfumaric acid (1) is treated with sulphuric acid benzo γ-pyrone carboxylic acid is produced (2)

and this when heated in a vacuum yields benzo  $\gamma$ -pyrone:

and its yellow solution in cold sulphuric acid possesses a blue fluorescence A. G. P

CHROMOTROPE or CHROMOTROPIC ACID, 1 8-Dihydroxynaphthalene-3 6-Disulphonic acid.

CHRYSANILINE. Diamidophenylacridine C<sub>19</sub>H<sub>16</sub>N<sub>3</sub>, is obtained as a by-product in the manufacture of rosaniline by the arsenic acid method, and was isolated by Nicholson (Dingl. poly. J 168, 133) by treating the residue with steam, whereby chrysaniline passes into solution and can be precipitated therefrom by addition of nitric acid It was further examined by Hofmann (Ber. 1869, 378), who prepared its methyl-, ethyl-, and phenyl- derivatives, and showed that it possessed the empirical formula ('20H17N3 Its composition and constitution were first established by Fischer and Körner (Ber 1884, 203, Annalen, 226, 175), who showed that a second lower homologue of composition ('19H<sub>15</sub>N', was present (compare also Anschutz, Bei 1884, 433), and who refer its formation in the rosaniline melt to a condensation and subsequent oxidation of orthotoluidine and aniline, since they have effected its synthesis by heating with aisenic acid at 180°-200° the orthodipalatrianimotriphenylmethane obtained by Renouf (Ber 1883, 1304) by the action of dehydrating agents on a mixture of orthonitrobenzaldehyde and aniline (v. also Ostrogovich and Silbermann, Chem Zentr 1907, 1 1195) The commercial product is a mixture of the two derivatives, and in the form of the nitrates or hydrochlorides appears on the market as phosphine

Properties—Chrysaniline crystallises with 2 mols of H<sub>2</sub>O from 50 p c alcohol in goldenyellow needles, and from benzene with I mol of benzene of crystallisation in golden-yellow scales, the latter melt, when placed in a bath heated at 150°-160°, but when slowly heated lose the associated benzene, and melt, like the former, at 267°-270° It is insoluble in water, and sparingly soluble in alcohol. On oxidation with chronic acid, it yields acridine and when diazotised and boiled with alcohol is converted into phenylacridine (mp 164°). Tetrazo compounds have been prepared, but then couple products with amines, phenols, &c, are not as good dyes as those obtained from chrysaniline and its salts (Trillat and de Raczkowski, Compt 1end 114, 1024) Formaldehyde reacts with chrysaniline, yielding an orange dyestuff similar to chrysaniline in its tinctorial properties (T and de R Compt rend 116, 1382) Chrysophenol (19 H<sub>14</sub>N<sub>2</sub>O, a yellow dye, is obtained when it is heated at 160°-180° with concentrated hydrochloric acid, and crystallises from dilute alcohol with 2 mols. of  $\rm H_2O$  in ruby-red needles. Chrysamline forms two series of salts; of these, the sparingly soluble intrate is the most characteristic: it crystallises in ruby-red needles, and is employed under various names as a valuable golden-yellow dve for silk, wool, and leather (v ACRIDINE DYESTUFFS)

CHRYSANTHEMIN v ANTHOCYANINS.
CHRYSAROBIN (B.P., USP) is a yellow crystalline mixture of substances obtained from Avaroba or Goa powder The latter varies in CO CH colour from primrose-yellow to bronze and purple, and collects, possibly as the result of oxidation of the resin in the cavities of the

stems and branches of Andira Araroba (Aguar) (N.O. Lequminsæ), a tree inhabiting the forests of Bahia (Aguar, Pharm. J. [in.] 10, 42; cf Greenish, ibid. [in.] 10, 814) The drug was formerly exported by the Portuguese to Goa, but its origin for a long time remained secret Goa powder is usually mixed with woody fragments from which it is freed by sifting, it is sometimes termed crude chrysarobin. After extraction of Goa powder with organic solvents (benzene, chloroform) there is left behind on evaporation a yellow crystalline powder, introduced in 1875 by a Bombay firm under the name Chrysarobin, which has since been included under this name in the British and United States.

Attheld (Pharm J 1875, [3] 5, 721) obtained chrysarobin in a yield of 80-84 p c of the crude drug, using benzene Tutin and Clewer (Chem Soc. Trans 1912, 101, 290), by successive exhaustion with light petroleum, ether, chloroform, ethyl acetate, and alcohol extracted only 57 5 p c The residue consists of woody fibre, inorganic and resinous constituents, a little

sugar, &c.

Chrysarobin was originally thought to be a pure, or nearly pure, substance, in reality it is a complex mixture, consisting chiefly of reduced di- and trihydroxymethylanthraquinones, which crystallise together and are difficult to separate by purely physical means. Later the name chrysarobin was applied to one of the pure constituents, but it is better to reserve this name for the commercial mixture. Tutin and Clewer found the following percentage composition for three samples of commercial chrysarobin.—

1	Chrysophanic acid	1		
	(=chrysophanol) 1	63	$7\cdot 2$	8.9
2.	Emodin monomethylether 1	}		
3	Emodin	trace	nıl	nıl
4.	Crude anthranol of chryso-			
	phanic acid .	26	46	62
5.	Anthranol of emodin mono-			
	methyl ether	small	amou	nts
6	Monomethyl ether of de-			
	hydroemodinanthianol	41 l	13 4	177
7.	Ararobinol	4 2	4 1	nıl
8.	Inseparable mixture of			
	partly amorphous sub-			
	stances .	23	30	12

The first three of these substances are anthraquinone derivatives (for their properties and constitution, see Rhubarb) Nos 4 and 5 result from Nos. 1 and 2 respectively, by reduction, they are derivatives of anthranol (9-hydroxyanthracene). No. 6 is a less strongly reduced anthraquinone. No. 7, of unknown constitution, is also an anthraquinone derivative, related to No. 1

Chrysophanic acid anthranol C<sub>15</sub>H<sub>12</sub>O<sub>3</sub> has

$$C_6H_3(OH)$$
 $C_{CH}$ 
 $C_6H_2(OH)CH_3$ 

and was called chrysarobin by Jowett and Potter (Chem Soc Trans 1902, 81, 1578). It is obtained from commercial chrysarobin by extraction with light petroleum; by shaking

About 3 or 4 parts of the former to 1 of the latter.

its chloroform solution with sodium carbonate traces of emodin are removed, and after evaporation of the chloroform the residue is crystallised from much ethyl acetate, when it forms lemon-yellow scales, m.p. 202° (corr) (regenerated from its acetyl derivative the substance melts at 204°). It is insoluble in sodium carbonate, soluble in caustic alkalis to a yellow solution, which becomes red by passing air through it, whereby it is oxidised to chrysophanic acid. The change is complete in 2 hours, as shown by measurement of the oxygen absorbed (Tutin and Clewer). The reverse change is brought about by hydriodic acid at 130°-140°. Chrysophanic acid anthranol dissolves in sulphuric acid with a yellow colour; it forms a diacetyl compound  $C_{15}H_{10}O_3Ac_2$ , m.p. 193°, and a triacetyl compound  $C_{15}H_{9}O_3Ac_3$ , m.p. 238°.

The anthranol of cmodin monomethyl other was not isolated by Tutin and Clewer as such, but its presence was inferred from aerial oxidation experiments, which converted it into emodin monomethyl other

The monomethyl other of dehydroemodinanthranol  $C_{16}H_{12}O_4$  is characteristic of chrysarobin. According to Eder (v infra), its constitution is most probably

$$\begin{array}{c|c} CH^2O & CH^2 \\ \hline \\ HO & C \\ \hline \\ OH \\ \end{array}$$

Tutin and Clewer converted it by boiling hydriodic acid into emodin anthranol, a substance containing a methyl group less and 2 hydrogen atoms more, by oxidation with chromic acid they converted it into emodin methyl other

Of the substances 1-6 chrysophanic acid had also been found by Attfield, its anthranol by Jowett and Potter, and emodin monomethylether by Oesterle and Johann (Arch Pharm 1910, 248, 476), but this was the full extent of the agreement among the various investigators of chrysarobin until Eder (Arch. Pharm 1915, 253, 1; 1916, 254, 1) confirmed all the principal results of Tutin and Clewer He oxidised the commercial substance with air in alkaline solution, and considers that hydrogen peroxide is formed in this reaction, and is responsible for further changes. He thus obtained the following percentages. emodin 02, emodin methylether 93, chrysophanic acid 227, dehydro-emodin anthranol monomethyl ether 18 (=chrysarobol of Hesse?), amorphous products 26 It should be remembered that most of the chrysophanic acid and some of the emodin methyl ether were originally present as anthranols. In his second paper, Eder acetylated and benzoylated chrysarobin and obtained by subsequent hydrolysis up to 14 pc. of chrysophanic acid anthranol, up to 9 pc. of emodin anthranol monomethyl ether, and up to 4 pc of emodin monomethyl ether, but no chrysophanic acid The chief discrepancy is that Eder did not find the last of Tutin and Clewer's substances, ararobinol. This, according to the latter authors, has the composition  $\Omega_{23}H_{16}O_5$ , and forms yellow crystals, decomposing without melting at about

225°. It dissolves in alkali with a yellow colour, but, like the methyl ether of dehydro-emodin anthranol, and unlike chrysophanic acid anthranol, it is not readily oxidised by air. It gives a delicate and characteristic reaction with sulphuric acid, a mere trace forms an orange solution, which on gentle agitation gives intense blue streaks, the solution then becomes green, and finally dull grey. Ararobinol gives a triacetyl derivative (decomp at 225°), is reduced by hydriodic acid to dehydroararobinol, and oxidised by chromic acid to chrysophanic acid, but not quantitatively.

With the exception of chrysophanic acid anthranol, Tutin and Clewer could find none of the substances described by Jowett and Potter They had access to the latter's specimens of dichrysarobin' and its 'methylether;' the former they separated into substance 4, and emodin anthranol, the latter into the substances 4 and 5. A mixture of the latter substances is similar in composition and melting-point to 'dichrysarobin methyl ether,' which illustrates the difficulty of separating the constituents of chrysarobin by mere crystallisation

Chrysarobin is occasionally employed intern-y as a purgative Léger (J. Pharm Chim ally as a purgative 1912, [vn ] 5, 588) has suggested that for this purpose chrysarobin should be substituted for chrysophanic acid, since they both have the same purgative effect, and the latter is difficult to obtain in a state of purity. Probably the chief constituent of chrysarobin, chrysophanic acid anthranol, does not exert a purgative action until it has been oxidised in the alimentary canal (to chrysophanic acid), as is the case with aloin (Meyer and Gottlieb, Experimentelle Pharmacologic, Berlin and Vienna, 1914, 198) The chief use of chrysarobin is, however, as an ointment in skin diseases (psoriasis), and the active constituent appears to be the anthranol of chrysophanic acid According to Unna's experiments (Baudisch, Ber 1916, 49, 179), the only active synthetic substitutes are the anthranols of 1-hydroxy and of 1 8-dihydroxy anthraquinone The latter, eignolin

is more active in psoriasis than the anthranol of chrysophanic acid (chrysaiobin), because it has not the dystherapeutic methyl group

Baudisch explains the effect of the 1 8hydroxyls in accordance with Pfeiffer's views by the formula

Various other substitutes have been suggested, e.g. acetyl chrysarobin (Knoll & Co D. R. P. 105871; Chem Zentr. 1900, 1 524), 'lenirobin'; eurobin is said to be triacetylchrysophanic acid (?)

chrysophanic acid (?)
'Dermol' is prepared by precipitating a bismuth nitrate solution by a solution of

chrysophanic acid in sodium hydroxide. 'Anthrarobin' is the anthranol of alizarin.

The different methods of extraction cause considerable variation in the composition of commercial chrysarobin and of its physiological action (Pharm J 1911, [1v] 87, 630) Hence, Tutin and Clewer consider it fallacious to ask for compliance with exact requirements as to solubility, etc (The USP states that 1 gram of chrysarobin dissolves in 385 cc of alcohol, 12 5 c c. of chloroform, 16 c c. of ether, 30 cc of benzene, and 180 cc. of carbon disulphide at 25°) Pure chrysarobin dissolves in concentrated sulphuric acid with a yellow colour, and is insoluble in dilute sodium hydroxide; concentrated sodium hydroxide dissolves it with a green colour Chrysophanic acid, on the other hand, yields a red solution with concentrated sulphuric acid and dilute sodium hydroxide (Liebermann and Seidler, Ber 11, Another method to distinguish chrysarobin from chrysophanic acid is to mix 0 05 gram with 0 2-0 3 gram sodium peroxide in a porcelain capsule, add 5 c c of alcohol, and after 5 minutes 15 c c of water Chrysaiobin yields a wine-lees colour, not destroyed by dilution with water, changing to yellow on the addition of acetic Chrysophanic acid yields a cherry-red colour, becoming brighter on dilution (Alvarez, Ann Chim anal 1907, 9) G. B.

CHRYSATROPIC ACID v LACTONES CHRYSAZIN v ALIZARIN AND ALLIED COLOURING MATTERS.

This hydrocarbon occurs in the highest boiling portions of coal tar, and in the tarry products obtained in the dry distillation of wood, fats, and oils (Laurent, Ann Chim Phys. [2] 66, 136) Synthetically, it can be prepared by passing through a red-hot tube the vapour of benzylnaphthylmethane (Graebe and Bungener, Ber 12, 1078), or those of cumarone and naphthalene, which condense with the loss of a molecule of water (Kraemer and Spilker, *ibid.* 23, 84), or by strongly heating indene. For a complete synthesis, see Beschke, Winograd-Finkel and Kohres, Annalen, 384, 143

Purification—(Chrysene is extracted from the mixture of solid hydrocarbons consisting chiefly of pyrene and chrysene, which boil at a higher temperature than anthracene, and constitute the last portions of the distillate from coal tar, by repeated digestion with carbon disulphide in the cold. This treatment removes all the hydrocarbons in the mixture except chrysene (present to the extent of 18–19 p c.), and this is further purified by crystallisation from coal oil (b p. 150°), from which it separates in golden-yellow scales. The yellow colour, due to an impurity, cannot be removed by repeated crystallisation, but is destroyed by boiling with alcohol and a small quantity of nitric acid (Liebermann, Annalen, 158, 299), or most simply by the action of perchloric acid (K. A. Hofmann. Ber 43, 1086)

A second method for obtaining chrysene from crude greenish-yellow anthracene (m.p. 207°-208°) has been described by Schmidt (J. pr. Chem. [2] 9, 250, 270). For this purpose, 40-50 grams of the anthracene are dissolved in 5 litres of strong (95 p.c.) alcohol, and the

solution, after filtration, is boiled with 30 grams of nitric acid (sp gr. 1·4) in a reflux apparatus for some time. On cooling, red needles of a sparingly soluble compound of chrysene and dimitroanthraquinone.  $C_{18}H_{12},C_{14}H_6(NO_2)_2O_2$  separate, which, when treated with tin and hydrochloric acid, decompose into chrysene and reduction compounds of dinitroanthraquinone. The hydrocarbon is then obtained pure and colourless by crystallisation from benzene

Properties - Chrysene crystallises in scales, or in well-defined, colourless rhombic plates, which show a violet fluorescence, melts at 250° and boils at 448° (Schweitzer, Annalen, 1891, 193) It is a sparingly soluble substance, for example, 100 parts of absolute alcohol dissolve 0 097 part at 16°, and 0 17 part at 18°, and 100 parts of toluene dissolve 0 24 part at 18°, and 5 39 parts at 100° (v Bechi, Ber. 12, 1978), whilst ether, carbon disulphide, benzene, and acetic acid dissolve it only to a slight extent at the ordinary temperature, but more readily on boiling The solutions, like the pure hydrocarbon, show a deep reddish-violet On adding chrysene to a solution fluorescence of formaldehyde and sulphuric acid, a reddishviolet colour is produced, this is destroyed by the addition of water (Ditz, Chem. Zeit 31, 445) The absorption spectrum of chrysene has been studied by Baly and Tuck (Chem Soc Trans 1902, 14) Chrysene combines with dinitroanthraquinone and with pierie acid (trinitrophenol) to form characteristic compounds; the merate  $C_{18}H_{12}, C_{6}H_{2}(NO_{2})_{3}OH$ , obtained by adding chrysene to pierie acid in benzene solution, crystallises in long red needles, and is decomposed by alcohol (Liebermann, Schmidt) When heated with concentrated sulphuric acid, chrysene yields a sulphonic acid, and when treated with nitric acid, under varying conditions, yields mono-, di-, and tetra-nitro derivatives (ibid), whilst chlorine and bromine convert it into substitution-derivatives (Schmidt) Ammochrysene is obtained by the reduction of nitrochrysene with phosphorus and hydriodic acid (Abegg, Ber 1893, 792), or with tin and hydrochlone acid (Bamberger and Burgdorf, ibid. 1893, 1006) On oxidation with chromic acid in acetic acid solution, chrysene is converted into chrysoquinone  $C_{18}H_{10}O_2$ , which crystallises in yellowish-red needles, melts at 235°, yields azines on treatment with ortho-diamines (Liebermann and Witt, *ibid* 20, 2242), and is characterised by dissolving in concentrated sulphuric acid with a blue colour On oxidation with lead peroxide in alkaline solution the quinone is converted into β-phenyl-a-naphthoic acid, from which by elimination of carbon dioxide, \$\beta-phenylnaphthalene is obtained.

CHRYSEOLIN v AZO- COLOURING MATTERS. CHRYSIN, 1 3-dioxyflavone C<sub>15</sub>H<sub>10</sub>O<sub>4</sub>, is obtained from poplar buds (Piccard, Ber 1874, 88; and Darier, ibid 1894, 21) It has been synthesised by treating phloracetophenone with ethyl benzoate in the presence of sodium, when 2:4:6-trimethoxybenzoylacetophenone is formed; on boiling with hydriodic acid, the methyl- groups are eliminated, condensation takes place with the production of 1:3-dioxyflavones (Emilewicz, v. Kostanecki and Tambor, ibid. 1899, 2448; 1904, 3167). It is a yellow crystalline solid, melting at 275°. By heating

it on the water-bath with methyl iodide and potassium methoxide, tectochrysin, which also occurs in poplar buds, is formed (Emilewicz, Kostanecki and Tambor, lc) Chrysin is a member of the quercitin series (Perkin, Chem Soc. Trans. 1896, 1443), and dyes cloth mordanted with aluminium a pure yellow, with chromium, an orange-yellow; and with iron, a pale chocolate (Perkin, ibid. 1897, 818)

CHRYSOBERYL. Aluminate of beryllium, BeAl<sub>2</sub>O<sub>4</sub>, crystallising in the orthorhombic system, and used as a gem stone It is usually met with in well-formed crystals, which as a result of twinning often simulate hexagonal forms, or as rolled pebbles in river gravels Sp gr 3 65-3 75; hardness 81, taking the third place amongst minerals, being exceeded only by diamond and corundum. Few minerals are so resistant to chemical reagents as chrysoberyl, it is not attacked by acids nor fusible before the blowpipe, and is decomposed only by fused alkalis The colour ranges in various shades of yellow and green The variety alexandrite is emerald-green in daylight, but violet-red in lamp-light Another gem variety, known as cumophane or 'oriental cat's-eye,' shows a blush milky band of reflected light which travels across the convex polished surface as the stone is moved about ('hrysoberyl occurs embedded in granite and crystalline schists Material of gem quality comes from Ceylon, Brazil, and the Urals By reason of its high degree of hardness it has occasionally been used for jewelling watch-bearings

CHRYSOCOLLA. A hydrated silicate of copper sometimes of importance as an ore of copper. The formula is usually given as CuSiO, 2H2O, but the composition is variable, the mineral often being mixed with various impurities-silica, alumina, copper carbonate or phosphate, limonite, &c On these differences in composition several trivial varieties have been distinguished by special names The mineral is of secondary origin, occurring in the upper portions of deposits of copper ores It forms encrusting or botryoidal masses, which may be viticous and translucent, resembling opal or enamel in appearance, or dull and earthy. The colour ranges from bright green to bright blue, and there is a wide range in the sp gr 2 0-2 8 Under the microscope it sometimes shows a minutely fibrous structure, and small accoular crystals from Idaho have been described (J B Umpleby, 1914) Such material is optically uniaxial and positive with refractive indices 1 57 and 1 46, sp gr 2 4 Interbanded with the microcrystalline material is often some optically isotropic material, and for this amorphous equivalent of chrysocolla the name cornuite has been proposed (A. F. Rogers, 1917)

A variety known as pitchy copper-ore (Ger Kupferpecherz), dark brown or black in colour and with the appearance of pitch, is of some importance as an ore of copper, particularly in Chile. It consists of a mixture of chrysocolla and limonite Chrysocolla of the more ordinary type has been mined for copper in South Anstralia, Belgian Congo, Chile, Arizona, Idaho, &c. The name chrysocolla, from  $\chi \rho \bar{\nu} \sigma \delta s$ , gold, and  $\kappa \delta \lambda \lambda \alpha$ , glue, was applied by the ancients to materials used for soldering gold, and included, besides certain copper minerals, also borax.

L. J. S.

CHRYSOFORM. Trade name for dibromoduodohexamethylenetetramine.

CHRYSOGEŇ. An orange-coloured stance, containing more than 94 p c. of carbon, and said to be a hydrocarbon, discovered by Fritzsche (Zeitsch Chem 1866, 139) in crude anthracene. It is sparingly soluble in the ordinary organic solvents. In sunlight, its solutions become rapidly bleached, and yield a colourless crystalline compound which, on fusion, becomes orange-yellow

CHRYSOIDINES v AZO- COLOURING MATTERS. CHRYSOIN v Azo- colouring matters

CHRYSOLITE v OLIVINE

CHRYSONAPHTHAZINE " AZINES.

CHRYSOTOLUIDINE C21H21N3 A yellow crystalline base of unknown constitution (cf Hofmann, Bei. 2, 380), occurring in the residue obtained in fuchsin manufacture by the aisenic acid method (Guard, De Laue, and Chapoteaud, Compt rend 63, 964, 64, 416) The hydrochloride is a yellow dyestuff

CHRYSYL. Trade name for zine boropiciate obtained by boiling together solutions of boric and pieric acids with zine oxide, used as an

antiseptic

CHURCHITE. A hydrated phosphate of cerium (('e<sub>2</sub>O<sub>3</sub> 51 87 p c ) and calcium, occurring as grey fan-like aggregates of acicular crystals encrusting quartz and slate in a Cornish copper Unfortunately nothing is known of the exact locality of the mineral CHYMASE v FERMENTATION

CICATRICINE. Trade name for a solution

of thiosinamine, antipyrine, and lucame lactate CICUTOXIN  $C_{19}II_{26}O_3$ , the poisonous principle in water-hemlock (Cicuta ragans) is contained in the tubers to the extent of 0.3-0.4pc It is found also in C virosa It is a yellow resin-like substance which readily decomposes and polymerises above 50° D<sup>22</sup> 0 9659  $h_{\mathrm{D}}^{25}$  1 5885. Unites energetically with bromine and ignites spontaneously in contact with strong On dry distillation it yields an oil nitric acid  $\mathrm{C_{13}H_{21}O_{2}}$  of sp gr 0 936 at 20° Distilled in a current of steam it gives an oil C14H22O, of a pleasant odour, it gradually polymerises to a transparent semi-solid resin On oxidation with nitric acid cicutoxin yields carbon dioxide, oxalic acid, hydrogen cyanide, isobutyric acid, and acetyl-2-cyclopentanone, b p  $735^{\circ}/15$  mm , Compounds of cicutoxin with lead, barium hydrogen chloride, ammonia, bromine, and iodine are known Cicutoxin appears to be a derivative of 4-pyrone (Jacobson, J. Amer. Chem Soc 1915, 37, 916)

CIDER or CYDER is a vinous beverage produced by expressing and fermenting the juice of Perry is a similar article made from pears The two are very much alike in character, and, the principles of manufacture being generally the same for each, reference will be made to eider only in this article, except when occasion requires the special mention of perry.

The largest cider-producing country of the world is France, followed by England, Germany, the United States and Canada, and it is now also produced in increasing quantities in other countries, notably Ireland and Australia England the principal eider-growing districts are the counties of Somerset, Devon, and Hereford, smaller quantities being made in Gloucester, Worcester, Monmouth, Kent, and Norfolk The mean annual production of the United Kingdom is estimated at 60,000,000 gallons, of a value of about 3,000,000l, including the Excise Duty of 4d per gallon.

The ordinary cider of commerce in England is a beverage of widely varying character. It may contain as little as 2 pe or as much as 8 pc of alcohol by weight, depending on the quality of the apples from which it is made, and the process of its manufacture, particularly the stage at which the fermentation has been stopped Apart from its characteristics of flavour, body, and colour, cider may be roughly divided into three classes or grades, viz: sweet, which has been only slightly fermented; dry, well fermented, and medium, between the two Apple juice of good average quality has a sp gr of about 1050 to 1055, corresponding to 10-12 pc of sugar As the fermentation produces, roughly, I p c of alcohol from every 2 p c of sugar, the following table shows the approximate comparative composition of apple juice, and the three grades mentioned —

	Sp gr	Sugar	Alcohol
Apple juice	1050-1055	10-12 p c	-
Sweet cider .	1025-1035	6-7	2-3 p c.
Medium eider	1015-1025	4 -5	3-4
Dry cider .	1000-1010	0-2	5-6

It must be understood that these figures are only approximate, and show the proportions of alcohol and sugar in cider made from apples of average quality, when the fermentation is stopped at the sp grs mentioned and no sugar is added

The rough cider of the farmhouse, found in the south-western counties, is of a very dry grade, being fully fermented, no attempt being made to check the 'working,' while the ordinary cider (bottled and draught), found in the average hotel in cities, is a beverage which has been but slightly fermented, and is of the sweet to medium grade, the greatest public demand being for cider as a summer beverage, light, sweet, and refreshing It must not be assumed, however, that all bottled eider is sweet, for it is obtainable from several firms of repute in four welldefined grades-sweet, medium, dry, and extra

The raw material from which eider is made varies in composition and character as much as the cider itself. The majority of English orchards were originally stocked with almost innumerable varieties of apples and pears, most of them of inferior quality, for either table use or for the manufacture of eider or perry, but great improvements have of late years been made in the planting and cultivation of the orchards, with a corresponding improvement in the quality of the beverages produced. Speaking generally, it may be said that good cider cannot be made from any but essentially vintage varieties of apples, most of which are quite

unsuited for table use because of their astringent flavour, due to the large proportion of tannin they contain The majority of table varieties yield a juice deficient in sugar and tannin, with an excess of acidity, as compared with the vintage sorts, which are cultivated specially for the manufacture of cider This is particularly applicable to perry pears, which are almost invariably very astringent in taste, although it is curious to note that the percentage of tannin they contain is not exceptionally high. To make good cider, the sp gr of the juice should not be under 1045, it should contain at least 0 15 pc of tannin, which gives keeping and clearing properties, with an acidity not exceeding 05 or 0 b pc of malic acid for sweet cider, and 03-04 p.c. for dry, while those substances which constitute 'body,' consisting of mucilage, albumen, salts, colouring matter, &c, are also of importance; but, having been very little investigated, it is impossible to state definitely what proportions of each are necessary high sp gr with a correspondingly high sugar content, is generally considered the most important quality, but some apples are known to yield a juice high in sp gr but deficient in colour and body (the two are usually associated), while others of a low sp gr but rich in colour and body, may produce cider of better quality than the first-mentioned Too much reliance, however, must not be placed on the mere chemical composition of the juice as indicative of the value of an apple for eider making, the characteristic flavour of the variety and the rate of fermentation, which varies greatly with different juices, being at least equally important

Vintage apples are roughly divided into three classes—sharp, containing normally not less than 0 45 p c malic acid; sweet, containing normally less than 0.45 pc of malic acid, and 02 pc of tannin, bitter sweet, containing normally less than 0.45 p.c. of malic acid and more than 02 pc of tannin The following table shows typical analyses of the juice of several of the best of each class, together with that of a hitherto unknown and unnamed variety recently found in Someiset ('Butleigh No 14'), which is of outstanding merit -

No	Variety	Sp gr.	Malic acid	Tannın	Total sugar

12.	'Butleigh No 14'	1104	0.24	0.258	22.22

Nos. 1, 2, and 3 are sharp varieties; 4 and 5, sweet; 6, 7, and 8, bitter-sweet; 9, 10, and 11, perry pears; 12, a bitter-sweet of unusually high quality.

ancient origin, but modern scientific eider making may be said to date from the year 1893, when the Bath and West of England Agricultural Society instituted some chemical and bacteriological research into the subject, a work which was carried on by Mr. F J. Lloyd for some seven years in Somerset, and has subsequently been continued on a more ambitious scale at the National Fruit and Cider Institute, associated with the University of Bustol, under the direction of Prof B T P. Barker The results of these investigations form the foundation of modern cider making, and annual reports thereon constitute the most trustworthy literature on the subject

Whereas the quality of the cider depends primarily on that of the apples used, the nature of the product is largely influenced by the methods of manufacture and fermentation, and general management To ensure good quality, care of the apples in the orchard is essential, for no good beverage can be made from fruit which has been carelessly gathered or stored It should be shaken from the trees when just ripe, bruising being avoided as far as possible, and stored in heaps (preferably under cover if the weather be wet), until it becomes soft and mellow, but not over-ripe, care being taken to avoid either washing by rain, which results in the loss of sugar and yeast, or heating, which produces fustiness in the cider, as well as a great When thotendency to acetic fermentation roughly mellow, the fruit is selected and blended in the proportions necessary to give the degree of sweetness, acidity, and astringency required for the variety of cider it is intended Sweet cider is best made from a to make blend of sweet, sharp, and bitter-sweet apples; while dry cider should be made from a blend giving a minimum of acidity, with only a moderate proportion of tannin Very few varieties of apples are individually capable of producing the finest cider, an appropriate This does not apply blending being necessary pears and perry making: single varieties, unblended, usually giving best results In the actual processes of grinding the fruit and expressing the juice, steam or hydraulic power is generally used in modern factory practice, but, apart from economic reasons, this has no advantage over the old-fashioned hand-power machinery of former days. The fruit is ground to a fine pulp, called 'pomace,' which falls upon the press, is held together in thin squares by manilla or hempen cloths, and is usually pressed In some places, however, the pomace is allowed to remain in tubs for 12 to 24 hours before pressing, which is said to improve the quality of the resulting liquor, but there seems to be no scientific reason for this custom, and investigations have failed to show that sufficient advantages are gained to compensate for the work it entails. With efficient presses, about 75-80 pc of the weight of apples is obtained as juice, and about 80 p c in the case of pears. The most profitable means of utilising the drypressed pomace is as cattle food In France the juice is sometimes extracted by the 'diffusion' process in use in the beet-sugar industry, but this does not meet with general approval, and has not been adopted in this country. The process of cider making is of very fresh juice is run into casks or open vats called

'keeves,' to undergo the important process of fermentation, which commences spontaneously in a few days, the time depending on the character of the juice and the temperature An important question here arises. Shall the cider be allowed to undergo a natural fermentation, or shall a pure culture of yeast be added to dominate it? At the present time this is a debatable point While in France and Germany it is generally acknowledged that the use of pure cultures improves the quality of the liquor, and they are largely used, in this country and America it seems doubtful whether the advantages of their use are sufficient to compensate for the extra expense and trouble involved Pure yeasts, isolated from the best growths of cider and wine, have been cultivated and added in sufficient quantity to dominate the fermentation and prevent the various wild races from exercising much influence (Owing to the difficulty of avoiding a cooked taste, sterilisation of the apple juice, even at comparatively low temperatures, is rather impracticable) The general results tend to show that fermentation by suitable yeasts give a somewhat superior product to that obtained by natural fermentation, but the full advantages are not apparent until the cider is about a year old, whereas, in general practice, it is usual for it to be consumed before it attains that age. The use of sumed before it attains that age pure cultures in the eider industry in this country is, for that reason, far from general, and it does not seem likely to make much headway in the present state of our knowledge of the subject Little is known of the various species of yeasts naturally occurring on the skin of the apple, which subsequently develop in the cider, forming the 'lees' at the bottom, and conducting the fermentation, but the largest number consist of forms allied to the Saccharomyces Ellipsoideus, S Pastorianus, and S apiculatus types A fairly slow fermentation is generally desirable, but, on the other hand, it is one of the most important points in the whole process that the primary alcoholic fermentation be vigorous enough, and is not checked too soon, otherwise the eider is laid open to the attacks of numerous undesirable organisms, which will show their effects in various 'diseases' during the following summer The 'keeving' system of fermentation, in open vats with loose covers, is preferable to that in closed casks, as the 'head,' which is soon thrown up, consisting of yeasts and light portions of tissue, can be skimmed off from time to time It is not advisable, however, to keep the order in the keeves longer than about a week, lest incipient acetic fermentation set in, and, as soon as no further head is thrown up, it is racked into closed casks to complete the primary fermentation. The subsequent conduct of this important process is governed by the grade of eider it is desired to make, the hydrometer being in regular use for watching the fall of the The rate of fermentation depends sp gr partly on the character and composition of the juice, and partly on the temperature; but these conditions are practically beyond control. Blending the apples to ensure the requisite degrees of sweetness and acidity in the juice will comply with one condition of a moderate rate, but as the proportion of nitrogenous matter is

of still greater importance, and is a subject on which, strangely enough, little is known, and no reliable figures obtainable, blending to ensure the proper percentage cannot be scientifically done at present Regulating the temperature is also impracticable, for a large quantity of cider would have to be handled in a very short space of time, and this would be too expensive a process. A large plant would have to be fixed up, which could only be in use a few weeks each year, and possibly it might not be required at all Whenever the spgr. approaches the point at which it is desired to stop the fermentation, the eider is racked off into clean casks, with or without sulphuring or the use of other This alone, however, is not preservative. usually sufficient to stop fermentation, unless an excessive quantity of preservative be used, or racking into sulphured casks be repeated several The best known means, which has the advantage of adding no materials of a questionable nature to the liquor, is to filter it through one of the many useful cotton-pulp filters now on the market Even the use of a filter is open to some objections, for it removes some of the body (probably of a colloid nature) and flavour from the cider The clarification also presents great difficulty with many ciders, neither isinglass finings nor boiled apple pulp, which are commonly used for the purpose, having any effect, so that the filter, which clarifies the cider, and at the same time stops the fermentation, is preferred, in the absence of anything better, for this purpose Depending on various circumstances, the cider is filtered and stored away to mature in casks, at any time from two to four or even six months from the time of making If filtered perfectly bright, and stored in clean casks, kept well filled, it will 'keep its sweets' for a whole season or longer, with the loss of only a few degrees of spgr, even though it may contain as much as 6 or 7 pc of fermentmay contain as much as 0 of 1 p o 3. Assume that a ble sugar. During this period of storage, it mellows and develops its fragrant aroma and delicate flavour, and also loses a certain proportion of its acidity and astringency. The strongest and best cider will keep in cask for some years, but that of average quality is at its best within the first year It keeps best and improves most in bottle, but only eider of good and sound quality should be bottled; it should have an original gravity of at least 1050, should undergo a vigorous primary fermentation, and be perfectly brilliant when bottled The best age for bottling is from four to six months, and if not more than a year old at the time, it will develop sparkling condition like champagne after a few weeks' storage. The carbonating process of bottling is becoming more general, and there seems to be no objection whatever to its use, some of the best brands on the market having been treated in this way

Matured cider is liable to several disorders or 'diseases,' the principal being acetification, 'sickness,' ropiness, and blackening Like all liquors of low alcoholic strength, it is particularly apt to acetify on very slight provocation, and for this reason, exposure to air at all stages of manufacture is to be avoided. 'Sickness' is a recommencement of alcoholic fermentation, which is set up during the summer following its manufacture, and may occur in cask or

bottle. The cider becomes very turbid, and the production of alcohol is accompanied by the development of a most disagreeable smell and flavour, due, it is thought, to formation of acetaldehyde, together with an increase in acidity, partly lactic and partly acetic, which renders the liquor quite undrinkable. It is a source of great loss, for it usually attacks the richest and most fruity ciders, and is due to the action of several special organisms, contributing causes being a deficiency of malic acid in the juice, and a weak primary fermentation Ropiness is not so frequently met with, and little is known of its causes in eider, but it is generally found where there is a deficiency of tannin. Some ciders turn dark very quickly on exposure to air, some almost black in less than half an This may be due either to an excess of iron acquired from the soil on which the apples are grown, but more often from the utensils used in the making, or to enzymic action, the use of a little preservative often prevents its development

A standard of chemical composition for what is sold as eider has been formulated in some countries, but not in Great Britain to the extreme variations in the character and composition of genuine cider, it is almost, if not quite, impossible to fix a definite chemical composition and say that it represents what should be considered a standard cider. For this reason, the standard fixed in foreign countries is necessarily very low, but while it probably admits of a certain amount of adulteration, it no doubt acts as a check. It can hardly be contended that nothing should be sold as eider which is not the pure juice of apples Brewers, wine makers, and distillers are not restricted by law to the use of malt and hops, grape juice and malt respectively, in the making of their products, so that a law to limit cider makers to the use of apples only would operate unfairly against them as compared with the other trades It has been stated that many mentioned varieties of cider apples grown in this country are not capable of making first-class cider, and the better sorts are in too small a minority to meet the demand In poor vintage seasons, also, the general quality is low, sugar being deficient and acidity excessive It is also deficient and acidity excessive It is also undoubtedly true that cider made from the poorer varieties of apples, and in poor vintage years, is capable of great improvement by the addition of a certain proportion of cane-sugar syrup, as is done in the process of 'gallisising' wines, to obtain the correct proportion of acidity to sugar It is difficult to say what maximum proportion of this syrup should be allowed, but there is seldom any occasion for the use of more than 10 p c to make the cider suitable for the English market. The fact that there are so-called 'ciders' on the market, which are innocent of a drop of apple juice, shows the necessity for some sort of standard Generally speaking, it may be concluded that no cider can be considered genuine which does not contain at least 2 p.c. of alcohol by weight, or which does not show an original gravity of 1045 or upwards. Another vexed question is that of the use of preservatives, some people contending that it is impossible to do without them, and others that they are not necessary if Andes, stretching from Columbia in the north,

the cider be well and carefully made There is much to be said on both sides Some makers sulphur their casks, thus adding a certain quantity of sulphurous acid to the cider, but it is generally considered, though very strangely, that this does not constitute the addition of any chemicals.' Others use sulphites or salicylic acid, and justify their use by the argument that all eider, no matter how carefully made, is peculiarly susceptible to the various 'diseases' previously mentioned, and has often to be kept under conditions which render them unpreventable by any other known means, for example, on draught in a warm bar, perhaps for some weeks. There is certainly a great deal of reason in this, and it would probably be a hardship to absolutely prohibit the use of any preservative, but, on the other hand, they are sometimes used in needlessly excessive quanti-ties, which, in the interest of the public health, should be avoided The consumption of eider is rapidly increasing, due partly to its being recommended by medical men, and if it is to hold its own as a popular, and above all as a healthful, drink, it must be kept free from any ingredients of doubtful physiological effects.

CIGNOLIN. Trade name for 18-dihydroxyanthranol Used as a remedy for psorrasis Has a more energetic action upon the skin than its 3-methyl derivative, chrysarobin (q v), Wochenschr (Unna, Dermatol 1916, Nos 6-8)

CINCHOMERONIC ACID & BONE OIL

CINCHONA ALKALOIDS. The Cinchona Barks. 1 Their Discovery—The febrifuge properties of the back of the einchona trees growing on the slopes of the Andes was probably known to the native Incas long before its curative properties became known to their Spanish conquerous The earliest mention of a 'cure' is by Jussieu in 1600. The introduction of the bark to European countries was due to the Countess of Chinchon, wife of the Viceroy of Peru, who having been cured of an attack of fever at Lima in 1638, on her return to Madrid in 1640, brought with her some of the precious bark, and administered it to fever-stricken patients on her Spanish estates It is in her honour that Linnaeus named the species 'cinchona' For nearly 200 years the drug was administered in the form of a decoction of powdered bark, and the alkaloids in it were not isolated till 1816, when Gomez discovered the alkaloid cinchonine, followed by Pelletier and Caventou, who isolated quinine

2 The natural Cinchona Trees occur in a long but very narrow belt on the slopes of the through Ecuador and Peru to Belivia on the south. For the greater part of the last century the trees were ruthlessly cut down and the bark stripped from them by the Indian collectors, no attempt being made to replace them or cultivate seedlings, and consequently the species was being rapidly exterminated when more scientific methods were gradually introduced

The trees were first classified botanically by Weddell, in 1849, and in 1860 John Eliot Howard, F.R.S., brought up-to-date and translated the notes of the Spanish botanist Pavon (compiled in 1800), under the title of the

'Nueva Quinologia of Pavon,' and these two books still maintain their position as the standard works on the subject. In 1880 Sir Clements Markham published a most comprehensive work entitled 'Peruvian Bark,' and it is from this book that the compilers of these notes have obtained much of their information. The following table shows the locality and the botanical species of the various commercial barks on the London market in about 1870, and the analyses given, except when otherwise stated, were made by the present authors, of typical commercial samples which had been preserved in a collection of that date

Note.—The analyses marked J E H are from records of John Eliot Howard The results must be accepted with reserve, as at the date mentioned, the methods of separation of the different alkaloids were very rudimentary.

3 Transplantation and Cultivation—In the middle of the last century the necessity of dealing adequately with the devastations of malaria in India and the diminishing supply of natural cinchonas, directed attention to the

importance of their cultivation in suitable districts in that country.

In 1859 Sir Clements Markham organised expeditions to South America for the purpose of securing seeds of all the cinchonas then of

commercial importance. He himself headed a search for calisaya seeds in Peru and Bolivia Spruce collected succirubra in Ecuador, while Pritchett was responsible for the grey barks of Huanuco in Peru. In order to complete the series further expeditions under Cross were carried out in 1861 for officinalis back from Loxa (S. Ecuador), in 1868 for Pitayo bark from Columbia, and a final search in 1877 for soft Columbian and Carthagena barks.

Markham's narrative of these expeditions tells of the immense difficulties which were surmounted by these public-spirited pioneers, not only from the actual hardships of the expeditions, but also from the suspicious and often actively hostile attitude of the Indians, and to crown all, the problem of transporting the collections to the coast, and carrying them alive to England, and subsequently through the

Red Sea to India

All these difficulties were, however, overcome, and a large proportion of the seedlings survived the ordeal and were successfully planted in the Nilgiri Hills in 1861, under the superintendence of MacIvor. The cultivation of cinchona in India from MacIvor's seedlings rapidly spread, and plantations were established by private owners in the Nilgins, and in the Palnai Hills of Travancore In 1865 plantations established at Hakgala in Ceylon and in Coorg, followed shortly after by further enterprises at Wainad, Mysore, Darpling in Sikkim, and the Karen Hills in Burmah Maclyoi introduced two methods of harvesting the bank .-

1. Coppicing and allowing the tree to shoot

again from the same trunk, and
2 'Renewing' by mossing In the latter
process the back was removed in longitudinal strips about an inch wide, leaving a space untouched between each strip denuded of bark The tree was then bound round with moss and the bark allowed to 'renew' and cover the This method, although more laborious than coppicing, largely increased the yield of each tree David Howard (J Soc Chem Ind 1906, 26, 97) states that renewed bark is richer in alkaloids than the original, and that the proportion of quinine to other alkaloids is

In 1880, when Markham's book was published, the Indian plantations gave every promise of becoming the main source of supply for the markets of the world The fact that India does not find herself to-day in that fortunate position is shown in the following

table, and the cause in the next paragraph

A summary of sources of bark sold in European markets -

The explanation obviously rests on the rise of Java as the greatest cinchona producer, and it is therefore necessary to sketch briefly the history of this wonderful success of the Dutch in their principal colony.

The first attempt at cultivation in Java in 1852 ended in complete failure through the poor alkaloid-producing characteristics of the varieties of cinchonas of which seedlings were secured from South America, the only trees producing a tolerable yield being a small number obtained from MacIvor's plantations in the Nilgiris In 1855, however, Charles Ledger secured some seeds of Cinchona calisava, half of which were planted in India and half in Java. Those in India failed, owing either to the chmatic conditions or the mismanagement of the plantations after MacIvor's death. Those in Java, however, flourished exceedingly, and have produced a wonderful strain of trees, which, by skilful scientific cultivation, have produced, and are producing, back containing up to 10 pc of quinine, and which have, therefore, far surpassed any other variety in its market value from a manufacturing standpoint

4. Hybridisation and Grafting — David Howard (J Soc Chem Ind 1906, 25, 97) deals Grafting — David with the effect of hybridisation (partly deliberate and partly accidental) on Java barks, and mentions a very common hybrid of commerce known as Robusta, a hardy growth, which nearly rivals Ledgeriana in its alkaloid value Regarding grafting, he states that the 'Enten Baast' of commerce, from Java, is the result of grafting Ledgeriana on to a Succirubra stock, the bark from branches giving the characteristics of Ledgenana, while the root back retains the proportion of alkaloids common to Succirubra.

From a large experience of analysis of samples from different parts of the same cinchona trees, he found that the elaboration of alkaloid takes place solely in the downward course of the sap, and that the percentage of alkaloid increases in the bark from the twigs down the stem to the ground, in the less flourishing tices the root back being richest in alkaloid value, but of this alkaloid, the proportion of quinine and cinchonidine is lower, while that of cinchonine and quinidine is higher

5 The Commercial Aspect -In the same paper David Howard shows that the conquest of the world's markets by the Java planters was due to the careful and scientific work of Moens and others in the cultivation of the phenomenally 11ch Ledgeriana to the exclusion of the lower alkaloid-producing varieties, which enabled the Dutch growers to hold on during a period of about 20 years of bitter competition and low prices, which gradually ousted a large number of the older established, but less scientifically managed, Indian plantations from the market.

To emphasise the effect of successful Java cultivation the table given below shows two A, typical of the very best natural analyses Calisaya bark produced from wild trees in about 1865; and B, of a typical good quality cultivated Ledgeriana bark sold in Amsterdam ın May, 1914.

Quini- Cincho-Cincho-Quinine nidine dine nine Amor-Total phous alkaloids рс 0 165 рс 0.34 3 615 рс 075 5.800.937 92 0 105 0.08 0.0850 91

This shows the triumph of skilful cultivation in producing an enormous alkaloid yield of almost pure quinine, over the best unaided

efforts of nature.

6. Other Bark-producing countries only require a passing mention. The barks formerly produced by Jamaica and Mexico have disappeared from the market. The Portuguese possessions in West Africa produce bark regularly, the best-known source being the island of St Thomé South America still produces a considerable amount of bark, presumably now entirely from cultivated and not natural sources. A start was made shortly before the war in German East Africa, and although the plantations are at present small, the analysis of the samples shown below, if they can be regarded as typical, indicate very promising conditions, being in quality well up to the best Java production.

### PERCENTAGES OF ALKALOIDS PRESENT

Samples from German East Africa	Quimme	Cinchonidine	Cinchonine	Quandine	Amorphous	Total alkaloids

7. Other Trees producing Cinchona Alkaloids -Two other varieties of trees must be mentioned which, although belonging to the Remijia species, and not being botanically cinchonas at all, yet contain alkaloids of the cinchona group, which will be mentioned below

Bark of the Remijia pedunculata, known as 'Cuprea Bark,' was sold in considerable quantities on the London market in the early eighties, and its analysis is interesting, as being the only natural bark known which contains quinine and other alkaloids (including the rare alkaloid cupreme), but absolutely no einchonidine

The Remijia Purdieana contains interesting but rare members of the family of cinchona alkaloids, viz cinchonamine, chairamine, con-chairamine, chairamidine, and conchairamidine, the peculiar properties of which will be mentioned

REMIJIA PEDUNCULATA ('CUPREA') BARK.

#### REMIJIA PURDIEANA BARK.

Cinchonamine nitrate Nitrate of other paricine bases 3 30,

There is one variety of cinchona which, although valueless from a commercial point of view, since it contains none of the four alkaloids of commerce, has yet provided a considerable field for research, as several rare members of the cinchona alkaloid family have been extracted from it—It is described by Markham under the name of Pubescens, but was also called Pelleteriana (after the discoverer of the quinine base) and Cusco bank in commerce.

It would appear to have been widely distributed over the forests of Peru, and was found to be growing freely by Markham in the Cara-The alkaloids isolated from it vava district are cusconine, cusconidine, cuscamine, cuscamidine and aricine (called after Arica, the coast

town from which it was exported).

Before leaving the subject of barks, the tree Aspidosperma Quebracho, a member of the Apocynacex, must be mentioned. This was considered by Hesse (Annalen, 1870, 154, 287) to be identical with the Quina Blanca of Mutis.

Two alkaloids have been extracted from it, Paytine and Paytamine (so called from the port Payta in North Peru), which although not actually classified under any group of cinchona alkaloids, have a very similar empirical formula, and possess certain febrifuge properties which justify their inclusion under this heading

Principles of Cinchona Barks.—The following are the names and formulæ of the alkaloids occurring naturally in these barks, isomers being bracketed together -

Cinchonidine Cinchonicine (cinchotoxin) 3 4 Hydrocinchonine (cinchotine)
5. Hydrocinchonidine (cinchami) dine) Cinchonamine Cupreine C<sub>19</sub>H<sub>22</sub>O<sub>2</sub>N<sub>2</sub> Quinamine Conquinamine C19H24O2N2 10. Quinine Quinidine Quinicine (quinotoxin)

13. Hydroquinine C<sub>20</sub>H<sub>26</sub>O<sub>2</sub>N<sub>2</sub>

15. Chairamine Conchairamine 16 17 Chairamidine

18 Conchairamidine 19. Aricine

1. Cinchonine

20 Cusconine 21 Concusconine

22 Dieinchonieine C38H42ON4 Diquinicine (diconquinine) C40H46O3N4

24. Javanine

25. Cusconidine formulæ not determined

27 Cuscamidine

Paricine C<sub>16</sub>H<sub>18</sub>ON<sub>2</sub> 29 Paytine

29 Paytine  $\left\{ C_{21}H_{24}ON_{2}\right\}$ 

These are combined in the bark mainly as quinates and cinchotannates with quinic acid  $C_7H_{12}O_6$ , and cinchotannic acid  $C_{14}H_{16}O_9$ ; the former occurring to the extent of 5-8 pc., and the latter 3-4 pc in the barks. Quinovic acid C<sub>32</sub>H<sub>48</sub>O<sub>6</sub> and oxalic acid (as the calcium salt) are also present in small amounts. The

quinates are soluble in water, but the cinchotannates only slightly soluble, dilute acids, however, decomposing them and effecting solution The colouring matter in the bark is cinchonared C<sub>12</sub>H<sub>14</sub>O<sub>7</sub>, occurring to as much as 10 p c It is soluble in alkalis, being reprecipitated by Two glucosides,  $\alpha$ -quinovin and  $\beta$ quinovin, are usually present in all cinchonas, and give on hydrolysis quinovic acid and quinovose, a sugar isomeric with rhamnose (Liebermann and Giesel, Ber 1883, 16, 926) The neutral bodies, cinchocerotine, and the isomers, cupreol and cinchol  $C_{20}H_{14}O+H_{2}O$  (Hosse, Annalen, 1884, 228, 288; 1886, 234) 375), together with cholestol (Thoms, Arch. Pharm 1897, 235, 39), appear to be constant constituents of cinchona barks

The ash of these barks falls usually between 3 pc and 4 pc, a curious fact being that the greater the altitude at which the bark is grown the higher is the ash. In Indian backs the highest ash is found in Crown barks grown at 7000-8000 feet above the sea, falling in red barks grown at 5000-6000 feet, a minimum ash being found in Ledger bark, which grows at an altitude of 3000-5000 feet (Hooper, Pharm J 1886, 17, 545)

Constitution of the Cinchona Alkaloids -Only a short account of the great amount of work done on this subject can be given here, for fuller details, consult 'Vegetable Alkaloids,' by Pictet (Biddle, 1904), 'Die Konstitution der Chinaalkaloide,' by Comanduci (Sammlung chem u chem Vottage, 1911, 16, Bande, 4-7), and Rabe's and Kaufmann's articles in the Berichte and Annalen since 1907

The constitution of cinchonine has been the most fully investigated of these alkaloids, and its relation to the other common alkaloids being simple, it is an easy matter to deduce their constitution from that of cinchonine

Cinchonine  $C_{19}H_{22}ON_2$  is a ditertiary base forming  $d\iota$ -alkyl iodide addition products. On distillation with potassium hydroxide it gives, as the main product, quinoline, and a smaller amount of lepidine (4-methylquinoline), showing that cinchonine has a methylquinoline nucleus Cinchonine may therefore be written

On treatment with the halogens, or haloid acids, it forms addition products, taking up 2 atoms of halogen or I molecule of acid, a fact pointing to the presence of a vinyl group By the action of permanganate in the cold, a body, cinchotenine, which does not contain the vinyl group, is formed, and an atom of carbon is split off as formic acid, thus

$$C_9H_6NC_9H_{13}ON(CH\cdot CH_2)+4O$$
  
Cinchonine

$$\begin{array}{c} \longrightarrow \mathrm{C_9H_6N \cdot C_8H_{13}ON \cdot COOH} + \mathrm{H \cdot COOH} \\ \mathrm{Cinchotenine} & \mathrm{Formic\ acid} \end{array}$$

The vinyl group probably exists, therefore, in a side chain. Cinchonine and cinchotenine both contain a hydroxyl group, giving mono-acetyl derivatives. This completes the knowledge of the simpler groups in cinchonine, which can now be written C<sub>9</sub>H<sub>6</sub>N·C<sub>8</sub>H<sub>12</sub>(OH)(CH: CH<sub>2</sub>)N There remains the constitution of the C<sub>8</sub>H<sub>12</sub> portion to be elucidated, together with the positions of the hydroxyl and vinyl groups.

Now, on oxidising einchonine with chromic acid, the molecule is split in two, yielding about one-half its weight of cinchonic acid (10H2O2N (4-carboxyquinoline), and about half its weight of a syrupy mass consisting of a primary body, meroquinene  $\rm C_8H_{14}$  COOH N, and its secondary oxidation products, eincholoiponic acid

and loponic acid C<sub>5</sub>H<sub>9</sub>(COOH)<sub>2</sub>N Cinchonine acid is evidently the product of the methylquinoline nucleus, and the other three acids the product of the 'second' half of cinchonine The primary oxidation product of the 'second' half, meroquinene, throws much light on the constitution of this portion of the cinchonine molecule, and is known to have the formula

Now meroquinene is a secondary base, but as emehonine is ditertiary, meroquinene must be derived from a portion of the 'second' half, having the formula

$$\begin{array}{c} \operatorname{CH}_{2}\operatorname{CH}_{2}\operatorname{C} = \\ \operatorname{CH}_{2} \\ \operatorname{CH}_{2} \\ \operatorname{CH}_{2} \end{array}$$

This and the quinoline portion account for  $C_{18}H_{19}N_2$  of the einchonine molecule, and there remains but  $CH_2(OH)$ , for which positions must be found.

On heating cinchonine with acetic acid it undergoes isometic transformation into einchonicine, a molecular rearrangement in which the hydroxyl group vanishes, and a carbonyl group appears, the tertiary character of the 'second' half becoming secondary at the same time This is a change which Rabe's researches have shown to be effected by this grouping -

$$-CH(OH)-('H-N-\rightarrow -('I)-CH_2 NH$$

This supplies the last link required in the cinchonine molecule, which may now be formulated as the basis of the cinchona alkaloids .-

In cinchonine, cinchonidine, cinchonicine, quinine, quinidine, and quinicine R=-CH CH2. In hydrocinchonine, hydrocinchonidine, hy-

droquinine, and hydroquinidine R=-CH<sub>2</sub> CH<sub>3</sub> In cinchonine, cinchonidine, cinchonicine,

hydrocinchonine, and hydrocinchonidine X=H. In quinine, quinidine, quinicine, hydroquinine, and hydroquinidine X=OCH<sub>3</sub>.

In cupreine X=OH (with phenolic proper-

ties).

VOL. II.-T

Cinchonicine and quinicine have the ketonic grouping at carbon 4, as indicated above

The numbered carbon atoms are asymmetric, and the isomerism among these alkaloids is frequently due to the spatial arrangement around the carbon atom 3, since the asymmetry of the other three carbon atoms 1, 2, and 4 may be destroyed without interfering with the isomerism of the products (Rabe, Annalen, 1910, 373, 85)

It may be noted here that in the ditertiary bases fluorescence only occurs in those in which  $X = OCH_{\eta}$ , or a higher alkyl group. The toxicity of these alkaloids also appears to increase as the alkyl group in the X position increases from methyl to octyl

mediyi to octyi

The known conversions of one alkaloid into

another may be given

Cinchonine or cinchonidine on heating with moderately strong sulphuric acid is converted to cinchonicine; quinine or quinidine yielding on similar treatment quinicine (Pasteur, Compt rend 1853, 37, 110, 166)

By heating cinchonine in amyl alcohol solution with potassium hydroxide part is converted to cinchonidine (Königs and Husman,

Ber 1896, 29, 2185)

Cupreine is converted to quinine by heating at 100°C under pressure with sodium and methyl chloride in methyl alcohol solution (Grimaux and Arnaud, Compt rend 1891, 112, 776, 1364) Similarly, higher alkylated bodies may be prepared. Hydroquinine, when heated under pressure to 140° with hydrochloric acid, sp.gr 1 125, or boiled with hydrobromic acid sp.gr 1 49, or hydrodic acid sp.gr 1 7 is converted to hydrocupreine, its methoxyl group being replaced by —OH (Hesse, Annalen, 1887, 241, 255; Pum, Monatsh. 1895, 16, 73).

73).

The hydro- bases (in which R=-CH<sub>2</sub> CH<sub>3</sub>) may be prepared from their respective unsaturated alkaloids, dissolved in dilute sulphuricand, by the action of hydrogen under pressure in the presence of palladium black (Eng. Pat. 3948, Feb. 16, 1912). Cinchonieme has been converted to einchonine by Rabe (Ber. 1908, 41,

67; 1911, 44, 2088)

Kaufmann and Huber have converted hydrocinchonicine into a mixture of hydrocinchonine and hydrocinchonidine (Ber 1913,

46, 2913)

No complete synthesis of any of the cinchona alkaloids has been effected, although bodies very closely related to them both in structural formulæ and medicinal properties have been obtained (Ber 1913, 46, 1032 and 1823; 1917, 50, 144) Robinson has suggested by an ingenious method a possible phytosynthesis of those bases from formaldehyde, ammonia, and an acotone derivative. It is interesting to note that Perkin discovered the aniline dyes whilst trying to synthesise these bases.

Therapeutic Value—The first work of importance on the comparative therapeutic effect of the various alkaloids was in 1868, when an Indian medical commission reported on the relative efficiency of the four principal alkaloids then commercially obtainable in the treatment of malaria. This commission placed the alkaloids in the following order of

efficiency:

1st | Quinine | Quinidine.
3rd Cinchonidine.
4th Cinchonine.

At about the same time, J E Howard reported, as a result of his administration to patients suffering from the mild English malaria or ague still common at that time in the Essex marshes, that he considered quinine and cinchonine equally effective, and einchonidine and quinidine somewhat less satisfactory Of late years the researches establishing the constitutional formulæ of these alkaloids has led pharmacologists to study the particular arrangement of the groups in the molecule which has the greatest effect in malaria prophylaxis and other uses of quinine, and these researches, though at present incomplete, are being actively pursued in various directions.

The modern uses of the cinchona alkaloids may be divided roughly under four headings

1 In small doses as a tonic and stomachic

2 As an antimalarial remedy, acting as an agent that will destroy the malaria parasite. The most comprehensive work hitherto published is that of Major A C. MacGilchrist (Indian Journal of Medical Research, 1914, 2, 315 and 516; 1915, 3, 1)

About one-third of the quinne ingested undergoes cleavage of the molecule in the body, but whether it is this decomposed portion or the remaining two-thirds of the dosage which possesses its antimalarial properties appears not as yet to have been determined. The cleavage would appear to be the breaking off of the 'loiponic ring' (or second half) from the quinoline ring portion of the molecule, the former yielding some such nucleus, as is described by Koenigs under the name of ethyl-quinuchidine

$$\begin{array}{c|c} CH \\ H_2C & CH_2 & CHC_2H_5 \\ & CH_2 & \\ H_2C & CH_2 \\ \end{array}$$

It would appear that the methoxy group or  $-\mathrm{OCH_3}$  side chain of quinine and hydroquinine render the specific action greater than those alkaloids, such as einchonine and cupreine, which do not possess it following up this side chain theory, efforts have been made to prove that by increasing the value of this group as methyl hydrocupreine, or its more highly alkylated homologues, the antimalarial effect is still further increased. Results have not so far been very conclusive, and the point remains to be established in the future.

Another channel in which much investigation has recently been conducted is in the quinotoxin group of compounds. These have for many years been administered as a febrifuge under the name of quinoidine, which is really a mixture of quincine, cinchonicine, diquinicine, and dicinchonicine. The present researches, which are being carried out with the individual bases obtained in as pure a state as possible, depend upon the theory that the quinicine or quinotoxin molecule, for instance, owing to the opening up of the 'loiponic ring,' possesses

a greater specific action than the corresponding 'saturated' molecule

These researches are still incomplete, but if the fact were established that, owing to its increased specific action, quinotoxin could be administered in a very much reduced desage as compared with quinne, then owing to the comparative simplicity of its preparation, it might well form a formidable rival to the natural alkaloids of commerce

3. In treatment of Pneumonia —Most of the work in this direction appears to have followed the 'side-chain theory,' and to have been carried on with ethyl hydrocupreine which was before the war manufactured in Germany and sold in small quantities on this market under the registered name of 'Optochin' No work has, up to the present, been published to show whether a further increase in the side chain to the higher homologues renders this treatment more effective

Apparently the results obtained up to August, 1918, do not show any marked superiority over the ordinary commercial alkaloids.

4 As an Antiseptic in the treatment of Wounds—A considerable amount of work has been done in Germany on the use of the higher alkylated homologues of the hydrocupreme series as a wound treatment in war surgery Prof Klapp, following on the work of Morgenroth and Tugendreich (Pharm Zeit Nov 7, 1917, 603; and Deut Med Woch 1917, 44), claims that, by lengthening the side chain as far as the isoctyl member of the hydrocupreme series, he has obtained an antiseptic superior to any known wound dressing. He claims that this compound has 20 times the power of quinine, and 10 times that of ethyl-hydrocupreme, in the destruction of streptococci.

These comparative results are quoted as having been obtained 'in vitro,' and must therefore be accepted with reserve, and time alone will show whether this treatment will really be found to be superior to the far simpler and cheaper Dakin's solution or the highly satisfactory 'chloramine-T' treatment.

Although the precise relation between the constitution of the alkaloids and their therapeutic value has clearly not been established, enough work has been done to indicate a possible future for derivatives of einchona alkaloids either of the 'unsaturated' (quinotoxin) or of the 'increased side chain' type, which from the purely scientific and medical point of view, might be of even greater importance than the present universal use of the parent alkaloids as one of our few standard remedies

General Properties of the Cinchona Alkaloids.—These bases are mostly white crystalline nonodorous bodies, with a bitter flavour and strong basic properties, some being sufficiently powerful to displace ammonia from its salts. On heating strongly they decompose, evolving fumes of a colour resembling iodine vapour, and with a quinolinic odour. They are very slightly soluble in water, but are fairly readily soluble in organic solvents, there being, however, notable exceptions. Acids dissolve these alkaloids forming two series of salts, neutral and acid, of the general types B<sub>2</sub>H<sub>2</sub>SO<sub>4</sub> and B·H<sub>2</sub>SO<sub>4</sub>. Even more acid salts of the type B·2H<sub>2</sub>SO<sub>4</sub> are

obtainable in some cases. These salts are generally white crystalline bodies, of very varying solubility in solvents generally, and with a very bitter taste. Solutions of the salts in water when treated with alkalis precipitate the alkaloid, with the exception of cupreme, which, being phenolic in character, is soluble in alkalis.

A strong blue fluorescent solution is obtained with many of these alkaloids when dissolved in dilute sulphuric acid, viz quinnine, quindine, hydroquinne, hydroquinneme. This is a very delicate test which is best seen by reflected light. The haloid salts do not show this fluorescence, which is also destroyed by adding a haloid salt or hyposulphite to the sulphuric acid solution.

All the cinchona alkaloids have, in solution, a marked rotatory influence on polarised light, which is affected by the temperature of the solution, the solvent employed, the concentration, and the amount of acid present With mineral acids the maximum rotation is observed when the acid is present in little more than the amount to form the acid salt, but with organic acids a much greater amount of free acid is required.

When certain of these bases are treated in dilute solution with chlorine- or bromine-water, followed by ammonia added drop by drop, a deep green colouration or precipitate is obtained. This is known as the thalleroquin test (thallos, a young twig), and is given by quinine, quinidine, quinicine, hydroquinidine, cupreine, and diquinicine.

The emchona bases are di-tertiary amines forming mono- and di-alkyl rodide additive compounds

The hydrochlorides of the bases form double compounds with several metallic chlorides, of which the chief are. (a) the chlorozincates of the general formula B,2HCl,ZnCl<sub>2</sub>; (b) the chloromereurates B,2HCl,HgCl<sub>2</sub>, (c) the chloro-aurates B,2HCl,AuCl<sub>3</sub>; (d) the platinochlorides, of which there are two types, B,2HCl,PtCl<sub>4</sub> and B<sub>22</sub>2HCl,PtCl<sub>4</sub> Of these (c) and (d) have been much used in the determination of the molecular weights of the bases

The cinchona alkaloids are nearly completely precipitated from solution by tannic, pieric, or phosphotungstic acid, potassium mercuric iodide (Mayer's reagent), and potassium bismuth iodide (Dragendoiff's reagent)

Methods of Extracting the Alkaloids of Cinchona Barks —Before extracting the bark it must be treated in such a manner as will ensure the alkaloids being in a suitable condition for extraction For this purpose the back must be in a finely powdered condition, the finer the powder the more rapid and thorough being the The whole of the bark should be extraction ground to pass a sieve with at least forty meshes to the linear inch This point is of special importance in assaying, as cases are known in which the harder portions of the bark (which might be rejected as gruffs if the whole were not finely ground) are richer in alkaloids than the softer parts. The next stage in the process is that of liberating the alkaloids from their combinations with the natural acids of the bark. in order to render them soluble in the solvent employed. This is effected by moistening the

bark with a dilute alkali, or by mixing it with lime and damping with water, and allowing to stand for some hours The whole may then be dried, powdered, and extracted with chloroform, ether, petroleum spirit, or a mixture of these; or the damp bark may be extracted direct with petroleum, amyl alcohol, benzene, naphtha, or mixtures of these Thus Landrin (Compt. rend. 1889, 108, 750) and Zebel (Chem. Zeit. 1891, 15, 735) describe processes using petroleum; the Brit Pharm. 1914, directs the use of a mixture of 3 volumes of benzene and 1 of amyl alcohol; while the U.S Pharm 1916, employs a mixture of 2 volumes of ether and 1 volume of chloroform On the large scale the solvent employed will naturally be the cheapest, while on the small scale, where an efficient reflux extraction apparatus can be used, chloroform or ether are convenient

Zebel (1 c) describes the commercial process thus: The finely powdered bark is ground to a thin paste with lime, sodium hydroxide, or sodium carbonate, and extracted with warm paraffin oil On standing the oil separates, when it is run off and shaken with sulphuric acid: this acid solution is boiled, and while boiling is neutralised (to litmus paper) with sodium carbonate and allowed to cool Quining sulphate crystallises out on cooling, while cinchonidine, einchonine, and quinidine remain in solution as sulphates The quinine sulphate is purified by recrystallisation from water after treating with animal charcoal The motherliquor containing the other alkaloids is treated with sodium hydroxide and the precipitate treated with dilute alcohol Of the three bases precipitated, quinidine and cinchonidine are dissolved by the alcohol, while cinchonine is left behind: the two former can then be separated by means of their neutral tartrates, that of quinidine being considerably the more soluble

Landrin (lc) gives this description of the small scale extraction 300 grams of bank are powdered and passed through a No 40 sieve, then mixed thoroughly with 1 litre of milk of soda-line containing 75 grams of quickline and 75 grams of solution of sodium hydroxide (sp gr 1 375). To this mixture, diluted if necessary by adding a little water, 2 litres of petroleum are added, heated to 100° for 20 minutes, with constant agitation; the oil is then decanted, and the extraction repeated with a second 2 litres. The 4 litres of extract are washed twice with 75 cc of 10 pc sulphuric acid added to 150 cc of water, and a third time with one-third of these quantities.

The British Pharmacopera, 1914, method is as follows: 10 grams of the bark in No. 60 powder are mixed with 6 grams of slaked lime, and the whole moistened with 22 c.c. of water and allowed to stand for 2 hours. This is transferred to a flask provided with a reflux condenser and boiled with 130 c.c. of benzolated amylic alcohol (benzene, 3 volumes; amyl alcohol, 1 volume) during 30 minutes. The liquid is filtered off and the treatment repeated twice, the mixture of bark and lime being finally transferred to the filter and washed with the solvent till exhausted

The U.S. Pharmacopecia (9th revision, 1916) process is: Introduce 5 grams of einchona in No 40 powder into a 500 c.c. flask, and add

200 c e of a mixture of chloroform and ether (1:2) Stopper the flask, shake it well, and let it stand 10 minutes. Then add 5 c c of ammonia water, shake the flask frequently for 1 hour, and let it stand from 8 to 10 hours. Now add 10 c c of distilled water, shake the mixture thoroughly, and when the drug has settled decant 160 c c of the solution, representing 4 grams of cinchona. Filter through a pledget of purified cotton into a separator, and rinse both cylinder and cotton with ether. Completely extract the alkaloids from the chloroform-ether solution by shaking out repeatedly with weak sulphuric acid.

An older method of extracting the bark, due to de Vrij, was that of treating the powdered bark with a large excess of milk of lime, diying down and extracting with alcohol But this has been entirely given up owing to the great amount of colouring matter extracted with the alkaloids, and the consequent difficulty in

purification

Assay of Cinchona Barks - The accurate assay of a bark is much more difficult than appears at first sight owing to the obstinacy with which one alkaloid will form more or less definite compounds with the others when crystallising as alkaloid or salt, and also on account of the changes in its solubility in solvents when varying quantities of other alkaloids are present For these reasons a process of assay giving good results when, for instance, a Ledger bark, in which quinine is the main constituent is tested, will not be accurate for a Succirubia bark in which the cinchonidine and cinchonine usually exceed the quinine in amount knowledge of the type of bark being assayed, and of its alkaloidal contents, is therefore of great importance, the experienced analyst being able to foretell the state of purity of his various precipitates and so regulate his analysis

A 'full' analysis of a back usually consists of the estimation of the quinine, quinidine, cinchonidine, cinchonine, and total amorphous alkaloids To obtain satisfactory results a quantity of alkaloid of about 5 grams should be available It is desirable to start the assay with the estimation of the total alkaloids, as the subsequent work is simplified by so doing and the result is a useful check on the estimation of the individual alkaloids. For this purpose it is only necessary to evaporate the extract obtained by any of the methods described under the previous heading to constant weight; or, m the case of the paraffin and sulphure acid extraction, to make alkalme with sodium hydroxide, wash out with chloroform, and evaporate to dryness Dry to constant weight at 100°-110°. Having obtained the weight of total alkaloids, add 3 cc of 10 pc sulphuric acid for every giam of alkaloid, and warm on the steam-bath till completely dissolved. Then add 80 c c of distilled water for every gram of alkaloid, boil, and while boiling neutralise exactly to litmus paper with dilute ammonia solution (10 pc) On cooling for 2 or 3 hours with occasional stirring practically the whole of the quinine will crystallise out as sulphate, owing to it being almost insoluble in ammonium sulphate solution. Filter through counterpoised filter papers on the filter-pump, press the crystals down well, pumping as dry as possible,

and following with two washes of cold water each about equal in volume to the bulk of the precipitate. The filter papers and crystals are now dried to constant weight at 100°. The weight of anhydrous quinine sulphate found multiplied by I 18 gives the amount of rough hydrated quinine sulphate, or by 0 868 the amount of rough quinine alkaloid. This quinine sulphate is neither white nor pure, being usually contaminated with colouring matter and cinchonidine sulphate, and requires further treatment, for which see under 'Quinine Sulphate.' But with the present-day pure Ledgeriana barks the weight may be taken as representing the true amount of quinine sulphate, as in some thousands of analyses of this back by the present writers the amount of quinine sulphate left in the mother liquor almost exactly compensates for the impurities in the crystals weighed. It is, however, a safeguard in all cases to test for any undue amount of emchandine as described under 'Quinine Sulphate

To the mother liquor and washings from the crystals add about 20 grams of Rochelle salt, dissolved in 30 cc of hot water, and still occasionally during 2 or 3 hours Cinchonidine is completely precipitated as tartrate collected on counterpoised filter papers at the pump, washed with three lots of cold water each about equal in bulk to the precipitate, which is then dried and weighed. This weight multiplied by 0.797 gives the cinchonidine alkaloid Should the bark contain very little cinchonidine, and no tartrate be obtained in the 3 hours' standing, it is best to leave the solution for a full 24 hours to ensure complete precipitation. The filtrate from the cinchonidine tartrate is now evaporated to one-half, half its volume of methylated spirit and 5 grams of neutral potassium iodide dissolved in 5 c c of water are added, and the liquid left for at least 2 hours with frequent stirring The quinidine hydrodide is filtered off at the pump on a counterpoised filter paper, washed with a little 50 p c methylated spirit, dired and weighed 0 0008 gram is added to this weight for each 1 cc of filtrate and washings, which total multiplied by 0.7186 gives the quinidine alkaloid filtrate is made alkaline with sodium hydroxide and shaken with other (fice from alcohol) in a separator, the aqueous portion drawn off and twice again shaken with small quantities of ether, the ether extracts bulked, allowed to stand I hour, and the emchanine filtered off on counterpoised papers at the pump, two small washes with ether being given. The cinchonine is dried and weighed, and to its weight is added 0 0027 gram for each 1 cc of filtrate and washings The ether evaporated to dryness and constant weight gives the total amorphous alkaloids, from which should be subtracted the weights added on as corrections for quinidine and cinchonine.

The above method is made up of the best points of the many published methods of assay, and will be found to give good results in inexperienced hands For other methods, see Allen's Commercial Organic Analysis, 1912, vol. vi 490-495.

The British Pharmacopæia, 1914, specifies that the bark (C. succirubra) 'when used for official purposes other than the preparation of

alkaloids or their salts, shall yield 5-6 p.c. of total alkaloids, of which not less than half shall consist of quinne and cinchondine. The method used is that of extracting the amylated benzene solution of alkaloids (see above) with dilute hydrochloric acid, neutralising the acid solution with ammonia, and precipitating the quinne and cinchonidine together as tartrates by the addition of Rochelle salt. The remaining alkaloids are then precipitated from the filtrate by ammonia.

The United States Pharmacopora, 1905, prescribes 5 p.c. of total alkaloids and 4 p.c. of ether-soluble alkaloids (i.e. quimine, quimine and cinchonidine). This is carried out by dividing the acid solution of the alkaloids into two equal portions, shaking one with ammonia and chloroform-ether mixture to obtain total alkaloids, and the other with ammonia and ether for other-soluble alkaloids. The USP, 1916, omits the 'ether-soluble alkaloid' test

The German Pharmacopara (1910) method consists of estimating the total alkaloids by extracting the chloroform-ether mixture (1-3) with decinormal acid in excess, and titiating back the excess of acid over the neutral point with decinormal alkali, using alcoholic hamatoxylin solution as indicator. 65 p.e. of total alkaloids are required

Titiation methods are hable to senious errors and cannot be recommended, but can be employed as useful rough checks on analysis Generally speaking, the free alkaloids are neutral to phenol-phthalem, the neutral sulphates (B<sub>2</sub> H<sub>2</sub>SO<sub>4</sub>) are neutral to litmus, brazil wood, lacmoid, cochineal, and hiematoxylin, but alkaline to methyl-orange, which roughly indicates the bisulphate point (B H<sub>2</sub>SO<sub>4</sub>) (Allen, Analyst, 1896, 21, 85; Farr and Wright, Pharm J. 1894, 25, 124, Messner, Zeitschangew. Chem. 1903, 16, 444, Engelhardt and Jones, Pharm J. 1910, 30, 236, Katz, Bei Deut, pharm Ges. 1910, 20, 316).

Oudemans (Annalen, 1876, 182, 33) has strongly recommended the polarimetric assay of the einchona alkaloids, and a good deal of controversy has raged around the subject, the majority of the evidence appears to be against the method, owing to the difficulty of obtaining the bases in a pure enough condition for accurate polarimetric reading (Hesse, Annalen, 1875, 176, 205, 1876, 182, 128, Koppeschar, Zeitsch anal. Chem 1885, 24, 362; Léger, J Pharm Chim 1904, 19, 427).

Quinine and its Derivatives and Salts—Quinine alkaloid is usually prepared by precipitating a solution of quinine hydrochloride with an alkali or ammonia, washing free from chloride and drying at a low temperature. The commercial article is a soft white granular odourless powder with micro-crystalline structure, and contains up to 11 pc H<sub>2</sub>O (dihydrate). It crystallises from ethereal solution below 10° with 3H<sub>2</sub>O (14.3 pc H<sub>2</sub>O), but the ethereal solution evaporated gives a resmoid mass containing 1H<sub>2</sub>O (most other cinchona alkaloids give crystalline residues from ether). Alcoholic or ammoniacal solutions deposit needles with 3H<sub>2</sub>O, which rapidly efficience in the air above 15° giving a dihydrate. This is the composition of the commercial article, although most pharmacopoeias require the trihydrate. The

trihydrate loses all its water over sulphuric acid. It melts at 57°, and in estimating the moisture it is therefore best to dry for some hours at 40°-50°, then gradually raise the temperature to 100°. In this way no melting takes place, and the dehydration is rapid. Other hydrates containing 1, 8, and 9H2O have been described Anhydrous pure quinine melts at 174.9° It is a strong base displacing ammonia from its salts in hot solution, and neutralising the strongest acids. The pure base has a bitter taste, which develops slowly; the commercial article is more bitter on account of the presence of impurities which give more rapid solution Ammonium and calcium salts notably increase the solubility of the alkaloid in water, while the alkalıs render it less soluble. The anhydrous alkaloid is soluble in 1750 parts of water, in 3450 parts of potassium hydioxide (5 p c), and in 1890 parts of ammonia (10 pc) at 25°C The trihydrate is soluble in 0.8 parts of alcohol, 11 parts of chloroform, 19 parts of ether, 212 parts of glycerm, and 166 parts of benzene at 25°C Quinine is Levorotatory, the trihydrate having in 97 p c alcohol  $|a|_{D}^{15} = -145 \ 2^{\circ} + 0 \ 657c$ The anhydrous alkaloid in ether has  $[\alpha]_{D}^{15}$  $=-1587^{\circ}+1911c$ , where  $\epsilon=15-60$ 

The chief impurities likely to be met with in the commercial article are chlorides and sulphates of the alkalis or ammonia, lime salts, hydroquinine, emehonidine, and emehonine I gram should dissolve in a mixture of 6 cc. absolute alcohol and 3 c c ether to give a solution remaining bright on cooling (absence of einchonidine and cinchonine, and inorganic salts) Hydroquinine, which is liable to occur up to 2 pc, may be tested for as given under 'Quinine Sulphate'

Quinine is distinguished from the other alka loids by its ready solubility in ether, fluorescent solution in dilute sulphuric acid (detectable to the extent of 1 part in 500,000), by the thallerogum test, its insoluble neutral sulphate, taitrate and chromate, and by its iotation

The following are the more important derivatives of quinine — Quitenine  $C_{19}H_{22}O_4N_2$  or

C<sub>17</sub>H<sub>18</sub>O OCH<sub>3</sub> COOHN<sub>2</sub>

(Skraup, Annalen, 1879, 199, 348). This feeble base, together with formic acid, is obtained when quimme is oxidised with permanganate in acid solution at 0°, and bears the same relation to quinine as einchotenine does to einchonine (see 'Constitution') The quitenine is carried down by the oxide of manganese, from which it may be extracted with 40 pc alcohol concentration and filtration quitenine comes out in thombic prisms containing 4H2O, slightly soluble in water, insoluble in ether, but dissolves in acids and alkalis. Quitenine is identical with Kerner's dihydroxyquinine (Zeitsch Chem 1869, 5, 593) It gives the thalleroquin reaction, and dissolves in dilute alcoholic sulphuric acid with fluorescence It is laworotatory, giving  $[\alpha]_D = -142^\circ$ ; mp of anhydrous base 228° It gives a sulphate B<sub>3</sub>·2H<sub>2</sub>SO<sub>4</sub>,15H<sub>2</sub>O in fine needles Heated with sulphuric acid it is converted into an isomeric amorphous dark red base, quitenicine, very soluble in water. Its

constitution is that of quinine in which the vinyl is replaced by a carboxyl group. Heated with hydrodic acid (sp.gr. 1.7) its methyl group is

eliminated, and a new base, quitenol, is obtained

Quitenol C<sub>17</sub>H<sub>18</sub>O OH COOH N<sub>2</sub> crystallises in fine needles containing 1H2O, very slightly soluble in water, alcohol, or ether. It dissolves readily in acids and alkalis, being precipitated from the latter by CO2. It gives the thalleloquin reaction, and a red colouration in hydrochloric acid solution with ferric chloride Quitenol bears the same relation to quitenine, that cupreme does to quinine (Bucher, Monatsh. 1893, 14, 598).

Quininic acid C<sub>2</sub>H<sub>5</sub> OCH<sub>3</sub> COOH N (6-methoxy-4-carboxyquinoline) This acid is obtained on oxidising quinine with chromic acid, being the p-methoxy derivative of emchanine acid derived from emchanine under similar treatment (Skraup, Ber 1879, 12, 1104, Comstock and Komgs, Ber 1884, 17, 1984, 1886, 19, 2853) It forms yellowish prisms, almost insoluble in water, very soluble in acids and alkaloids. It is slightly soluble in absolute alcohol, giving a beautiful blue fluorescence, which is destroyed by water or acids with fuming hydrochloric acid under pressure it

loses its methyl group, yielding a phenolic body xanthoquinine acid C<sub>9</sub>H<sub>5</sub> OH COOH N

Meroquinene C<sub>6</sub>H<sub>10</sub> CH CH<sub>2</sub> COOH NH (v

Constitution (Skraup, Monatsh 1903, 24, This body forms small colourless needles, m p 223°-224°, very soluble in water and acids, almost insoluble in alcohol It is an interesting example of a body in which the acidity of the carboxyl group is neutralised by the alkaline properties of the remainder of the molecule  $[\alpha]_D$  in 10 pc aqueous solution  $+27.9^{\circ}$ . It readily forms esters On oxidation with chromic acid it gives cincholorponic and lorponic acids.

Cincholoiponic acid C<sub>6</sub>H<sub>10</sub>(COOH), NH This acid is derived from meroquinene by the oxidaacids and alkalis It forms rhombic prisms containing 1H<sub>2</sub>O, melting at 126°-127°, and when anhydrous, at 225°-226° It is a dibasic acid and a secondary base (Skraup, Monatsh 1896, 17, 372, 1900, 21, 879) When the hydrochloride of this acid is heated with resorein and concentrated sulphure acid, or zinc chloride, a fluorescein is formed, which indicates that the two carboxyls are in an ortho position to each other (Muller and Rohde, Ber. 1894, 27, 1188). A great deal of work has been done on the constitution of this acid, for upon it depends the proof of the constitution of the 'second' half of the molecule of the cinchona alkaloid later work on its stereoisomerides, see Konigs, Ber 1901, 34, 4336; Wohl, Ber 1907, 40, 4693, 4711, 1909, 42, 627 Loiponic acid  $C_5H_8(COOH)_2NH$  (hexahydro-

pyridine-3 4-dicarboxylic acid) v. 'Constitution' Prismatic crystals, m p 259°-260°, fairly soluble in water, easily soluble in alkalis and mineral

n water, cashy soluble in alkalis and mineral acids (Skraup, Monatsh 1896, 17, 366)

Quinine chloride C<sub>20</sub>H<sub>23</sub>(N)<sub>2</sub>Cl This body is formed when dry quinine hydrochloride is treated with phosphorus pentachloride in chloroform solution, the hydroxyl group of the quinine being replaced by chlorine It has basic properties, melts at 151°, gives the thalleoquin reaction, but does not fluoresce in acid

solution (Comstock and Konigs, Ber. 1884, 17, 1984; 1885, 18, 1219, 1892, 25, 1545) On treatment with alcoholic potash hydrochloric acid is eliminated with the formation of quinene.

Quinene  $C_{20}H_{22}ON_2,2H_2O$  forms large thombre crystals melting at  $81^\circ-82^\circ$ . On hydrolysis with 25 p c phosphoric acid it yields meroquinene and p-methoxylepidine (Konigs, Ber 1890, 23, 2669, 1894, 27, 900; 1895, 28, 3143, 1896, 29, 372). On heating with HBi (sp.gr 149) quinene yields apoquinene (p-oxyapocimeheno), thus.

 $\begin{array}{c} {\rm C_{20}H_{22}ON_2 + HBr + H_2O} \\ {\rm = C_{10}H_{19}O_2N + CH_3Br + NH_3} \end{array}$ 

Apoquinene  $\rm C_{19}H_{19}O_2N$  forms crystals melting at 246°, very slightly soluble in water, benzene, or ether, readily soluble in alcohol its solutions in sodium hydroxide or dilute hydrochloric acid are yellow (Konigs and Comstock, Bei 1885, 18, 1226 , 1886, 20, 2675)

Quininone C<sub>20</sub>H<sub>22</sub>O<sub>2</sub>N<sub>2</sub> (p-methoxyem hommon) is obtained by carefully oxidising quinine (or quinidine) with chromic acid in the presence of acetic acid. Treated with introus acid it yields quininic acid, and an oxime which splits up on hydrolysis into meroquimene and hydroxylamine (Rabe, Ber 1907, 40, 3655, 1908, 41, 62, Annalen, 1909, 365, 353, 1910, 373, 85, 1911, 382, 365). Upon this hydrolysis Rabe has based his formula for the cinchona alkaloids (see p. 89).

Dhydroquinine (1,0H2,0U2N). Schutzenberger (Annalen, 1858, 108, 348) obtained an only body by the action of zinc and sulphuric acid on quinine, which he named dihydroquinine. This is not the dihydroquinine of commerce, v. Hydroquinine (Hesse, Ber. 1882, 15, 854). Pum, Monatsh. 1895, 16, 72)

Tetrahydroquinine C<sub>20</sub>H<sub>28</sub>O<sub>2</sub>N<sub>2</sub> is obtained by the action of sodium and alcohol on quinine (Lippmann and Fleissner, Monatsh 1895, 16, 630), also by electrolytic reduction (Freund and Bredenberg, Annalen, 1914, 407, 43)

Dichlorquinine  $C_{20}H_{24}N_2O_2$   $Cl_2$  is formed when quinne hydrochloride, dissolved in a mixture of acetic and hydrochloric acids, is treated with 1 molecule of chlorine. It is a colourless amorphous compound, melting at 97°, and closely resembles quinne in its chemical behaviour. Treated with alcoholic potash it loses 2HCl, yielding dehydroquinine  $C_{20}H_{22}O_2N_2$ . By the further action of chlorine on dichlorquinine, a tetra-chlorimated body  $C_{19}H_{20}O_2N_2Cl_4$  is obtained (Christensen, Ber. Deut. pharm. Ges. 1915, 25, 256)

Hydroxychlorquinine  $C_{20}H_{24}O_2N_2ClOH$  is obtained as an amorphous colourless powder, mp 110°, when quinine dissolved in cold dilute hydrochloric acid is treated with 1 molecule of chlorine dissolved in water (Christensen, bid) When 3 molecules of chlorine are employed a tri-chlorinated body  $C_{19}H_{21}O_3N_2$   $Cl_3$  is obtained

Tetrabromquinine  $\rm C_{20}H_{24}O_2N_2$  Br<sub>4</sub>, obtained by treating quinine dissolved in sulphuric acid with excess of bromine-water. It is a yellow amorphous body with an odour of bromine.

Tribromquinine ('20 H24O2N2, Br3, obtained by treating an alcoholic solution of tetrabromquinine with H<sub>2</sub>S.

Dibromquinine  $C_{20}H_{24}O_2N_2\cdot Br_2+2H_2O$  is

obtained from the mother liquor of tribiomquinine by precipitation with ammonia. Another anhydrous dibromquinine is obtained by acting on a chloroform-alcohol solution of quinine hydrochloride with bromine dissolved in chloroform (Comstock and Konigs, Ber 1892, 25, 1500)

Iodoquinines. By the action of rodine dissolved in alcohol or potassium rodide many badly defined rodoquinines have been obtained, e.g. 4B 3I, 4B 5I, B HI I, B 2HI, B HI I4 (Bauer, Arch. Pharm. 1874, 5, 392)

Hydrochloroquinine C<sub>20</sub>H<sub>25</sub>ClO<sub>2</sub>N<sub>2</sub>, obtained by treating quinine at low temperature with HCl saturated at - 17°, mp 186°-187°. Insoluble in water, soluble in ether or methyl alcohol. It shows fluorescence and gives the thalleroquin reaction. Quinine is regenerated on treatment with alcoholic potash (Comstock and Konigs, Ber. 1887, 20, 2510, 1892, 25, 1539). Hesse obtained this body by heating quinine with HCl (sp.gr. 1189) at 85° (Annalen, 1868, 147, 241).

Hydrobromoquinine C<sub>20</sub>H<sub>26</sub>BrO<sub>2</sub>N<sub>2</sub> is obtained by treating quinne hydrobromide with HBi saturated at - 17°C, at a low temperature for 5 days. It is soluble in ether, but its sulphuric acid solution does not fluoresce (Connected and Konge, Rev. 1896, 20, 203).

(Comstock and Komgs, Ber. 1896, 29, 803) Hydroiodoquinine ( $^{\prime}_{20}$ H $_{28}$ IO $_2$ N $_2$ , obtained by treating quinne with H1 (sp gr. 19) on the water-bath for 1 hour Crystals melt at 150°–155° Soluble in ether, from which crystals containing I(C $_2$ H $_8$ ) $_2$ O are obtained. Its solution in sulphure acid is fluorescent, and gives the thalleroquin test. Heated with alcoholic potash it yields a mixture of quinne, pseudoquinne, isoquinne, and inquine (Skraup, Monatsh 1893, 14, 431, 446, Lippmann and Fleissner, ibid. 1891, 12, 327, 372, 1892, 13, 429, 1893, 14, 553)

Apoquinine  $C_{10}H_{20}(OH)_2N_2$  is obtained by heating quinine under pressure to 145° with HI (sp gr 1 25-135). It is an isomeride of cupteme, which is also converted to apoquinine by heating under pressure with HCl (sp gr 1 125). It crystallises in large needles of m p 210°, and  $\lfloor \alpha \rfloor_D^{15} = -178$  1° for a 2 p c solution in 97 p c alcohol. The acid oxalate  $B_2 \, 3C_2H_2O_4$  and iodohydrate  $B_2 \, 2H_1$  crystallise readily. It gives similar addition products to quinine with the haloid acids, hydroiodoapoquinine yielding on treatment with alcoholic potash the isomer isoapoquinine melting at 176° (Lippmann and Fleissner, Monatsh 1891, 12, 332, 1893, 14, 553; 1895, 16, 33, Mauther, Ber. 1895, 28, 1972)

Derivatives Isomeric with Quinine — Niquine  $C_{19}H_{24}O_2N_2$  (see Hydroiodoquinine) This alkaloid behaves very similarly to quinine, forming similar salts, addition products, &c. Its sulphuric acid solution fluoresces, and it gives the thalleloquin reaction. It is soluble in alcohol, ether, chloroform, or benzene, slightly soluble in boiling water, from which crystals containing  $2H_2O$  are obtained,  $\lfloor \alpha \rfloor_D = -129~2^\circ$  for a 1 p c solution in 98 p.c. alcohol (Skraup, Ber. 1892, 25, 2911, Monatsh. 1893, 14, 428, Lippmann and Fleissner, Monatsh. 1893, 14, 426, 553) By treating the bihydrioidde of hydroiodo-niquine with alcoholic potash inquine is

in part reformed together with an isomer isoniquine.

**Isoniquine**  $C_{19}H_{24}O_2N_2$  crystallises from alcohol-in the form of benzoic acid and melts at  $208^\circ-209^\circ$ . It shows fluorescence in sulphuric acid, and gives the thalleroquin reaction (Skraup, Lippmann and Fleissner,  $l\,c$ )

**Pseudoquinine**  $C_{20}H_{24}O_{2}N_{2}$ , an isomer of quinine ( $\theta$  hydriodoquinine), forms prisms melting at  $190^{\circ}-191^{\circ}$  It is not very soluble in other, readily soluble in alcohol,  $[\alpha]_{D} = -164 \ 4^{\circ}$ 

for a 1 p c solution in 98 p c alcohol

Isoquinine  $C_{20}H_{24}O_2N_2$ , an isomer of quinine (v hydroiodoquinine), crystallises in needles, melting at  $185^\circ$ – $186^\circ$ , and having  $[\alpha]_D^{27}=-186^\circ$ 8° for 0.9 p.c. solution in 97 p.c. alcohol. It is readily soluble in ether and benzene, very slightly soluble in boiling water, and reacts generally slike quinine (Skraup, Monatsh. 1893, 15, 433, 1894, 16, 37). Hesse has also named a base isoquinine, which he obtained by the action of concentrated  $H_2SO_4$  on quinine at  $120^\circ$ – $130^\circ$ , or by heating with glycerin at  $180^\circ$ – $210^\circ$  (Annalen, 1874, 174, 340, 1875, 178, 253, 1888, 243, 149, 1893, 276, 103)

Quinicine (qumotoxin) C<sub>20</sub>H<sub>24</sub>O<sub>2</sub>N<sub>2</sub>, an isomer of qumine, was first prepared by Pasteur in 1853 by heating quinine bisulphate with a little water at 160°, and afterwards isolated from quinine tails by Howard (Chem. Soc Trans. 1871, 24, 61, 1872, 25, 1011). It forms a reddish-yellow amorphous mass melting at about 50°, nearly insoluble in water, soluble in chloroform, ether, and alcohol, the latter solution rapidly absorbing CO<sub>2</sub> from the air. It forms salts of which the oxalate B<sub>2</sub> C<sub>2</sub>H<sub>2</sub>O<sub>4</sub>,9H<sub>2</sub>O bitartiate B C<sub>4</sub>H<sub>6</sub>O<sub>6</sub>,6H<sub>2</sub>O, sulphocyanide

B HCNS, 1H,O

hydriodide B HI, H2O, chloroplatmate

B H, PtCl, 2H, ()

and aurichloride are crystalline. Hesse also obtained a crystalline sulphate  $B_2$   $H_2SO_4$ ,8 $H_2O$ . It is completely precipitated from its solutions by excess of potassium thiocyanate as an oil rapidly becoming crystalline.  $[a]_D^{15} = +44$   $1^\circ$  for a 2 p c. solution in CHCl $_3$ . It gives the thalle-ioquin reaction, but does not show fluorescence in sulphuric acid solution. It is soluble in ammoniacal salt solutions, from which ether extracts it (separation from other cinchona alkaloids). (Hesse, Annalen, 1875, 178, 213; Miller and Rohde, Bei 1895, 28, 1058; Skraup, Monatsh 1899, 20, 573, Howard and Chick, J. Soc. Chem. Ind. 1909, 28, 53; Pharm. J. 1917, 99, 143)

Quinine Salts — Quinine sulphate

 $B_2 H_2 SO_4, 7\frac{1}{2} H_2 O$ 

This salt occurs as white light silky needles, odourless, but with an intensely bitter taste. The hydration is rather indefinite, being recognised as  $8\mathrm{H}_2\mathrm{O}$  by the French Pharmacoperu (=16 17 p.c.),  $7\frac{1}{2}\mathrm{H}_2\mathrm{O}$  by the B P. (=15·3 p.c.), and  $7\mathrm{H}_2\mathrm{O}$  by the USP. (=14·5 p.c.) It is completely dehydrated at  $100^\circ$ . Exposed to the air it loses water until  $2\mathrm{H}_2\mathrm{O}$  remain (=4·8 p.c.), the same amount being absorbed if the fully exsiccated salt is exposed to moist air. The chemically pure salt crystallises in large heavy

needles, the lighter character of the commercial article being due to the presence of a little hydroquinine and cinchonidine, or by being crystallised slightly alkaline or from solutions containing ammonium sulphate. It is soluble m 740 parts of water at 15°, in 30 parts at 100°; in 65 parts of alcohol at 15°, in 6 parts at boiling-point, in 24 parts of glyceim at 15°, 1000 parts of chloroform at 15°, leadily soluble (1 m 7) in a mixture of chloroform, 2 parts, absolute alcohol, 1 part. The sulphates of the other cinchona bases and morganic impurities are insoluble in this mixture, which is therefore a good test for the purity. It is much less soluble in water containing magnesium, sodium, or ammonium sulphate, but more soluble if calcium, sodium, or ammonium chloride, or potassium nitiate or chlorate be present. Quinine sulphate has  $[\alpha]_D^{17} = -157 \ 4^\circ$  in absolute alcohol at a concentration of 22 pc of the 7½H2O salt Alpc solution of the anhydrous sulphate m excess of dilute  $H_2SO_4$  has  $[a]_0^{15} = -235^\circ$ . A dilute  $H_2SO_4$  solution shows a strong blue fluorescence, detectable with about 1 part of quinine in 500,000 On treating a neutral solution of the sulphate in cold water with a slight excess of chlorine- or bromine-water added drop by drop, agitating for 20 seconds, and then adding ammonia drop by drop until faintly alkaline, a deep green colour is produced, or if more than I in 1000 of quimine is present a green precipitate is obtained (thalle-loquin reaction). On neutralising the alkaline solution with dilute acid the colour changes to blue, which with more acid becomes red, reverting to green on again making alkaline By a modified procedure Ramsden and Lipkin (Annals Trop Med 1918, 11, 443) are able to detect 1 part of quinine in 400,000 Neutral solutions of quimine sulphate in water give the following almost insoluble precipitates with potassium chromate  $B_2 H_2 Cr O_4, 2H_2 O$ , soluble 1 in 3150, with potassium oxalate

 $B_2, C_2H_2O_4, 6H_2O$ 

soluble 1 in 1400, with potassium picrate  $B_2$ ,  $C_8H_3N_2O_7$ , soluble 1 in 3400, with sodium salicylate B,  $C_7H_6O_3$ ,  $H_2O$ , soluble 1 in 2100, with tannic acid B,  $(C_{14}H_{10}O_9)_3$ ,  $8H_2O$ , soluble 1 in 2000, with Rochelle salt  $B_2$ ,  $C_4H_6O_8$ ,  $H_2O$ , soluble 1 in 950, all at 25° These are the solubilities of the respective precipitates in water; the solubility is less in excess of the reagent

On adding alcoholic iodine solution to an alcoholic solution of quinine acidined with sulphuric acid an iodosulphate of quinine  $B_4(H_2SO_4)_3(HI)_2I_4,6H_2O$ , called after its discoverer, Herepathite, is thrown down as a reddish precipitate (Ann Chim Phys 1854, 40, 249) It crystallises from strong alcohol in tabular crystals, green by reflected light, and red by transmitted light, almost insoluble in cold water or dilute alcohol, soluble I in 1000 of hot water, but much more soluble in acidified alcohol. By a special method of concentration, Ramsden and Lipkin have been enabled to identify as little as I part of quinine in 4,000,000 of urine, or in 20,000,000 of water by the herepathite reaction under the micropolariscope (Anpals, Trop. Med. 1918, 11, 444). Jorgensen

(J pr. Chem. 3, 145; 14, 213, 256; 15, 65) has prepared whole series of salts similar to herepathite, having varying quantities of acid, iodine, and water.

Most of the above-mentioned insoluble salts have been proposed as means for the estimation of quinine in mixtures of the cinchona alkaloids, but none have stood the test of time on account of the separations not being at all perfect, others of the alkaloids being co-precipitated

Estimation—Two classes of products will be dealt with here (a) the rough quinine sulphate obtained as described under 'Assay of Cinchona Barks,' and (b) commercial quinine sulphate The only alkaloidal impurities likely to occur in either are cinchonidine and hydrogumine. Of these two, hydroquinine is easily and rapidly estimated, but the estimation of cinchonidine is a much more difficult matter For instance, it might be thought that advantage might be taken of the different solubilities of quinine sulphate (1 in 740) and einchonidine sulphate (1 in 92) in water at 15° But it is found that on dissolving a quinine sulphate containing cinchonidine in water at 100°, and allowing the solution to cool to 15°, the majority of the emchanidine will crystallise out again with the quinne. As many as four recrystallisations will be necessary to remove the whole of the emchanidine from the quinine. If now the mother liquois be combined and evaporated to dryness on the steam-bath a product is obtained containing about one-fifth of the original quinine together with all its impurities. If this salt be now shaken into purified ether and aqueous ammonia (sp gr 0 959) and cooled down to 0° for 24 hours, most of the anchonidine will crystallise out at the layer of the two liquids, and may be filtered off, dried, and weighed. A modified form of this test, due to Prunier (J Pharm Chim. 1891, [v.] 23, 163 and 265), was the official method of the BP. 1898, but being a very tedious process is no longer employed. Another method consists in pre-cipitating a neutral solution of the quinine sulphate with Rochelle salt, drying and weighing the combined quinine and cinchonidine tartrates, and taking the polarimetric reading still employed in some laboratories, and usually gives fairly accurate results in experienced hands. But it must be remembered that as the optical relations of the alkaloids are so diverse that should even a small percentage of hydroquinine taitrate be co-precipitated it will lead to inaccurate results. The temperature of the reading is also very important, as well as the concentration of the solution (Oudemans, Annalen, 1876, 182, 33, Hesse, ibid. 128; Koppeschar, Zeitsch anal. Chem 1885, 24, 362; Hooper, Pharm. J. 1886, 17, 61; Jung-fleisch, J. Pharm. Chim. 1887, 15, 5, Léger, ibid. 1904, 19, 427; Montemartini and Bovini, Gazz. chim ital. 1916, 46, 153)

De Vrij proposed a method of precipitating the quinine as neutral chromate (Arch Pharm 1887, 24, 1073), which was severely criticised by Hesse (Pharm J. 1887, 17, 585, 665; see also Paul, ibid 585, footnote).

Schaefer (Arch Pharm. 1887, 25, 64) proposed a separation by means of the insoluble neutral oxalate of quinine, but the separation is not complete.

A better method is that proposed by De Vrij (Chem Zeit. 1885, 968), and recommended by Hesse (Pharm J. 1886, 17, 486) and D. Howard (Pharm J. 1896, 3, 505), which takes advantage of the fact that when 5 grams of quinine sulphate are dissolved in 12 cc, of N/1H<sub>2</sub>SO<sub>4</sub>, and allowed to crystallise, 80-90 p c. of the quimine crystallises out as bisulphate, the whole of the emehomdine remaining in the mother liquor. The crystal is filter-pumped and washed with 3 e.c. of cold water, and the filtrate shaken into 16 c c ether (sp gr. 0721-0.728) and 3 cc of ammonia (sp gr 0.959), and left to stand for 24 hours, preferably at 0° The cinchonidine crystallises out and may be filtered off, washed with a little water saturated with ether, dried, and weighed. Hesse points out that this einchonidine is not pure, but consists of a double compound of quinne and conchonidine  $(C_{20}H_{24}O_2N_2\cdot 2C_{19}H_{22}ON_2)$ , and a portion of the cinchonidine is also soluble in the ethereal quinine liquor, these errors almost exactly compensating each other (Howard, l.c.). However, should quite accurate results be desired, the process may be modified by evaporating the first bisulphate mother liquor until it will again crystallise (sp gr 1 100), filter-pump the crystals and wash as before, and shake this more concentrated cinchondine liquor into ether and ammonia solution. The impure cinchonidine obtained is dired and weighed, then dissolved in hot absolute alcohol, and 2.1 c c of 50 p c H2SO4 added for each gram, and allowed to cool and stand, when the cinchonidine crystallises out entirely as tetrasulphate is filtered off on the pump, washed with a little alcohol, dissolved in water, precipitated with sodium hydroxide, filtered, washed with water, dried, and weighed as alkaloid. The alcohol mother liquor is diluted with water, the alcohol evaporated off on the water-bath, the two lots of bisulphate crystals added, and the solution diluted and neutralised with ammonia, when, on cooling, the pure quinine sulphate crystallises out and may be filtered off, dried, and weighed. For rough quinine sulphate products (a) it

is best to dissolve them in 40 times their weight of boiling water in a flask, add 10 p c of animal black and a few drops of dilute sulphune acid, boil for 20 minutes, filter, and allow to crystal-Filter off the quinine sulphate and return the mother liquor to the flask, together with the filter-paper and animal black, boil for 20 minutes, filter at the pump, wash the filter-paper with two or three lots of boiling water, evaporate down to about one-sixth of its bulk and neutralise with ammonia to litmus paper Allow to cool and crystallise, filter off the quinine sulphate, and add this to the first crystals Dry and weigh the decolourised quinine sulphate. This should then be put through one of the tests for cinchonidine given above, for preference De Vrij's bisulphate test. The mother liquor from the decofoursed sulphate is added to the mother liquor from which the original impure sulphate was obtained, and is put through tests for other alkaloids described under the 'Assay of Cinchona Barks.' It should be noted here that neutral quinine sulphate is absorbed from its solutions by animal black (up to 15 p.c. of the weight of black used), and for that reason 'blacking in neutral solution is not permissible.

For commercial quinine sulphates (b) similar methods to the above may be employed, but as no (or infinitesimal) colouring matter is present the first decolourising process is not But as the above methods take considerable time to carry out the phaimacopæias adopt a qualitative test, in various forms, suggested by Keiner (Zeitsch anal Chem. 1862, 150, Arch Pharm 1878, 14, 438; ibid. 1887, 25, 712, 749) This test depends upon the fact that quinine sulphate is the least soluble of the sulphates of the cinchona bases, and that quinine is the most soluble of the common bases in dilute ammonia. When 2 grams of pure quinine sulphate is shaken with 20 ce of water at 60° for some time, and then cooled to 15° for at least half an hour (to prevent supersaturation), it gives a filtrate which precipitates with aqueous ammonia (sp gr. 0 959), the precipitate just redissolving when 4 3 c c ammonia have been added Now, quinine sulphate containing any of the other cinchona sulphates when treated in this manner takes more ammonia to give a clear solution; and by this means some idea of the purity of the quinine sulphate This test has been universally is obtained adopted by the pharmacopeeas, to which reference should be made for full details, as the directions vary in the different pharmacopæias Quinine sulphate containing about 5 p c total of cinchonidine and hydrogumine sulphates will require between 6 and 7 cc of ammonia, while one containing about 10 p c of these impurities will require about 10 c c Points to be noticed in applying the test are that the weights of quinine sulphate and water taken do not, within reasonable limits, affect the result, the solution should be cooled gradually to 15° (never below), and retained at that temperature for not less than 30 minutes, the filtration should be rapid and the mixing very carefully done by gently rotating and tilting the testing tube, otherwise clotting of the precipitate may take place and a false result obtained test is greatly influenced should the quimine sulphate have an alkaline reaction (presence of free quinine), when the result is much in excess of that required for a neutral sulphate of the same degree of purity (D. Howard, Pharm. J. 1896, iv. 3, 505); and also by the presence of alkaline sulphates, which make it appear purer than it is (Tutin, Pharm J 1909, iv. 29, 606) These points should be ascertained by testing the filtrate for neutrality with litinus paper, and by evaporating 5 c c to dryness and constant weight, when the residue should not weigh more than 0 008 gram, showing the absence of soluble morganic salts (Biginelli, Monit Scient 1908, 22, 175) Should the cooling of the mixture be carried out above 15° a larger amount of ammonia will be required, and between 15° and 20° a correction of 0.5 c c of ammonia for each degree above 15° may be applied

Hydroquinine is best tested for by dissolving the quinine sulphate in dilute  $H_2SO_4$ , cooling to  $0^\circ$ , and adding 4 p.c. permanganate solution with constant stirring, so long as it is rapidly decolourised. The solution is then warmed, the coagulated manganese dioxide filtered off, the filtrate made alkaline with ammonia and shaken out with ether. The ether

solution filtered and dried to constant weight will give the amount of hydroquinine present

Quinidine, einchonine, and amorphous alkaloid, which are seldom met with except in very rough quinine sulphate, are best estimated by recrystallising the salt and putting the mother liquor through the process given under the 'Assay of Cinchona Barks.'

Cupreine, never present now in commercial barks, may be estimated by shaking the recrystallised quimine sulphate into ether and sodium hydroxide, running off the aqueous portion, and washing it twice with more ether. The aqueous liquor is then run into a basin, acidified with sulphuric acid, and neutralised with ammonia. On cooling any cupreine sulphate present crystallises out.

For the estimation and examination of quinine sulphate, see Hille, Arch Pharm 1903, 241, 54, and Lenz, Zeitsch anal Chem 1888, 27, 549.

Kerner's test is recommended also for the other salts of quinine by all the pharmacopenas, but Tutin ( $l\,\epsilon$ ) has pointed out that the results obtained are quite useless, this is confirmed by the present writers' experience. The best method of examination of quinine salts, other than sulphate, is that of obtaining the alkaloid by putting through ether and ammonia, and following the procedure given under 'Assay of Cinchona Barks'

Quinine disulphate B H<sub>2</sub>SO<sub>4</sub>,7H<sub>2</sub>O crystallises out in white rhombic prisms when the normal sulphate is dissolved in an equivalent of 5 p c H<sub>2</sub>SO<sub>4</sub>. The salt effloresces readily, losing 6H<sub>2</sub>O over sulphune acid, and becoming anhydrous at 100°. When fully hydrated the salt softens at 60°, and as it melts gradually decomposes into quinicine bisulphate (Howard and Chick, Pharm J. 1917, 99, 143). The dehydrated salt melts at 160°. It has an intensely bitter taste and the aqueous solution is strongly fluorescent. It is soluble in 10 parts of water and m 45 parts of alcohol at 15°, in 18 parts of glycerin, 920 parts of chloroform, and in 1770 parts of ether at 25°, in 1 part of water, and 0.5 part of alcohol at 60°. On exposure to light it turns yellow to brown on the surface of the crystals. This salt is usually very pure on account of the bi-sulphates of the other bases being much more soluble.

Quinine tetrasulphate B2H<sub>2</sub>SO<sub>4</sub>,7H<sub>2</sub>O is obtained by dissolving the bisulphate in excess of strong sulphuric acid and concentrating over H<sub>2</sub>SO<sub>4</sub>. It is very soluble in water, less so in alcohol (Hesse, Annalen, 1873, 166, 222).

Quinine hydrochloride B HCl,2H<sub>2</sub>O is obtained by decomposing a solution of quinine sulphate with barium chloride 1t forms long needles, which become anhydrous at 100°, and melt at 158°-160° without decomposition. The commercial salt contains about 8 pc H<sub>2</sub>O, and is usually very pure 1t is soluble in 40 parts of water, in 9 parts of chloroform, and in 3 parts of alcohol at 15°, in 1 part of bolling water or 90 pc alcohol It is largely replacing the sulphate in medicine on account of its superior solubility

Quinine dihydrochloride B.2HCl, made by adding an equivalent of hydrochloric acid to the normal hydrochloride and carefully drying. It is a white crystalline powder containing

2-3 p.c H<sub>2</sub>O. Soluble in 0.75 part of water, 5 parts of alcohol, or 7 parts of chloroform, at 15°; insoluble in ether.

Quinine hydrobromide B·HBr,H<sub>2</sub>O, made similarly to the hydrochloride, or by dissolving quinine alkaloid in one equivalent of HBr Long white silky needles, soluble in 50 parts of water, 7 parts of alcohol, or 10 parts of chloroform at 15°, in 1 part of boiling water. It fuses at 152°, melting completely at 200°.

Quinine dihydrobromide H 2HBr, 3H<sub>2</sub>O, made by adding one equivalent of HBr to the normal hydrobromide Large yellowish prisms, melting at 81°-82°, and soluble in 7 parts of water at 15°. Very soluble in hot water or alcohol, insoluble in other

1 in 120 at 15° (73 0 p c). There are three general methods employed in making quinine salts: (1) to decompose as aqueous solution of quinine sulphate with the barium salt of the acid, (2) to dissolve quinine alkaloid in a dilute aqueous solution of the acid, and (3) to dissolve quinine alkaloid and the acid in separate portions of an organic solvent by heating, mix the solutions, and allow to cool and crystallise, or evaporate off the solvent.

lise, or evaporate off the solvent

\*Quinine Esters\*\*—The following esters of quinine are also in use \*—\*

Acetylquinine  $C_{20}H_{23}O_2N_2$  COCH<sub>3</sub>, made by heating quinine alkaloid with acetic anhydride at  $60^\circ$ – $80^\circ$  for several hours. The product is diluted with water, piccipitated with ammonia, the acetylquinine collected, diied, and recrystallised from petroleum ether, in p. 116°–117°

Anisylquinine

made by heating quinine alkaloid with phenylanisate at  $120^{\circ}-130^{\circ}$  for several hours. The warm melted mass is treated with benzene and the free phenol removed with dilute NaOH. The ester is shaken out with dilute acid. Fine white needles. Mp. 87°-88° Benzoyl-quinineC $_{20}H_{43}ON_{2}$  O CO C $_{6}H_{5}$ , made

Benzoyl-quinineC<sub>20</sub>H<sub>23</sub>ON<sub>2</sub>O CO C<sub>6</sub>H<sub>5</sub>, made in a similar way to the above, by heating together quinine alkaloid and phenyl benzoate for several hours at 130°–140°

 $\begin{array}{ccc} \textbf{Cinnamyl-quinine} & C_{20}H_{24}ON_2 \ O \ COC_8H_7, \\ \text{made by treating quinine suspended in benzene} \\ \text{with a solution of cinnamyl chloride in benzene.} \\ \text{Tasteless needles, soluble in hot, sparingly soluble in cold, water} & M p. 235°-236° \\ \end{array}$ 

Diquinine carbonate ('Aristoquinine')

made by adding quinine alkaloid to a solution of phosgene in benzol, washing the resulting mass with water, and recrystallising the rough aristoquinine from alcohol—It forms crystalline groups of needles of m p—189°—It is an important ester on account of its tastelessness and its high percentage of quinine—96 I p c

Quinine ethyl carbonate (Euquinine)

$$\mathrm{C}_{20}\mathrm{H}_{23}\mathrm{ON}_2\mathrm{O},\mathrm{CO}|\mathrm{OC}_2\mathrm{H}_5$$

is similarly made by adding quimine to a benzol solution of ethylchloroformic ester. It occurs as white needles, tasteless; mp 95°. Easily soluble in alcohol, ether, and chloroform, not in water. It gives the thalleroquin reaction and fluoresces in dilute H<sub>2</sub>SO<sub>4</sub>. It forms similar

salts to quinine, but does not give the herepathite reaction. Its salicylate, a white tasteless crystalline powder, m.p. 195°, is the only commercial salt

Salicylquinine ('Saloquinine')

 $\mathrm{C}_{20}\mathrm{H}_{23}\mathrm{ON}_2\mathrm{O}\mathrm{COC}_6\mathrm{H}_4\mathrm{OH}$ 

made by heating quinine alkaloid with salol for several hours at 140°-150°. It crystallises from ether in large colourless crystals insoluble in water, mp 140°. Its salicylate is known as 'Rheumatine'

Quinine carbophenetidide ('Chmaphenme')  $C_{20}H_{23}ON_2O$  CO  $NHC_6H_4OC_2H_6$  occurs as a white tasteless powder, slightly soluble in water, easily soluble in organic solvents

Hydroquinine, its derivatives and salts.

**Hydroquinine**  $C_{20}H_{26}O_2N_2$  is invariably present in commercial quinine sulphate to the extent of 1–2 p c. It may be prepared (and estimated) by converting the quinine sulphate into bisulphate by the addition of 12 ce of N/IH2SO4 for each 5 grams of salt taken, filtering off the crystals, evaporating the mother liquoi again to crystallising-point, filtering off the second crystals, adding ice to the mother hquor till cooled to 0° and then adding ice-cold permanganate solution drop by drop with constant sturing until the colour of the permanganate is no longer rapidly discharged The liquor is now warmed until the manganese oxide coagulates, when it is filtered and shaken with ammonia and ether The aqueous portion is given two more washes with ether, the ethereal solutions bulked and evaporated to dryness, the hydroquimine alkaloid being obtained as a pale yellow crystalline mass

Commercially, hydroquinine is now prepared by the hydrogenisation of quinine sulphate in dilute acid solution in the presence of (a) spongy metals of the platinum group (D R P 252136, 1912), (b) palladium black (Eng. Pat 3948, 1912), (c) palladium coated on barium sulphate (D R P 234137, 1911), or (d) by the action of 2 p c formic acid in the presence of palladium (D R P 267306, 1913) In the last process the formic acid decomposes into carbon dioxide, which escapes, and hydrogen, which enters the quinine molecule at the vinyl

group

Hydroquinine crystallises in fine anhydrous needles from chloroform or ether, readily soluble in most organic solvents, sparingly in water, but more soluble in dilute ammonia,  $[a]_D^{20^\circ} = -142 \cdot 2^\circ$ in 95 pc alcohol (c=2.4 p.e.), m.p. 172° physical and chemical properties it closely resembles quinine, forming similar crystalline

salts of like solubility

The chief salts of hydroquinine are: acetate
B C<sub>2</sub>H<sub>4</sub>O<sub>2</sub>,5H<sub>2</sub>O, needles, soluble in water and arsenate B<sub>2</sub> H<sub>3</sub>AsO<sub>4</sub>,10H<sub>2</sub>O, zoate B C<sub>1</sub>H<sub>6</sub>O<sub>2</sub>, soluble in alcohol, chromate B<sub>2</sub>H<sub>2</sub>UrO<sub>4</sub>,6H<sub>2</sub>O, yellow needles, soluble 1 in 663 of water at 15°; citrate B<sub>2</sub> C<sub>6</sub>H<sub>6</sub>O<sub>7</sub>,10H<sub>2</sub>O, sparingly soluble in water, hydrobromide B HBr,2H<sub>2</sub>O, needles, freely soluble in water dihydrobromide B.2HBr,3H2O, needles, very soluble in water; hydrochloride B HCl,2H,O, long flat prisms, freely soluble in water and alcohol; dihydrochloride B 2HCl, very soluble in water; herepathite, 4B 3H<sub>2</sub>SO<sub>4</sub>·2HI·I<sub>4</sub>,6H<sub>2</sub>O, insoluble; hydriodide B·HI, amorphous, freely soluble in water; dihydriodide B 2HI,4H2O, yellow crystals, soluble in hot water; iodo-hydriodide B 2HI I4, dichroic needles; hyposulphite B<sub>2</sub> H<sub>2</sub>S<sub>2</sub>O<sub>3</sub>,2H<sub>2</sub>O, small prisms, sparingly soluble in water; oxalate B<sub>2</sub> C<sub>2</sub>H<sub>2</sub>O<sub>4</sub>,6H<sub>2</sub>O, sparingly soluble in water; phosphate B<sub>2</sub> H<sub>3</sub>PO<sub>4</sub>,7H<sub>2</sub>O, needles, sparingly soluble in water, platinochloride B<sub>2</sub> H<sub>2</sub>PtCl<sub>8</sub>,3H<sub>2</sub>O, amorther than the solution of t phous, spanngly soluble in water, diplatinochloride B H, PtCl<sub>6</sub>, 2H<sub>2</sub>O, amorphous, sparingly soluble in water, salicylate B  $C_7H_6O_3$ , needles, soluble in alcohol, sulphate B<sub>2</sub>  $H_2SO_4$ , 6 or 8H<sub>2</sub>O, needles, soluble in 348 of water at 15°, disulphate B  $\rm H_2SO_4, 3H_2O$ , long thin needles, very soluble in water, tetrasulphate B  $\rm 2H_2SO_4$ , amorphous, very soluble in water; tartiate B<sub>2</sub> C<sub>4</sub>H<sub>6</sub>O<sub>6</sub>,2H<sub>2</sub>O, prisms, soluble in 545 parts of water at 17°

Hydroquinine unites with I molecule of cupreine, quinidine, or hydroquinidine, and with 2 and 3 molecules of cinchonidine or hydrocinchonidine to form crystalline compounds (Hesse, Ber 1882, 15, 854, Annalen, 1887, 241, 255, Pum, Monatsh 1895, 16, 72)

Hydroquinicine. On heating hydroquinine disulphate to 140° it is converted into its isomer hydroquinicine The pure base is obtained by pouring the incited mass into water, and shaking the solution with NaOH and ether The residue left on evaporation when dissolved in alcohol and neutralised with H,SO, yields the crystalline sulphate, which is filtered off from the thick brown mother liquor and recrystallised to give the pure salt, in delicate acicular colourless needles readily soluble in water and in alcohol A solution of the sulphate in water is pale yellow, which on acidification assumes an intense yellowish-green colour Alkaline hydroxides precipitate the free alkaloid as a resmoid mass which gradually dissolves in ammonia or ammonium salts solutions, but not The hydrochloride is in the fixed alkalis amorphous and gives  $[\alpha]_D^{15} = -17^\circ$ , c=3 in excess of dilute HCl It yields a platinochloride B H2PtCl<sub>8</sub>, H2O, as a pale-yellow flocculent precipitate changing to orange-coloured crystals, insoluble in water and spannigly soluble ın dılute HCl An ethereal solution of oxalic acid produces in an ethereal solution of the alkaloid an amorphous brown precipitate, soluble in chloroform This distinguishes it from quinicine, which yields a voluminous precipitate of minute needles under similar conditions.

Hydrocupreine C<sub>19</sub>H<sub>24</sub>O<sub>2</sub>N<sub>2</sub> is derived from hydroquinine by heating it with 8 parts of HCl (sp gr 1 125) at 150° in scaled tubes. The unchanged hydroquinine is removed by shaking the acid solution with NaOH and ether, the hydrocupreine being obtained as sulphate by neutralising the alkaline layer with dilute H<sub>2</sub>SO<sub>4</sub>. The free alkaloid forms a crystalline powder C<sub>19</sub>H<sub>24</sub>O<sub>2</sub>N<sub>2</sub>,2H<sub>2</sub>O, freely soluble in organic solvents, slightly soluble in ammonia. It melts at 168°-170°, is strongly basic, forming crystalline salts, but is also phenolic, dissolving m alkalis. Its sulphate B<sub>2</sub>·H<sub>2</sub>SO<sub>4</sub> is sparingly soluble in water and in alcohol, the dihydrochloride B 2HCl,H<sub>2</sub>O being freely soluble. It forms a sparingly soluble crystalline tartrate  $\rm B_2\cdot C_4H_6O_6, 2H_2O,$  and an orange-red crystalline platinochloride B  $\rm H_2PtCl_2,$  insoluble in water and dilute HCl. Hydrocuprene is important as it is the source of the alkyl-hydrocuprenes of which ethyl-hydrocuprene hydrochloride  $\rm C_{21}H_{28}O_2N_2\cdot HCl$  (optochin) has been tried recently as a specific for pneumonia (Morgenroth, Berl. Klin Woch 1911, 34, 44; ibid 1914, 47–48; Sir Almroth Wright, Lancet, 1912, 1633, 1705; Pyman, Chem Soc Trans 1917, 662, 1127); and the isoctyl derivatives as a wound disinfectant (Morgenroth and Tugendreich, Biochem Zeitsch 1917, 79, 257; Schaeffer, ibid 1917, 83, 269, Bieling, ibid 1918, 85, 188)

Ethyl-hydrocuprēine hydrochloride occurs as a white crystalline powder, m p 242°, soluble in 10 parts of water, giving a blue fluorescence with dilute H<sub>2</sub>SO<sub>4</sub>, and having a bitter flavour Soluble in 90 p c alcohol The free alkaloid is precipitated by NaOH, and is soluble in chloroform

The hydrochlorides of the higher alkyl-hydrocuprenes are insoluble in water, the dihydrochlorides, which are soluble in 30-40 parts of water, being the salts prepared for use Iso-octyl-hydrocupreine dihydrochloride ('Vuzin') occurs as a greenish-yellow amorphous powder giving a milky solution in 30-40 parts of water, which at higher dilution is merely

opalescent.

Quinidine, its Derivatives and Salts -Quinidine (originally called 'conquinine') (C20H24O2N2), the only known natural stereo-isomer of quinine, occurs in most cinchona barks, especially C pitayensis, and also in cuprea bark. It was not prepared commercially at one time, but was precipitated with the amorphous alkaloids in the quinine tails, the whole being termed 'quinoidine' This was then a convenient source of quinidine, which could be extracted from the powdered quinoidine by means of ether (Hesse, Annalen, 1868, 146, 357, 1873, 166, 232) However, quinidine is now extracted and purified on the commercial scale, only a small amount being precipitated with the amorphous quinoidine. It is most conveniently isolated from the quinine mother liquor as hydriodide, as given under the 'Assay of Cinchona Barks,' being the least soluble of the cinchona hydriodides in neutral aqueous solution It crystallises from dilute alcohol in large prismatic crystals containing 2½H<sub>2</sub>O, losing ½H<sub>2</sub>O on exposure to air From ether rhombohedra containing 2H2O are obtained, and from boiling water plates containing 11H2O From benzene anhydrous needles separate which melt with decomposition at 171.5° (corr) [ $\alpha$ ]<sub>D</sub><sup>15°</sup> = +236 S°-3.0c in 97 pc alcohol, c=1-3. It is soluble in 6900 parts of water at 25°, 750 parts at 100°, 26 parts of alcohol at 20°, and in 22 parts of ether at 20°; slightly soluble in chloroform, benzene, amyl alcohol, and carbon disulphide.

Chemically, quinidine behaves similarly to quinine, yielding salts which, however, with the exception of the hydriodide, are more soluble than those of quinine. Its decomposition products are also the same as, or isomeric with, those of quinine. The disulphate on heating with acid gives quinicine. Treated with fuming sulphuric acid the alkaloid yields quinidine isosulphonic acid  $C_{20}H_{22}O_2N_2$ :HSO<sub>3</sub>, identical with the product obtained from quinine under

similar treatment (Hesse, Annalen, 1892, 267, 141). By the action of permanganate in the cold a base quitenidine, isomeric with quitenine  $(q \ v)$  is obtained

Quitenidine C<sub>19</sub>H<sub>22</sub>O<sub>4</sub>N<sub>2</sub> forms thin plates from dilute alcohol, mp. 246°, soluble in ammonia, from which solution it crystallises in large prisms on evaporation. It is readily soluble in boiling water, acids, and alkalis, less so in alcohol. Its H<sub>2</sub>SO<sub>4</sub> solution is fluorescent and it gives the thalleioquin reaction, which on adding ferrocyanide turns violet-black. It yields a sulphate B·H<sub>2</sub>SO<sub>4</sub>,3H<sub>2</sub>O, colourless prisms, and a platinochloride B H<sub>2</sub>Pt(I<sub>6</sub>,3H<sub>2</sub>O,

large orange-vellow crystals.

Apoquinidine  $C_{19}H_{22}O_2N_2$ , isomeric with apoquinine, is formed similarly by heating the base in a sealed tube to 140° with HCl (sp gr 1125). It is a white amorphous powder, readily soluble in alcohol and ether, giving the thalleloquin reaction, but not showing fluorescence with  $H_2SO_4$ . It melts at 137° (uncorr), and has  $[\alpha]_0^{15} = +153$  3° in 97 p.c. alcohol, c=2. It yields a hydrochloride in needles easily soluble in water. Its acetyl derivative, unlike the base, fluoresces in  $H_2SO_4$  solution

Chloroquinidine  $\rm C_{20}H_{23}ON_2Cl$  is obtained similarly to its isomer, chloroquinine. It is readily soluble in alcohol, benzene or chloroform; m.p. 131°-132°. On treatment with alcoholic potash it gives the same product as chloro-

quinine, i e quinene

Hydrochloroquinidine  $C_{20}H_{20}ClO_2N_2$  is obtained similarly to its isomer, hydrochloroquinine. It forms large crystals soluble in alcohol and in excess of ammonia. It gives the thalleroquin reaction. By longer heating methyl chloride is eliminated and hydrochlorapoquinidine results.

a-Isoquinidine  $C_{20}H_{14}O_{2}N_{2}$ ,  $2H_{3}O$  is formed together with hydrochloroquinidine by heating quinidine with HCl (sp.gr. 1189) at 85°. It forms fine rhombohedra soluble in ether.

Hydroiodoquinidine  $C_{20}H_{2\delta}IO_2N_2$  is obtained when quinidine is dissolved in 10 times its weight of HI (sp gr 1 9) and left for 3 days in the dark Its dihydriodide crystallises in large yellow tables, mp 230°, soluble in alcohol Ammonia liberates the base, which is recrystallised from alcohol as colourless transparent piisms, mp 205°–206°, slightly soluble in water. It gives the thalleioquin reaction and yields a crystalline sulphate, nitiate, hydrochloride, hydrodide, and platinochloride

Quantume Salts—Sulphate  $B_2 H_2SO_4, 2H_2O$  crystallises as white needles or long hard prisms, soluble in 100 parts of water at 15°, or 7 parts at 100°, 20 of chloroform at 15°, insoluble in ether. The salt requires a temperature of 120° for dehydration, and reabsorbs  $2H_2O$  on exposure to air.  $[a]_D^{17} = +2115°$  in absolute alcohol, c=194 p c of hydrated salt. A chloroform solution gradually assumes a yellow colour with slight green fluorescence. On shaking this solution with water the aqueous portion acquires a beautiful green fluorescence.

Commercial quinidine sulphate is usually fairly pure; cinchonine is the most frequent impurity, cinchonidine and quinine being rarely found. To test for other alkaloids dissolve

0.5 gram in 20 c.c. of warm water, add 0.5 gram of KI, and stir vigorously for a few minutes. After half an hour filter off the insoluble hydriodide and add ammonia to the filtrate any decided precipitate occurs (none with the pure salt) shake with chloroform, evaporate the extract to dryness, and weigh Test the residue for quinine, einchonidine, and einchonine Should the two latter be present the precipitated hydriodide will tend to be resinous instead of sandy (De Viij, Pharm J. 1877, 8, 745)

Disulphate BH,SO4,4H,O occurs in long asbestos-like prisms, soluble in 7 parts of water at 15°, giving a beautiful blue fluorescence

met with are Other salts benzoate B C, H, O, H, O, soluble in alcohol, chromate B·H<sub>2</sub>CrO<sub>4</sub>,6H<sub>2</sub>(), large yellow tables; hydrobromide B HBr, soluble in 200 of water at 14°, hydrochloride B HCl, H<sub>2</sub>O, asbestos-like needles, soluble in 75 parts of water at 15°, [a]<sub>D</sub>=+212° -2 56c in alcohol, dihydrochloride B 2HCl,H,O, very soluble in water, hydrodide B HI, short prisms, soluble in 1250 of water at 15°, very slightly soluble in alcohol, dihydriodide B·2HI,3H<sub>2</sub>O, large golden prisms, soluble in 90 of water at 15°; hyposulphite

short prisms, soluble in 415 of water at 10°, oxalate B, C,H<sub>2</sub>O<sub>4</sub>,H<sub>2</sub>O, soluble in 151 of water at 15°, nitrate B HNO<sub>3</sub>, small prisms, soluble in 85 of water at 15°, phosphate B H<sub>2</sub>PO<sub>4</sub>, short prisms, soluble in 31 of water at 10°, platinochloride B<sub>2</sub> H<sub>2</sub>Pt(l<sub>8</sub>,3H<sub>2</sub>O, orange needles, diplatinochloride B H<sub>2</sub>Pt(l<sub>8</sub>,H<sub>2</sub>O, yellow amorphous precipitate, insoluble in water; salicylate B  $C_7H_6O_7$ , soluble in 1650 of water at 25°; succinate B  $C_4H_6O_4$ ,2 $H_2O$ , fine prisms, soluble in 41 of water at 10°, very soluble in alcohol, sulphocyanide B HCNS, colourless prisms, soluble in 1477 of water at 20°, disulphocyanide, B 2HCNS, H2O, long yellow prisms, tannate, indefinite composition, soluble in about I in 2000 of water at 20°; tartrate

# $B_2 C_4 H_6 O_6, H_9 O$

silky prisms, soluble in 39 of water at 15°; bitartrate B C<sub>4</sub>H<sub>6</sub>O<sub>6</sub>,3H<sub>2</sub>O, short prisms, soluble in 350 of water at 15°.

Hydroquinidine  $C_{20}H_{26}O_2N_2$  usually occurs in commercial quinidine sulphate sometimes to the extent of 20 pc It may be separated by repeated recrystallisation from water, but it is preferably obtained by oxidising quinidine sulphate mother liquors with permanganate at

0° (v Hydroquinine).

Quinidine may also be hydrogenated in the presence of palladium black yielding hydro-Forst and Bohringer's statement quinidine that this base is formed by the oxidation of quinidine is inaccurate, being due to their using quinidine containing hydroquinidine (Ber 1881, 14, 1954; 1882, 15, 520, 854, Hesse, *ibid.* 1882, 15, 3010; Annalen, 1888, 243, 146) It forms efflorescent prismatic needles containing 2½H<sub>2</sub>O, m.p. 167°, readily soluble in alcohol and chloroform, slightly soluble in ether Its rotatory power is almost the same as that of quinidine It gives the thalleroquin reaction and behaves generally like quinidine. Oxidation with chromic acid yields quininic

Salts.—Its sulphate B, H,SO4,2H,O occurs as fine needles, soluble in 92.3 of water at 16°, or B2·H2SO4,8H2O, thick efflorescent prisms (Hesse) Its H,SO<sub>4</sub> solution shows blue fluorescence. Other salts are . benzoate B C7H6O2, colourless plates, hydrobromide, fragile scales, slightly soluble in water; hydrochloride B HCl, short needles or thick prismatic plates, readily soluble in water; hydrochide B HI, large colourless needles, very slightly soluble in water, dihydriodide B.2HI,3H2O, orange-yellow prisms, fairly soluble in water, platinochloride

## B·H, PtCl, 2H, O

small orange-yellow needles, salicylate B.C. H.O., six-sided plates; tartrate  $B_2C_4H_6O_6.2H_2O$ , brilliant prisms, readily soluble in water, bitartrate  $B_2C_4H_6O_6.3H_2O$ , needles, slightly soluble in water.

Cinchonine, its Derivatives and Salts .- Cinchonine (C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub>) occurs in all cinchona barks It is readily prepared from quinine mother liquors, after removal of the cinchonidine as tartrate, by rendering alkaline and shaking with a limited quantity of washed ether. The cinchonine crystallises out from the ether in small hard pusms, and may be filtered off and recrystallised from dilute alcohol The crystals melt at 264°, subliming with some decomposition at a higher temperature as monoclinic prisms Ammonia precipitates the alkaloid from acid solutions in white flocks gradually becoming crystalline; but from hot solutions of ammonium salts cinchonine displaces ammonia The freshly precipitated alkaloid is much more soluble in solvents generally than crystalline cinchonine. The crystals dissolve in 3670 of water at 20°, in 2500 of water at 100°, in 115 of absolute alcohol at 17°, in 356 of chloroform at 17°, in 371 of ether (sp gr 0 730) at 10°, in 40 of amyl alcohol at 17°, and in 18 parts of a mixture of alcohol and chloroform (4 · 1) at 17°. Readily soluble in acids, but the salts of cinchonine are hable to hydrolyse with water and deposit alkaloid Cinchonine is easily distinguished from the other alkaloids by giving neither fluorescent solutions nor an insoluble tartrate, and by being insoluble in ether  $[a]_D^{15^{\circ}} = +226 5^{\circ}$ in 97 p.c. alcohol, c=0.5Cmchonine does not give the thalleioquin reaction. On oxidation it yields the same products as quinine, except that the quinolinic products lack the p-methoxy group

Cinchotenine  $C_{18}H_{20}O_3N_2$  is obtained on oxidising einchonine with permanganate in acid solution (Skraup, Annalen, 1879, 197, 374) It is purified similarly to quitenine (q v) It forms efflorescent needles or plates containing 3H<sub>2</sub>O, m p 198°.  $[a]_D^{15} = +135^\circ$  in alcohol solution, c=2 of hydrated base. A 2 p.c. solution in dilute H<sub>2</sub>SO<sub>4</sub> gives  $[a]_D^{15} = +175$ 5°. It gives a platinochloride B H<sub>2</sub>PtCl<sub>6</sub>, large orange prisms, and an aurichloride B H<sub>2</sub>Au<sub>2</sub>Cl<sub>8</sub>, yellow needles; both soluble in water and in alcohol.

Cinchotenicine  $C_{18}H_{20}O_3N_2$ , isomeric with cinchotenine, is formed from it by heating to 140° with H2SO4. A brown amorphous body soluble in water, giving amorphous platino-and auri-chlorides.  $[\alpha]_D^{15^\circ} = +0.9^\circ$ .

Cinchoninic acid  $C_9H_6$  COOH N (4-carboxy-quinoline), obtained by oxidising cinchonine with chromic acid (v Quinnine acid) Forms caffeine-like needles containing 1H<sub>2</sub>O, or tables or prisms with 2H<sub>2</sub>O; m p. 253°-254°, subliming with decomposition (Caventou and Willin, Annalen, Supl 1870, 7, 247; Skraup, Annalen, 1880, 201, 294) It is only slightly soluble in water, more so in acids and alkalis, but its salts dissociate in water Heated with lime it yields quinoline Permanganate oxidises it to a-carbocinchomeronic acid (Ramsay and Dobbie, Chem Soe Trans 1884, 35, 189), nitric acid at 120°-140° yields einchomeromic acid (Weidel, Annalen, 1874, 173, 76), and chromic acid gives kynurine (Skraup, Monatsh 1888, 9, 783; 1896, 17, 366) On fusion with potassium hydroxide oxyemchommic acid sublimes (Komgs and Kerner, Ber 1883, 16, 2152) Cinchommic acid may also be prepared by oxidation of lepidine and 4-ethylquinoline

Cinchene C<sub>19</sub>H<sub>20</sub>N<sub>2</sub> is obtained by refluxing cinchonine chloride with alcoholic potash (v. Quinene), as trimetric tables, m.p. 123°-125° It is a ditertiary base, soluble in ether, dextrorotatory, and yields crystalline salts hydrolysis with 25 pc. phosphoric acid it yields lepidine and meroquinene. Chromic acid oxidises it to cinchoninic acid Treated with bromine in chloroform solution two isomeric dibromides ( $\alpha$  and  $\beta$ ) of cinchene are formed, both of which are converted into a new base, dehydrocinchene ( $C_{19}H_{18}N_2$ ), with loss of 2HBr (Comstock and Konigs, Ber. 1886, 19, 2857) Chlorine reacts similarly to bromine with cinchene On heating cinchene in a sealed tube with HBr (sp gr 1 49) to 190° it loses a molecule of ammonia and adds a molecule of

water to form apocinchene (v Apoquinene).

Apocinchene C<sub>19</sub>H<sub>19</sub>ON, colourless needles, 209°, volatilising without decomposing, soluble in alcohol, acids, and alkalis (Comstock and Konigs, Ber. 1881, 14, 1854; 1884, 17, 1989). Its salts give yellow solutions which readily hydrolyse, and its solutions in alkalis are precipitated by CO. It readily forms ethers, which with dilute HNO<sub>3</sub> oxidise to alkylapocinehenic acids. Chromic acid oxidises it to cinehoninic acid, and fusion with potassium hydroxide gives oxyapocinchene C<sub>19</sub>H<sub>19</sub>O<sub>2</sub>N, a base isomeric with apoquinene.

### Ethylapocinchenic acid

#### C<sub>17</sub>H<sub>13</sub> OC<sub>2</sub>H<sub>5</sub> COOH N

on refluxing with HBr (sp gr 1 49) gives rise to a lower homologue of appenihene named homopocinchene  $C_{17}H_{16}ON$ . This body melts at 184°-185°, is very soluble in ether, benzene, or hot alcohol, insoluble in water

Dihydrocinchene  $C_{19}H_{22}N_2$  was found by Konigs in the mother liquors from appointhene, and was derived from the hydrocinchonine present in the cinchonine from which the latter was prepared.

Cinchonine chloride  $C_{19}H_{21}N_2Cl$ , obtained similarly to quinine chloride (qv.). It crystallises in prisms, melting at 72°, and is dextrorotatory On reduction with iron and H<sub>2</sub>SO<sub>4</sub> it gives desoxycinchonine C<sub>19</sub>H<sub>22</sub>N<sub>2</sub>, m p 90°-92°, dextrorotatory. With alcoholic potash cinchene is obtained (q.v.).

Cinchonine dichloride C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub>Cl<sub>2</sub> is made from cinchonine dibromide (q.v). It crystallises

by passing chlorine into a cooled HCl solution of cinchonine. It is very similar to dichlorocinchonine, and may be identical with it.

Dichlorocinchonine C<sub>19</sub>H<sub>20</sub>OCl<sub>2</sub>N<sub>2</sub> is obtained by passing chlorine into a hot concentrated alcoholic solution of cinchonine hydrochloride It crystallises as microscopic needles from alcohol, and gives crystalline salts with 2HCl, 2HBr, and  $H_{\star}$ PtCl<sub>8</sub> (Laurent, Annal Chim Phys (3) 24, 302)

Bromocinchonine C19H21OBrN2 is formed by adding bromine to an alcoholic solution of cinchonine hydrochloride (Laurent, lc, Kopp, Arch Pharm (3), 9, 34) Its dihydrochloride crystallises in rhombic tables. Treated with alcoholic potash it exchanges Br for OH, and

gives oxycinchonine  $C_{19}H_{22}O_3N_2$ Sesquibromocinchonine  $C_{38}H_{41}O_2Br_3N_4$ , obtained by the action of excess of bromine on an alcoholic solution of cinchonine It crystallises in fine needles and forms salts with 4 molecules of monobasic acids Treated with alcoholic

 $\begin{array}{c} \text{potash it yields sesquioxycmchonine } C_{19}H_{20}\mathrm{OBr}_2N, \quad \text{formed} \end{array}$ by adding excess of biomine to an aqueous solution of cinchonine hydrochloride (Comstock and Konigs, Ber 1884, 17, 1995) It gives colourless crystals containing 1H2O from alcohol, msoluble in water Alcoholic potash yields dioxycinchonine C<sub>19</sub>H<sub>22</sub>O<sub>3</sub>N<sub>2</sub>.

Cinchonine  $\alpha$ - and  $\beta$ -dibromides

$$C_{19}H_{22}OBr_2N_2$$

formed by adding biomine to a solution of cinchonine in chloroform and alcohol hydrobromide of the a-compound being less soluble than the β-compound crystallises out, the latter remaining in the mother liquor free α-base crystallises out from algohol (90 p c) and chloroform (1.3) with 1H2O, the B-base being anhydrous. Both behave as true bases Heated with alcoholic KOH forming salts they lose 2HBr, yielding a new base, dehydrocinchonine (Comstock and Konigs, Ber 1886, 19, 2854, 1887, 20, 2510).

Hydrochlorocinchonine  $\rm C_{19}H_{23}CION_2$ , formed by allowing 10 parts of HCl saturated at  $-17^{\circ}$ to act on cinchonine at a low temperature for some weeks. The base crystallises from alcohol in white needles, mp 212°-213° Heated with alcoholic KOH an isomer of cinchonine, (Comstock and a-isocinchonine, is formed

Konigs, Ber 1887, 20, 2519)

Hydrobromocinchonine C<sub>19</sub>H<sub>23</sub>BrON<sub>2</sub> formed similarly to the last compound, but the reaction is more rapid and works equally well at higher temperatures The base crystallises from alcohol in white scales Heated with 85 p c alcohol it is converted into a mixture of apocinchonine, α-isocinchonine and δ-cinchonine Heated with alcoholic KOH a mixture of apocinehonine a-isocinehonine and cinchonifine (? hydrocinchonine) is formed

Hydroiodocinchonine C<sub>19</sub>H<sub>23</sub>ION<sub>2</sub> is obtained by heating dry einchonine with 5 parts of HI (sp gr 17) on the steam-bath The free base crystallises from alcohol in silky needles melting at 158°-160° with decomposition It readily combines with 2 molecules of monobasic acids to form crystalline salts

C19H20ON2, Dehydrocinchonine

from alcohol in needles melting at 202°-203°, subliming at a higher temperature; very soluble in alcohol, acetone, and chloroform, less so in ether or benzene It behaves very similarly to cinchonine, giving salts and halogen derivatives containing H<sub>2</sub> less

Derivatives Isomeric with Cinchonine—

About 20 isomers of cinchonine have been described by various workers, but Skraup's investigations have shown that many of these bodies are identical, and several others are mixtures with cinchonine Hydrocinchonine has also been mistaken for an isomer of cinchonine (Monatsh 1897, 18, 411, 1899, 20, 571, 1901, 22, 1103, 1903, 24, 294, Langer, ibid 1901, 22, 151)

Cinchonicine (cinchotoxin) C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub> occurs in commercial quinoidine, but may be prepared by heating the acid sulphate or tartrate of einchonine or cinchonidine to 130°-140° (Pasteur, Compt rend 1853, 37, 110; Hesse, Annalen, 1875, 178, 213, D Howard, Chem Soc Trans, 1872, 25, 102) It forms a viscid mass, yellow to red, melting at about 50° Roques obtained it in long prismatic needles, mp 49°-50°, by evaporating an ethereal solution at 45°, in a current of hydrogen.  $[\alpha]_{\rm D}^{15}$ =47.2° for 1 pc. solution in chloroform or absolute alcohol It is very soluble in alcohol or ether, slightly soluble in water Its solutions absorb CO2 from the air and expel ammonia from its salts gives the same oxidation products as einchonine Like quinicine, it gives a precipitate with hypochlorites, but does not give the thalleroquin reaction (distinction from quinicine) Many of its salts are amorphous, but the following are ciystalline. hydrodide B.HI, prisms, slightly soluble in water; oxalate B<sub>2</sub> C<sub>2</sub>H<sub>2</sub>O<sub>4</sub>,7H<sub>2</sub>O, BH<sub>2</sub>PtCl<sub>8</sub>,H<sub>2</sub>O, bitartrate B (¹<sub>4</sub>H<sub>6</sub>O<sub>6</sub>,H<sub>2</sub>O Allocinchonine (pseudocinchonine)C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub>

is obtained by heating the hydriodide of hydroiodocinehonne  $C_{19}H_{21}TON_2HI$  with 10 parts of water at  $150^{\circ}-160^{\circ}$  It melts at  $214^{\circ}-216^{\circ}$ , slightly soluble in alcohol or ether, and gives  $[\alpha]_{D}^{20} = +164.8^{\circ}$  for 3 pc solution in absolute alcohol. Its sulphate B<sub>2</sub> H<sub>2</sub>SO<sub>4</sub> is less soluble in water than cinchonine sulphate. On oxidation it yields einchonine acid and allometo-quinene (Lippman and Fleissner, Monatsh 1893, 14, 371)

Tautocinchonine  $C_{19}H_{22}ON_2$  is obtained by the action of alcoholic KOH and silver nitrate on hydrobromocinchonine hydrobromide

# C<sub>19</sub>H<sub>23</sub>BrON<sub>2</sub> HBr

It is soluble in alcohol, slightly soluble in ether, m p  $~252~5^{\circ},$  and gives [a]  $_{D}^{20}\!=\!+209~4^{\circ}$  for 3 p c solution in absolute alcohol (Lowenhaupt, Monatsh. 1898, 19, 461)

α-Isocinchonine (cinchoniline) C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub> is obtained by heating cinchonine with sulphuric acid or HCl (sp gr 1·125); or by heating hydro-bromocinchonine or its salts with alcoholic KOH (Jungfleisch and Leger, Bull. Soc chim 1888, 49, 747; Compt. rend 1892, 113, 651; *ibid* 1894, 118, 536; Hesse, Annalen, 1888, 243, 147; *ibid.* 1890, 260, 213; 1893, 276, 91, Comstock and Königs, Ber. 1887, 20, 2510, 1892, 25, 1539; Skraup, Monatsh 1899, 20,

581; 1902, 22, 1097; Pum, *ibid.* 1892, 13, 676) It crystallises in silky needles from ether containing 3H2O; from petroleum ether in large prisms, volatile, m.p 126 5°.  $[a]_{n}^{15} = +51 6°$ for 3 pc. solution in absolute alcohol. It is readily soluble in ether, alcohol, or benzene, little soluble in water. It forms crystalline salts, all of which except the dhydriodide are very soluble in water Heated with HCl (sp gr 1·125) at 140°-150° it is converted into apoisoeinchonine (apocinchonigine), mp 216°, and with concentrated  $H_2SO_4$  at  $60^\circ-80^\circ$  it changes into  $\beta$ -isoeinchonine. On oxidation it yields cinchoninic acid and a-isomeroquinene.

 $\beta$ -Isocinchonine (cinchonigine)  $C_{19}H_{22}ON_2$ , references under Isocinchonine. It crystallises from alcohol in colourless prisms, volatile, 126°-127°.  $[a]_{\rm D}^{18} = -59.5$ ° in absolute l Very soluble in alcohol, ether, or m.p benzol. Its salts, including the dihydriodide, are very soluble in water. Heated with HCl (sp gr I 125) it yields a poisocinchonine (apocinchinigine), m p.  $216^{\circ}$ . On oxidation it gives cinchoninic acid and B-isomeroquinene.

δ-Cinchonine C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub> is formed at the same time as  $\alpha$ -isocinchonine (q v) when hydrobromocinchonine dihydrobromide is heated with alcohol or alcoholic KOH Long prisms, mp 150°, very soluble in alcohol, benzene, or chloroform, slightly soluble in ether  $[a]_{\rm D}^{17} = +125.2^{\circ}$  for 1 p c solution in 97 p c alcohol. Its salts are very soluble with the exception of the hydrochloride, hydrobromide, and oxalate (Jung-

fleisch and Leger, Compt rend 1894, 118, 29)

ε-Cinehonine C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub> was isolated by
Lowenhaupt from tautocinchonine (q v) It is a base melting at 150°-152°, giving crystalline salts  $[\alpha]_{\rm p}^{20} = +67^{\circ}$  for 1 p c solution in alcohol

Cinchonidine  $C_{19}H_{12}ON_2$  was obtained in 5 pc yield by Konigs and Hussman from emchanine by heating it for 15 hours with an amyl alcohol solution of KOH (Ber 1896, 29 2185)

Hydro-derivatives of Cinchonine -On reducing einchonine with zine and H2SO4, Schutzenberger obtained a resinous body which he termed a hydrate of cinchonine, assigning to it the formula  $C_{19}H_{22}ON_{2},2H_{2}O$ . This body is stable up to 120°, but at 140° it loses  $\frac{1}{2}H_{2}O$ , and at 150° retains 1H<sub>2</sub>O (Annalen, 1858, 108, 348) Zorn reducing cinchonine with sodium amalgam in acetic acid obtained an oily mass containing two bases separated by ether The one insoluble in ether he named hydrocinchonine (the dihydrodicinchonine of Skraup) C<sub>19</sub>H<sub>24</sub>ON<sub>2</sub>, the other soluble in ether he called amorphous Skraup) C<sub>19</sub>H<sub>26</sub>ON<sub>2</sub> The first crystallises from alcohol in small colourless anhydrous plates or scales, mp 257°-258° It yields a crystalline sulphate B·H<sub>2</sub>SO<sub>4</sub>,2H<sub>2</sub>O (or anhydrous) in long needles It is readily attacked by permanga-nate, but on further treatment with sodiumamalgam is unattacked The second dissolves in ether with a fine violet fluorescence, and is obtained as a yellowish amorphous mass on evaporation. It yields no crystalline salts or derivatives. It is a stronger base than cinchonine, dissolving in acids with elevation of

iperature, and is readily attacked by peraganate (Zorn, J pr Chem. 1873, 8, 279, ; Skraup, Ber. 1878, 11, 312, Howard, m. Soc. Trans. 1873, 26, 1180). By the ion of sodium and anhydrous amyl alcohol cinchonine Norwall obtained an oily base  $\rm H_{26}ON_2$ , which he termed tetrahydrocinnine (Monatsh 1895, 16, 321)

None of the above is identical with the lrocinchonine which occurs naturally in shona barks (Caventou and Wilm, Annalen, l. 1870, 7, 247, Forst and Bohringer, Ber. 1, 14, 436; Hosse, Ber. 1895, 28, 1421)

Hydrocinchonine (Cinchotine) C<sub>19</sub>H<sub>24</sub>ON<sub>2</sub> is onstant associate of cinchonine, which may tain up to 10 pc It may be prepared alarly to hydroquinine (qv.), by oxidation the emchanine with permanganate; or by urating an alcoholic solution of cinchonine trochloride with HCl gas, when the dihydrooride of cinchonine separates out, leaving the frocinchonine in solution (Hesse, Annalen, 3, 276, 88). It forms slender anhydrous sms or scales, m p 277°, subliming at higher iperature Soluble in 136 parts of 90 p cohol, or 187 of ether at 20°, slightly soluble boiling water It is not attacked by cold manganate, but chromic acid oxidises it to chonine and cincholoiponic acids With sphorus pentachloride it yields hydrochonine chloride C<sub>19</sub>H<sub>23</sub>ON,Cl, m p 85°-87°, iverted by alcoholic KOH to dihydrochene C<sub>19</sub>H<sub>22</sub>N Its chief salts are . benzoate 17H6O2, small needles, slightly soluble in ter: hydrobromide B HBr,2H2O, dihydromide B 2HBi, prismatic needles, very soluble water, insoluble in alcohol, hydrochloride ICl,2H<sub>2</sub>O, needles, soluble in 47 of water, ydrochloride B 2HCl, very soluble in water, htly soluble in alcohol; hydriodide B·HI,H<sub>2</sub>O, builess prisms, readily soluble in water and shol, nitrate B'HNO<sub>3</sub>,H<sub>2</sub>O, transparent les, oxalate B C<sub>2</sub>H<sub>2</sub>O<sub>4</sub>,H<sub>2</sub>O, fine needles, y slightly soluble in water; platinochloride  $1.PtCl_6$ , orange-yellow crystals, sulphate  $H_2SO_4, 12H_2O$ , fine needles or prisms, efflorent, soluble in 30 5 of water at 13°, sulphoand B HCNS, long needles, slightly soluble water; tartrate  $C_4H_6O_6, 2H_2O, B_2$ , needles ible in 57 of water at 16°; bitartrate L4H6O6,4H2O, needles, soluble in 78 of water

Salts of Cinchonine—Cinchonine sulphate H<sub>2</sub>SO<sub>4</sub>,2H<sub>2</sub>O forms short haid prisms or dles, melting at 198 5° when dehydrated, omposing at 200° It is soluble in 70 parts water at 15°, in 13 parts at 100°, in 9 parts at ing-point, in 2300 of ether at 25° As the phates of quinne and cinchonidine are insole in chloroform, this solvent forms a good test the purity of cinchonine sulphate —A soluroscient of this base in dilute H<sub>2</sub>SO<sub>4</sub> does not presce (although the commercial salt usually as so slightly owing to the presence of a little nine or quindine), nor does it give the illeioquin reaction. With iodine it yields ducts analogous to herepathite, the principal ing 8B·6H<sub>2</sub>SO<sub>4</sub>·6HI I<sub>10</sub>·12H<sub>2</sub>O,

 $4B H_2SO_4\cdot 4HI\cdot I_{10}$ ,  $2B\cdot H_2SO_4\cdot 2HI\cdot I_2$  rgensen). Vol. 1I.-T.

Cinchonine disuiphate B  $\rm H_2SO_4, 3$  or  $\rm 4H_2O$ , large colourless prisms, very soluble in water, and crystallising with difficulty.

Cinchonine hydrochloride B HCl,2H,O occurs as prismatic needles, melting at 130° It is soluble in 24 parts of water at 10°, the solution dissociating slightly and depositing alkaloid. Soluble in 2 parts of 85 p.c. alcohol and 290 parts of ether at 15°.

Other salts are . benzoate B C2H6O2, soluble in 166 of water at 15°, citrate B<sub>7</sub> C<sub>6</sub>H<sub>8</sub>O<sub>7</sub>,4H<sub>2</sub>O, soluble in 48 of water at 12°, and citrate B<sub>2</sub> C<sub>6</sub>H<sub>8</sub>O<sub>7</sub>,4H<sub>2</sub>O, soluble in 55 of water at 15°; hydrobiomide B HB1,H2O, long needles, soluble in 33 5 of water at 15°, more soluble in alcohol; dihydrobromide B 2HBr, large rhombohedra, soluble in 1.4 of water at 15°, less soluble in alcohol, dihydrochloride B 2HCl, rhombic tables, very soluble in water, insoluble in alcohol; hydriodide B HI,H2O, white crystals, dihydriodide B 2H1, H2O, golden-yellow prisms, hydrodate B HIO, crystals, exploding at 120°, intrate B HNO, H,O, long monoclinic crystals, soluble in 26 4 of water at 12°, oxalate of water at 10°, platmochloride B H<sub>2</sub>Pt(1<sub>6</sub>, pale yellow amorphous precipitate, succinate B C<sub>4</sub>H<sub>6</sub>O<sub>4</sub>,1 or 1½H<sub>2</sub>O, long needles or thick prisms, readily soluble in water, sulphocarbolate B C. H. HSO, OH, reddish-white needles, sulphocyanide B HCNS, prisms, soluble in 474 of water at 20°, salicylate B C<sub>2</sub>H<sub>6</sub>O<sub>3</sub>, soluble in 590 of water at 25°, taitrate B<sub>2</sub> C<sub>4</sub>H<sub>6</sub>O<sub>4</sub>, 2H<sub>2</sub>O, crystals, soluble in 33 of water at 16°, bitaitrate (lievo-) B (4H6O6, H2O, soluble in 100 of water at 16°, bitaitrate (dextro-), soluble in 101 of water at 16° (Pasteur)

Cinchonidine and its Derivatives and Salts.

Cinchonidine C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub>, a stereoisomer of emchonine, occurs in most emchona barks, especially in C succirubia. It is prepared from quinine sulphate mother liquoi by precipitation as neutral tartrate with Rochelle salt This tartrate is washed with water and decomposed with ammonia, the rough base being dried carefully at a low temperature On dissolving this in 21 cc of 50 pe H,SO4 and 11 cc of absolute alcohol for every gram of base, and allowing to cool, pure einchonidine tetrasulphate crystallises out nearly quantita-This is filtered off, washed with absolute alcohol, dissolved in water, and precipitated as alkaloid with NaOH, being finally recrystalhised from alcohol It forms short anhydrous prisms or thin plates, soluble in 16 parts of 97 p c alcohol at  $15^{\circ}$ , in 188 parts of ether, or in 4800 parts of water at  $25^{\circ}$ , readily soluble in chloroform or amyl alcohol. It melts at 210 5°, and has  $[a]_D^{15} = -10748^{\circ} + 03c \text{ in } 97 \text{ p c.}$ alcohol, c=1-5Like einchonine, its solutions do not fluoresce, nor give the thalleroquin reaction (distinction from quinine and quinidine). It differs from cinchonine in giving an insoluble tartrate, by its greater solubility in ether, and by being laworotatory For its estimation in cinchona barks, see under 'Quinine Sulphate.' It gives the same oxidation products as cinchonine with chromic or nitric acid, and cinchonicine, identical with that from cinchonine, is obtained by heating with glycerin to 200°,

or with strong H<sub>2</sub>SO<sub>4</sub> to 130°. The following solution in 97 pc. alcohol. It forms very are the most important derivatives of einchoni-

Cinchotenidine C<sub>18</sub>H<sub>20</sub>O<sub>3</sub>N<sub>2</sub>, obtained similarly to quitenine by oxidation of cinchonidine with permanganate at 0°. It forms filiform or thick prismatic crystals containing 3H<sub>2</sub>O, slightly efflorescent. It melts at 256°, and has  $[\alpha]_D^{15} = -189^{\circ}$  in alcohol — Its acid solutions do not fluoresce Its salts are very soluble and difficult to crystallise It forms a sulphate B<sub>2</sub> H<sub>2</sub>SO<sub>4</sub>,2½H<sub>2</sub>O, very soluble in water, and a platinochloride B, H, PtCl, orange-yellow tables Its solutions in alkalis are readily decomposed by CO<sub>2</sub> (Skraup, Annalen, 1880, 201, 300, Hesse, Ber. 1881, 14, 1892).

Cinchonidine chloride C<sub>19</sub>H<sub>21</sub>N<sub>2</sub>Cl is obtained by the action of phosphorus pentachloride on cinchonidine It forms large crystals melting at 108°-109°, soluble in other and possessing basic properties On heating with alcoholic KOH it yields cinchene (similarly to cinchonine chloride), which on treatment with HCl is converted to apocinchene

**Dibromocinchonidine** C<sub>19</sub>H<sub>20</sub>ON<sub>2</sub>Br<sub>2</sub> is formed by adding 4 atoms of bromine to 1 molecule of cinchonidine suspended in CS<sub>2</sub>. Its dihydro-bromide crystallises in fine yellow needles readily soluble in alcohol (Skalweit, Annalen, 1874, 172, 103). On heating with alcoholic KOH it yields dioxycinchonidine

**Dioxycinchonidine**  $C_{19}H_{22}(OH)_2ON_2$ tallises from alcohol in ramified crystals gives two sulphates, B<sub>2</sub> H<sub>2</sub>SO<sub>4</sub>,2H<sub>2</sub>O and B H<sub>2</sub>SO<sub>4</sub>, and a platinochloride B H<sub>2</sub>PtCl<sub>6</sub>

Hydrochlorocinchonidine C<sub>19</sub>H<sub>23</sub>ClON<sub>2</sub> formed by heating cinchonidine with HCl (sp gr 1 189) at 85° for two days. It is a base indistinguishable from hydrochloroapocinchonidine and is probably identical with it

Hydrochloroapocinchonidine C<sub>18</sub>H<sub>23</sub>ClON<sub>2</sub> is obtained together with apprinchonidine by heating cinchonidine in a sealed tube at 150° with fuming HCl for 6 hours - It crystallises in plates from alcohol, m p 200°,  $\left[\alpha\right]_{\rm D}^{15} = -142.2^{\circ}$ in dilute HCl, slightly soluble in ether, chloro-form, or alcohol. It forms a dihydrochloride B 2HCl, very soluble in water, and a platino-chloride B H<sub>2</sub>PtCl<sub>6</sub>,2H<sub>2</sub>O (Hesse, Annalen, 1880, 205, 327)

Hydroiodocinchonidine  $C_{19}H_{23}ION_2$  is obtained by heating cinchonidine on the waterbath with 5 parts of HI (sp gr. 17) for 21 hours It is a base very slightly soluble in hot alcohol, from which it falls on cooling as a crystalline precipitate, mp 166°. It gives a sulphate B H<sub>2</sub>SO<sub>4</sub>, soluble m 25 p c alcohol Heated with alcoholic KOH it yields an isomeride of cinchonidine, \beta-cinchonidine, and with silver nitrate another isomeride, \gamma-cinchonidine (Neumann, Monatsh. 1892, 13, 651)

Derivatives Isomeric with Cinchonidine -Apocinchonidine C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub> is formed by the action of HCl on cinchonidine (v Hydrochloroapocinchonidine) Slightly soluble in strong alcohol, very slightly soluble in dilute alcohol, ether, or chloroform, almost insoluble in water. It forms small plates, m p. 225°, with decomposition, and has  $\left[\alpha\right]_{\mathbf{p}}^{15} = -129 \cdot 2^{\circ}$  for 0.8 p.c. soluble amorphous salts, whose acid solutions do not fluoresce, and is markedly different from cinchonidine in giving a soluble tartrate.

Isocinchonidine C<sub>19</sub>H<sub>22</sub>ON<sub>2</sub> is obtained as its sulphonate when cinchonidine is dissolved in fuming H<sub>2</sub>SO<sub>4</sub> The base melts at 235°, and is very soluble in alcohol or chloroform, very slightly soluble in ether (Hesse, Annalen, 1888, 243, 149)

 $\beta$ -Cinchonidine  $C_{19}H_{22}ON_2$  is obtained by heating hydroidocinchonidine for 4 hours with alcoholic KOH, and is probably identical with Hesse's homocinchonidine It forms plates or prisms, m p 207°,  $[\alpha]_D^{1.0} = -181^{\circ}$  for 1 25 p.c. solution in dilute HCl. On prolonged heating with HCl it is converted into apocinchonidine, from which it may be separated by means of its insoluble taitrate (Hesse, Annalen, 1880, 205, 327)

Hydro-derivatives of Cinchonidine — On reduction with zine and H<sub>2</sub>SO<sub>4</sub>, or sodium and alcohol, cinchonidine yields products very similar, chemically and physically, to those obtained from einchonine Norwall describes a tetrahydrocinchonidine C<sub>19</sub>H<sub>26</sub>ON<sub>2</sub>, obtained with sodium and pure amyl alcohol (Norwall, Ber 1896, 29, 801)

 $Hvdrocinehonidine(cinchamidine)C_{19}H_{24}ON_{2}$ , usually accompanies circhonidine in its commercial salts, and may be obtained from cinchonidine sulphate mother liquors by treatment with permanganate at 0° (v Hydroquinine) The base crystallises from dilute alcohol in hexagonal plates, and from strong alcohol in short anhydrous prisms, melting at 230°,  $\left[\alpha\right]_{D}^{15} = -98.4^{\circ}$  for 2 pc solution in 97 pc alcohol It is almost insoluble in ether, chloroform, or water, and less soluble in alcohol than cinchonidine. Its salts crystallise readily and fluoresce in sulphuric acid solution (Hesse, Bei 1881, 14, 1683, Forst and Bohunger, Ber. 1882, 15, 520)

Salts of Cinchonidine —Cinchonidine sulphate B<sub>2</sub> H<sub>2</sub>SO<sub>4</sub>,3H<sub>2</sub>O occurs as prismatic needles. From dilute aqueous solutions needles contaming 6H<sub>2</sub>O crystallise, and from alcohol fine prisms with 2H<sub>2</sub>O. These salts are completely dehydrated at 100°, but absorb 2H<sub>2</sub>O again on exposure to air. The anhydrous salt melts at 205° with decomposition It is soluble in 100 parts of water, in 60 of alcohol, or 1000 of chloroform, at 15°, soluble in 21 of water at 80°, insoluble in ether or benzene. The commercial salt usually gives the thalleroquin reaction and fluoresces with dilute H,SO4 owing to the presence of quinine which may occur to even 60 p c Cinchonine and quinidine are also frequent impurities A strong hot aqueous solution of the salt stirred with half its weight of Rochelle salt and allowed to cool and filtered, should not show more than a slight turbidity when the filtrate is treated with ammonia (Hesse, Zeitsch anal Chem 1876, 15, 464).

Cinchonidine disulphate B·H<sub>2</sub>SO<sub>4</sub>,5H<sub>2</sub>O occurs in long colourless efflorescent crystals, very soluble in water and alcohol (separation from

quinine, see 'Assay').

Cinchonidine tetrasulphate B·2H<sub>2</sub>SO<sub>4</sub>,2H<sub>2</sub>O<sub>4</sub>
for the preparation see under 'Quinine Sulphate.'

Short colourless prisms, slowly soluble in cold water, almost insoluble in absolute alcohol.

Cinchonidine hydrochloride B HCl, H2O occurs as fine monoclinic prisms, soluble in 30 of water or 300 of ether at 12°; soluble in alcohol or chloroform. From alcohol fine needles containing 2H,O are obtained,

Other salts are: benzoate B C, H,O, soluble in 333 of water at 10°; hydrobromide B HBr,H2O slightly soluble in water, more soluble in alcohol; dihydrochloride B.2HCl,H<sub>2</sub>O, large prisms, very soluble in water and alcohol; hydrodide B  $HI, H_2O$ , colourless needles, slightly soluble in water; dihydriodide B2HI,H2O, lemon-yellow prisms, intrate B  $\overline{\rm HNO_3, H_2O}$ , needles or large prisms, soluble in 71 of water at 10°, oxalate B<sub>2</sub> H<sub>2</sub>C<sub>2</sub>O<sub>4</sub>,6H<sub>2</sub>O, prisms, soluble in 250 of water at 10°, platinochloride B<sub>2</sub> H<sub>2</sub>PtCl<sub>6</sub>,2H<sub>2</sub>O, small orange prisms, diplatinochloride B H2Pt(I6, H2O, orange-yellow crystalline powder, insoluble in water, salicylate Succinate B<sub>2</sub> C<sub>4</sub>H<sub>6</sub>O<sub>3</sub>, soluble in 77 of water at 18°, succinate B<sub>2</sub> C<sub>4</sub>H<sub>6</sub>O<sub>4</sub>,2H<sub>2</sub>O, small prisms, soluble in 583 of water at 10°, tartrate B<sub>2</sub> C<sub>4</sub>H<sub>6</sub>O<sub>6</sub>,2H<sub>2</sub>O, fine needles, soluble in 1265 of water at 10°, insoluble in Rochelle salt solution, acid tartrate B 2C<sub>4</sub>H<sub>6</sub>O<sub>6</sub>,3H<sub>2</sub>O, long prisms

Quinamine and its Derivatives and Salts—Quinamine C<sub>19</sub>H<sub>24</sub>O<sub>2</sub>N<sub>2</sub> occurs in nearly all cinchona barks to a very small extent (Hesse, Annalen, 1873, 106, 266, Ber 1877, 10, 2157) It accumulates in quinine sulphate mother liquois, from which it may be obtained by precipitating quinine and cinchonidine with Rochelfe salt, precipitating the filtrate with ammonia and extracting the precipitate with ether The ether is washed out with acetic acid, the acid solution neutralised, and while still warm treated with thiocyanate, until on cooling emchanine can no longer be detected. The filtrate is precipitated with NaOH, and the resinous precipitate dissolved in a minimum of boiling 80 pe alcohol, from which quinamine crystallises on cooling One gallon of quinine sulphate mother liquor will yield about 3 grams of quinamine The base crystallises in delicate white anhydrous needles, melting at 172°, and has  $\left[\alpha\right]_{D}^{15} = +94^{\circ}$  for 1.5 p c solution in chloroform. It is nearly insoluble in cold water, soluble in 105 of 80 p c alcohol at 20°, and in 50 of ether (Oudemans, Annalen, 1879, 197, 150), also soluble in petioleum, ether, or benzene. Quinamine differs from the other cinchona bases in being monobasic, and therefore giving but one series of salts It is coloured yellow by warm sulphuric acid, and

orange by nitric acid The chief derivatives of quinamine are .—

Quinamicine C<sub>19</sub>H<sub>24</sub>O<sub>2</sub>N<sub>2</sub>, formed by heating quinamine for a few minutes at 100° with concentrated H2SO4. The product is treated with sodium bicarbonate, which precipitates the quinamicine in flocks, gradually becoming crystalline It melts at 109°, has  $[\alpha]_D^{15} = +3.8^\circ$ for 2 p c. solution in alcohol, and is soluble in alcohol, chloroform, or ether (Hesse, Annalen, 1881, 207, 303) Its salts are amorphous.

Protoquinamicine  $C_{17}H_{20}O_2N_2$  is formed by heating quinamine to  $130^\circ$  with concentrated  $H_2SO_4$ . It is an amorphous brown base.

Quinamidine C<sub>19</sub>H<sub>24</sub>O<sub>2</sub>N<sub>2</sub> is formed when quinamine is heated with dilute mineral acids or with tartaric acid. Ammonia does not precipitate the base from its solution, but NaOH does so It crystallises from alcohol in small white tufts of needles, not very soluble in ether or chloroform. It melts at 93°, and has  $[\alpha]_{\rm p} = +4.5^{\circ}$  for 2 p.c solution in alcohol Heated with concentrated HCl it gives a yellow solution turning to brown, which on dilution turns 10se, with a strong green fluorescence Quinamidine yields a crystalline hydrochloride B  $HCl_1H_2O$ , hydrobromide B  $HBr_1H_2O$ ; oxalate  $B_2H_2C_2O_4AH_2O$ , and a platinochloride  $B_2H_2PtCl_6AH_2O$ . Its hydrochloride gives a purple colour with AuCl3 in aqueous solution

Apoquinamine  $C_{19}H_{22}ON_2$  is obtained by boiling quinamine or quinamicine with HCl (sp.gr. 1 125), or with 25 p.c.  $H_2SO_4$  for 3 minutes (Hesse, Annalen, 1881, 207, 294). It crystallises in colourless scales, melting at 114°, soluble in alcohol, chloroform, or ether alcoholic solution is optically mactive and neutral to litmus. It is a feeble base, but gives a crystalline hydrochloride readily B HCl, 1H2O (lavorotatory), mitrate B HNO3, oxalate B, H2C2O4, H2O, tartrate

$$B_2 C_4 H_6 O_6, \lambda H_2 O$$
;

and platmochloride B<sub>2</sub> H<sub>2</sub>PtCl<sub>6</sub>,2H<sub>2</sub>O

Salts of Quinamine—Quinamine gives a crystalline chlorate B HClO3, perchlorate crystallino chlorate B HClO<sub>3</sub>, perchlorate B HClO<sub>4</sub>, hydrobromide B HBr,H<sub>2</sub>O, thick prisms, very soluble in water or alcohol, hydrochloude B HCl, H2O, colourless pusms, readily soluble in water, hydrodide BH, small colourless prisms, soluble in 71 of water at 16°, nitiate B HNO<sub>3</sub>, prisms, soluble in 16.5 of water at 15°, sulphate, hexagonal plates or short prisms, very soluble in water, and an amorphous yellow platmochloride

decomposing in the light

#### Conquinamine and its Salts

Conquinamine, C<sub>19</sub>H<sub>24</sub>O<sub>2</sub>N<sub>2</sub>, an isomeride of quinamine is found in the alcoholic mother liquor from which quinamine is crystallised, and is separated from it by fractional crystallisation of their nitiates, oxalates, or hydrobromides, the conquinamine salts being the more soluble (Oudemans, Annalen, 1881, 209, 38, Hesse, ibid 62) It crystallises from alcohol in long pusms or pyramids, melting at 123°, and has  $[\alpha]_D^{15} = +204.4^{\circ}$  for 1 pc solution in absolute alcohol. It is soluble in 74 parts of 91 pc. alcohol at 19°; in 74 parts of ether at 15°; m 4·1 parts of benzene at 18°, almost insoluble in 50 p.e. alcohol of in water. It behaves very like quinamine and is monobasic, but its salts are generally the more soluble. Its oxalate, heated to 105°, melts and changes to quinamiene oxalate and then to apoquinamine oxalate. Heated with HCl (sp gr 1 125) it is converted into apoquinamine Its acid solution with AuCl<sub>3</sub> gives a golden precipitate followed by a purple colouration

Salts —Acetate B·C<sub>2</sub>H<sub>4</sub>O<sub>2</sub>, dimetric crystals, soluble in 10.1 of water at 13.5°; chlorate B·HClO<sub>3</sub>, needles, soluble in 104 of water at 16°; perchlorate B HClO<sub>4</sub>, long needles or short prisms, soluble in 396 of water at 16°; formate B·CH<sub>2</sub>O<sub>2</sub>, monoclinic crystals, soluble in 10·8 of water at 15°; hydrochloride B HCl, large octahedra, moderately soluble in water, hydrobromide B HBr, monoclinic prisms, soluble in 25·8 of water at 16°, hydrodide B HI, plates, soluble in 106 of water at 16°; initiate B·HNO<sub>3</sub>, rhombic crystals, soluble in 76 of water at 15°; oxalate B<sub>2</sub> C<sub>2</sub>H<sub>2</sub>O<sub>4</sub>,3H<sub>2</sub>O, rhombic crystals, soluble in 82·3 of water at 17°, quinate B C<sub>2</sub>H<sub>1</sub>O<sub>4</sub>,2H<sub>2</sub>O, prisms, platinochloride B<sub>2</sub>·H<sub>2</sub>PtCl<sub>6</sub>,2H<sub>2</sub>O, amorphous orange-yellow precipitate, sulphate B<sub>2</sub>·H<sub>2</sub>SO<sub>4</sub>, long prisms, readily soluble in water or alcohol

#### Amorphous Bases.

Diquinicine (diconquinine) C<sub>40</sub>H<sub>46</sub>O<sub>3</sub>N<sub>4</sub> Thus amorphous base is the chief constituent of commercial quinoidine, and its constitution is very doubtful. Hesse found the molecular weight by the cryoscopic method to be about one-half of that represented by the above formula (Ber. 1877, 10, 2155) It is prepared by neutralising quinoidine with oxalic acid. thoroughly dehydrating, powdering the oxalate and extracting with cold chloroform Quinicine oxalate remains undissolved, and on adding a little water to the chloroform solution and allowing to stand a short time, cinchonicine oxalate crystallises out, and is filtered off evaporating the chloroform solution to dryness diquinicine remains as an amorphous red mass It is dextrorotatory, gives a fluorescent solution in dilute H2SO4, and gives the thalleroquin re-No crystalline salts have been obtained

Dicinchonicine (dicinchonine) C<sub>38</sub>H<sub>44</sub>O<sub>2</sub>N<sub>4</sub> This base occurs in the bark of C rosulenta and C succirubra, together with the principal cinchona bases It is prepared from the mother liquor, after precipitating the einchonidine as tartrate, by rendering alkaline and extracting The ethereal solution is extracted with ether with dilute acetic acid and the acid solution exactly neutralised with NaOH and fractionally precipitated with potassium sulphocyanide The dicinchonine thrown down, mainly in the middle fractions, is again put through ether and crystallised as hydrochloride (Hesse, Annalen, 1885, 227, 153) The free base is a yellow amorphous body with a strong alkaline reaction, m p  $40^{\circ}$ ,  $[\alpha]_{D}^{15} = +91.7^{\circ}$  for a 1.52 p c solution in 97 pc alcohol It is very soluble in ether, acetone, alcohol, chloroform, or benzene, ınsoluble ın alkalıs The molecular weight determined by the cryoscopic method indicates half that of the above formula It gives a crystalline hydrochloride B 2HCl, easily soluble platinochloride B 2H<sub>2</sub>PtCl<sub>8</sub>,4H<sub>2</sub>O, orange flakes, hydrodide, compact crystals, readily soluble in water, insoluble in NaCl or KI solution, and oxalate, easily soluble prisms, but its other salts are amorphous On heating with HCl to 140°-160° it is converted into an isomeride, diapocinchoninine, an amorphous base soluble in ether, alcohol, or chloroform, having  $[a]_{D}^{15} = +20^{\circ}$  in alcoholic solution (Hesse, Annalen, 1880, 205, 333)

Paricine C<sub>16</sub>H<sub>18</sub>ON<sub>2</sub> was discovered by Winckler (Jahresber. 1845, 27, 338) in the barks

of Buena hexandra and C. lutea. Later, Hesse found it in C. succirubra of Darjeeling (Pharm J. 1870, [3] 1, 344; Annalen, 1873, 166, 263). It is separated from the other cinchona bases by intric acid, paricine nitrate being insoluble. The free base is obtained by suspending the nitrate in alcohol, decomposing with ammonia, and crystallising from petioleum ether. It is purified by dissolving in dilute HCl, decolourising with animal black and precipitating with ammonia. The pure paricine thus obtained is a yellow amorphous powder, soluble in water, alcohol, ether, and petroleum ether; in p. 116°. Its salts are amorphous

Javanine was found by Hesse among the amorphous bases of C. Calisaya Javanica. It separates from water in rhombic scales, very soluble in ether, and gives an intense yellow colour with dilute H<sub>2</sub>SO<sub>4</sub>—It yields a crystalline oxalate (Ber. 1878, 10, 2162).

# REMIJIA BASES.

Cupreine and its Derivatives and Salts -Cuproine  $C_{19}H_{22}O_2N_2$  occurs in cuprea bark (Remijia pedunculata) together with the other cinchona alkaloids, except cinchonidine Its molecular combination with quinine was at first mistaken for a new alkaloid, and called homoquinine (Howard and Hodgkin, Chem. Soc Trans 1882, 41, 66, Paul and Cownley, Pharm J 1881, 12, 497) Three years later, Paul and Cownley isolated the new alkaloid cupreme from homoquinine (Pharm J 1884, 15, 221, 401, Hesse, Annalen, 1884, 225, 98, ibid 226, 242, 1885, 230, 72) Cupreine completely crystallises out with the quinine when a sulphuric acid solution of the bases is neutralised It is separated from the quinine by dissolving this rough sulphate in acid, precipitating the solution with eacess of NaOH, and extracting the quinine with ether. The alkaline aqueous hquor on neutralising with H<sub>2</sub>SO<sub>4</sub> throws out cupreinc sulphate. The base crystallises from ether in concentric prisms containing 2H2O, or from alcohol as a crystalline powder containing  $\frac{1}{3}H_2O$ , dehydrating at  $120^\circ$  It is spaningly soluble in ether or chloroform, easily soluble in alcohol, m p 198°,  $[a]_{\rm p}^{16} = -175 \ 3^{\circ}$  for 1 5 p c. solution in 97 p.c. alcohol Its solution in dilute  $\rm H_2SO_4$  does not fluoresce, but gives the thalleroquin reaction, and with ferric chloride a reddish-brown colour is obtained is the lower homologue of quinine having a hydroxyl group replacing the methoxy group of quinine in the para-position of the quinoline ring. This —OH group has phenolic properties which enables cupreme to form salts with the alkalis, and strong compounds with the other cinchona bases. It is also dibasic, forming readily crystalline salts with acids Heated with HCl (sp gr 1 125) to 150° it is converted into an isomer, apoquinine, the same body being obtained from quinine under similar treatment (q v)When sodium cupreinate is treated in methyl alcohol solution with methyl chloride or methyl nitrate, quinine (methyl-cupreine) is obtained (Grimaux and Arnaud, Compt rend. 1891, 112, 374, 766; 114, 548, 612) By this reaction the following higher homologues of quinine were obtained by Grimaux and Arnaud :--

Quinethyline  $C_{19}H_{20}N_2(OH)OC_2H_5$ , a white powder, m.p.  $160^\circ$ ,  $[a]_D = -169 \cdot 4^\circ$ ; sulphate  $B_2 \cdot H_2SO_4, H_2O$ , plates, soluble in 397 of water at  $15^\circ$ .

**Quinpropyline**  $C_{19}H_{20}N_2(OH)OC_3H_7$ , a white powder, m.p.  $164^\circ$ , sulphate  $B_2 \cdot H_2SO_4$ ,  $1\frac{1}{2}H_2O$ , needles, soluble in 454 of water at 13°.

needles, soluble in 454 of water at 13°.

Quinisopropyline C<sub>19</sub>H<sub>20</sub>N<sub>2</sub>(OH)OC<sub>3</sub>H<sub>7</sub>, a white powder, m.p 154°; sulphate B<sub>2</sub>·H<sub>2</sub>SO<sub>4</sub>, H<sub>2</sub>O, needles, soluble in 367 of water at 10°

Quinisoamyline  $C_{19}H_{20}N_2(OH)OC_5H_{11}$ , amorphous, mp 167°, sulphate  $B_2$   $H_2SO_4$ , needles, soluble in 4170 of water at 115°.

These ethers all give fluorescent solutions in dilute  $\rm H_2SO_4$ , whereas cupreine does not — They are strongly febrifugal, but more toxic than quinine

Homoquinine. The molecular compound of quinine and cupreine named homoquinine

C<sub>20</sub>H<sub>24</sub>O<sub>2</sub>N<sub>2</sub> C<sub>19</sub>H<sub>22</sub>O<sub>2</sub>N<sub>2</sub>,1, 2, or 4H<sub>2</sub>O may be obtained by dissolving equi-molecular proportions of the two alkaloids in alcohol and evaporating to dryness, or by mixing 1 molecule of quintine hydrochloride with 1 molecule of sodium cupremate (Hesse, *lc*) It behaves like a simple alkaloid, alkalis alone breaking it up, and forms well-defined salts. It melts at 177°, is lævorotatory, and dissolves with difficulty in ether, but readily in alcohol

For Hydrocupreme, see 'Hydroquinne.' Salts of Cupreine —Acetate B C<sub>2</sub>H<sub>4</sub>O<sub>2</sub>,2H<sub>2</sub>O, fine needles, soluble in 85 of water at 17°; hydrobromide B HBr,H<sub>2</sub>O, needles, soluble in 122 of water at 16°, dhydrobromide B 2HBr, soluble in 125 of water at 16°; hydrochloride B·HCl,H<sub>2</sub>O, small needles, soluble in 53°5 of water at 16°; dhydrochloride B·2HCl, short prisms, readily soluble in cold water, hydrochde B HI, soluble in 106 6 of water at 16°; dhydrochloride B 2HI,H<sub>2</sub>O, orange crystals, soluble in 15 of water at 16°, intrate B HNO<sub>3</sub>,2H<sub>2</sub>O, needles, soluble in 86 of water at 16°; dintrate B 2HNO<sub>3</sub>,H<sub>2</sub>O, yellow transparent crystals, soluble in 12 of water at 17°; oxalate B C<sub>2</sub>H<sub>2</sub>O<sub>4</sub>,2H<sub>2</sub>O, colouiless crystals, soluble in 407 of water at 18°; platinochloride

B2H2PtCl6,4H2O

yellow amorphous precipitate; diplatinochloride  $B\cdot H_2PtCl_6, H_2O$ , orange needles; sulphate  $B_2H_2SO_4, 6H_2O$  (Hesse), anhydrous (Howard and Chick, J. Soc Chem Ind 1909, 28, 53), needles, soluble in 813 of water at  $17^\circ$ ; disulphate  $B\cdot H_2SO_4, H_2O$ , thick prisms, soluble in  $70\cdot 4$  of water at  $16^\circ$ ; tetrasulphate

## B·2H<sub>2</sub>SO<sub>4</sub>,3H<sub>2</sub>O

short silky needles, very soluble in water, less soluble in alcohol; tartrate  $B_2$   $C_4H_6O_6,H_2O$ , white needles, soluble in 517 of water at 16°.

Crachonamine and its Salts—Cinchonamine C<sub>19</sub>H<sub>24</sub>ON<sub>2</sub> occurs in the bark of Remijia Purdicana, together with cinchonine, concusconine, chairamine, chairamidine, conchairamine, and conchairamidine. It is obtained by extracting the powdered bark with hot dilute H<sub>2</sub>SO<sub>4</sub>, the acid extract is precipitated by ammonia, and the precipitated bases filtered and dried. This dried mass is then extracted with boiling alcohol, the alcohol extract concentrated, cooled, and treated with HNO<sub>3</sub> (sp gr. 1 200) until decidedly acid. Cinchonamen intrate is

precipitated and is purified by recrystallisation from boiling water (Arnaud, Compt rend 1881, 93, 593; 1885, 97, 174; Hesse, Annalen, 1884, 225, 218).

The base crystallises in needles or orthorhombic prisms, melting at 185°, and subliming,  $[\mathfrak{a}]_D^{15} = +121\cdot1^\circ$  for 2 pc solution in 97 pc alcohol. It dissolves in alcohol or chloroform, and in 100 of ether at 17°; slightly soluble in benzene, petroleum ether, CS2, or water. It is a strong base, giving well-defined salts, and differs from its isomerides, hydrocinchonine and hydrocinchonidine, in being readily attacked by permanganate at 0° in  $H_2SO_4$  solution. It differs from the cinchona bases in the great solubility of its sulphate and the insolubility of its nitrate. Arnaud proposed the use of this alkaloid for the estimation of nitrates, but the method is limited in its application (Ann. Chim. Phys 1890, 19, 93, Howard and Chick, J. Soc. Chem. Ind. 1909, 28, 53). Treated with excess of nitric acid (sp.gr. 106) a yellow amorphous explosive body, dinitrocinchonamine.

 $C_{1y}H_{22}(NO_2)_2ON_2$ 

is formed, soluble in alcohol, chloroform, or ether, and melting at 118°. This base is insoluble in strong HCl, but soluble in the dilute acid; and on heating with strong HCl does not give methyl chloride. It is strongly febrifugal, but also very toxic

Salts—Citrate B<sub>2</sub> C<sub>6</sub>H<sub>8</sub>O<sub>7</sub>, prisms, soluble in 51 of water at 15°, hydrobromide B·HBr, long needles, soluble in 600 of water at 15° hydrochloride B HCl, soft laminæ, or B HCl, H, O, transparent cubes, both soluble in 200 of water at 27° (Howard and Perry, J Soc Chem Ind. 1905, 24, 1281), hydrodide B HI, long prisms or plates, soluble in 950 of water at 15° hyposulphite B·H<sub>2</sub>S<sub>2</sub>O<sub>3</sub>, prisms, slightly soluble in water; malate B<sub>2</sub> C<sub>4</sub>H<sub>6</sub>O<sub>5</sub>, H<sub>2</sub>O, flaky crystals, soluble in 100 of water at 15°; intrate B HNO<sub>3</sub>, short prisms, soluble in 500 of water at 15° platinochloride B<sub>2</sub> H<sub>2</sub>Pt('l<sub>6</sub>, semi-crystalline yellow precipitate, insoluble in water, picrate B  $C_6\dot{H}_2(N\dot{O}_2)_3$  OH,  $\frac{1}{2}H_2O$ , yellow flocks, insoluble in water, "sulphate B. H. SO4, transparent prisms, very soluble in water, less soluble in alcohol, disulphate BH2SO4, octahedra or prisms, very soluble in water, sulphocyanide B HCNS, laminæ or short prisms, insoluble in water, taitrate  $B_2$  ( ${}^t_4H_6O_8$ , crystalline powder or thick prisms, soluble in 87 of water at 15°.

Concusconine  $C_{23}H_{26}O_4N_{\circ}$ . To produce this base Hosse extracted Remijia Purdicana with alcohol, evaporated the extract to dryness, added a large excess of NaOH, and extracted with ether. On shaking the ethereal extract with excess of dilute H2SO4 the concusconine is precipitated as sulphate together with the chairamine isomerides, the cinchonine and cinchonamine remaining in the acid solution rough sulphate is boiled with Na<sub>2</sub>CO<sub>3</sub> solution. and the freed bases washed, dired, weighed, dissolved in boiling alcohol, and I part of H<sub>2</sub>SO<sub>4</sub> added for every 8 parts of alkaloid. Concusconine sulphate separates out completely on cooling (Annalen, 1884, 225, 234). The base cooling (Annalen, 1884, 225, 234). forms colourless monoclinic prisms containing 1H<sub>2</sub>O; mp, after drying, 206°-208° with decomposition;  $[a]_{p}^{15} = +40.8^{\circ}$  for 2 p.c. solution

in 97 p.c. alcohol. It is slightly soluble in strong alcohol, less so in dilute, very soluble in chloroform, ether, or benzene. A solution in acetic acid or HCl gives a dark-green colour with concentrated HNO3. This reaction is also given with the chairamine isomerides. Concentrated H<sub>2</sub>SO<sub>4</sub> gives a blush-green solution, turning olive-green on warming. It is a weak base, its salts are mostly gelatinous, but it gives a crystalline sulphate B<sub>2</sub>·H<sub>2</sub>SO<sub>4</sub> in small white prisms almost insoluble in water or alcohol; an oxalate B<sub>2</sub>·C<sub>2</sub>H<sub>2</sub>O<sub>4</sub>; and a platinochloride B·H<sub>2</sub>Pt(l<sub>8</sub>. Concusconine is isomeric with brucine It contains two methyoxy groups

Chairamine C<sub>22</sub>H<sub>26</sub>O<sub>4</sub>N<sub>2</sub>. On adding a little concentrated HCl to the alcoholic mother liquor of the concusconine sulphate (above), chairamine hydrochloride crystallises out in small needles. The base crystallises from dilute alcohol in slender white needles or from strong alcohol in thick prisms containing 1H2O, which melt at 140°, and, after drying, at  $233^{\circ}$ ,  $[\alpha]_D = \text{about}$ + 100 in 97 p.c. alcohol It is readily soluble in chloroform or ether, and in 540 of 97 p c alcohol at 11° Its acctic acid solution gives a dark-green colour with concentrated HNO<sub>3</sub> In concentrated H2SO4 the base gives a colourless solution, slowly turning dark green It gives a hydrochloride B·HCl, H2O, needles, soluble in water, slightly soluble in alcohol—a platino-chloride  $B\cdot H_2PtCl_6, 2H_2O$ , and a sulphate B<sub>2</sub>·H<sub>2</sub>SO<sub>4</sub>,8H<sub>2</sub>O

Conchairamine C<sub>22</sub>H<sub>26</sub>O<sub>4</sub>N<sub>2</sub>. On adding a little solution of pota-sium sulphocyanide to the chairamine hydrochloride mother liquor (above), conchairamine sulphocyanide 18 obtained The base is liberated with NaOH and re-Thick crystallised from alcohol. colourless prisms BH,OC,H,OH are obtained, melting at 82°-86°, and losing their water and alcohol of crystallisation at 120°, being at the same time converted into an amorphous form An acetic acid solution of the base precipitated with ammonia yields white crystalline flocks containing  $1\rm{H}_2O$ , melting and dehydrating at  $110^\circ$  The anhydrous base melts at 120°, and has  $\lceil \alpha \rceil_D^{15} = +68.4^\circ$  for 2 p c solution in 97 p c alcohol. It is soluble in chloroform or ether and in boiling alcohol In concentrated H<sub>2</sub>SO<sub>4</sub> the base gives a brown solution turning dark green It gives a dark-green coloui in acetic acid solution with concentrated HNO3 A solution of the base in alcohol is neutral to litmus Its salts are readily crystalline, the chief being hydrochloride B HCl; hydriodide B HI, $H_2O$ , platinochloride B  $H_2$ PtCl $_6$ 5 $H_2O$ , sulphocyanide B HCNS, H<sub>2</sub>O; sulphate

### B<sub>2</sub> H<sub>2</sub>SO<sub>4</sub>,9H<sub>2</sub>O

Chairamidine ('22H26O4N2. When more potassium sulphocyamde is added to the filtrate from the conchairamine sulphocyamde until the dark colour of the solution becomes light brown a pitch-like mass separates. The mother liquor is now treated with excess of ammonia and shaken out with benzene; the benzene is extracted with a saturated solution of ammonium sulphate, when a mixture of chairamidine and conchairamidine sulphate is precipitated. The mixed

sulphates are dissolved in boiling water and cooled, a gelatinous mass precipitating, part of which becomes crystalline after standing some days. On now warming to 40°, the gelatinous part redissolves, leaving the crystals of conchair-amidine sulphate. On re-cooling chairamidine sulphate falls again as a jelly, which is drained off, re dissolved in water, and the base precipitated with ammonia.

Chairamidine is a white amorphous powder containing IH<sub>2</sub>O, melting, when dry, at  $126^\circ$ -128° with decomposition, and has  $[a]_D^{15} = +7.3^\circ$  for 3 pc solution in 97 pc alcohol. It is insoluble in water, readily soluble in alcohol, ether, chloroform, or benzene. It is a feeble base, its alcoholic solution being neutral to lithius. It gives a yellow solution in concentrated H<sub>2</sub>SO<sub>4</sub>, slowly turning green. Animal black completely removes it from its solution in acetic acid. Its salts, which are amorphous, have been little studied

Conchairamidine  $C_{22}H_{26}O_4N_2$ . This base is obtained as crystalline sulphate in the preparation of chairamidine (above). The free base crystalline, contains  $1H_2O$ , melts at  $114^\circ-115^\circ$  after drying, and has  $\lfloor \alpha \rfloor_D^{15} = -60^\circ$  for 3 p c solution of the anhydrous base in 97 p c alcohol it is very soluble in alcohol, ether, chloroform, benzene, or acctone. It is a feeble base and neutral to litmus. It gives a dark-green colour in concentrated  $H_2SO_4$ . It gives crystalline salts, the chief being hydrochloride B  $HC_13H_2O$ , platinochloride. B  $H_2PtCl_6,5H_2O$ , sulphate  $B_2H_2SO_4,14H_2O$ 

# Cusco Bases

Aricine C<sub>23</sub>H<sub>26</sub>O<sub>4</sub>N<sub>2</sub>. This alkaloid was discovered in Cusco bank by Pelletier and Corriol (J. Pharm. Chim. 1829, 15, 575), and is identical with Manzini's cinchovatine obtained this base by extracting the powdered bark with alcohol, treating the alcoholic extract with excess of NaOH, and extracting with ether. The ethereal solution was shaken out with acctic acid, and the acid solution partially neutralised with ammonia, when aricine acetate separates out The filtrate mixed with a strong solution of ammonium sulphate, yielded cusconine sulphate (Annalen, 1878, 185, 296) Moissan and Landrin, after powdering the bank, treating it with lime and 40 pc NaOH and re-drying, extract the alkaloids with ether. On washing out the ethereal solution with dilute H<sub>2</sub>SO<sub>4</sub> aricine sulphate falls out, is decomposed with ammonia, and the free base crystallised from alcohol (J. Pharm Chim 1890, [5] 21, 337).

Ariene forms large colouriess prisms, insoluble in water, soluble in 100 of 90 p c alcohol, or in 33 of ether, at 15°; very soluble in chloroform. It melts at 188° and has  $\lceil \alpha \rceil_D^{15} = -58$  2° for 2 p.c solution in 97 p c alcohol. In account in 3 dextrorotatory,  $\lceil \alpha \rceil_D = +14$  5°. It gives a yellow-green colour in strong  $H_2SO_4$ , turning a fine deep blue on addition of ammonium molybdate, which on warming turns olive-green, reverting to blue on cooling. This reaction is characteristic for arieine and cusconino. Nitric acid colours arieine deep green, and dissolves

CINNABAR 279

it to a greenish-yellow solution. Aricine is not | (uncorr), with decomposition, very soluble in is a feeble base, its salts partly dissociating in water

The chief salts are: acetate

# B·C,H,O,3H,O

small white granular crystals, almost insoluble in cold water, slightly soluble in hot; citrate B  $\rm C_6H_7O_6$ , colourless needles, slightly soluble in water, hydrochloride B HCl,2H<sub>2</sub>O, colourless prisms, slightly soluble in cold water: hydriodide B·Hl, colourless prisms, almost insoluble in water; oxalate, granular white crystalline powder; binoxalate B C<sub>2</sub>H<sub>2</sub>O<sub>4</sub>2H<sub>2</sub>O, prisms, rapidly changing to ihombohedra, soluble in 2025 of water at 18°, platinochloride B<sub>2</sub> H<sub>2</sub>PtCl<sub>6</sub>,5H<sub>2</sub>O, orange-yellow precipitate, sparingly soluble in water, salicylate

B C, H, O, 2H, O

pale yellow pulverulent precipitate, sparingly soluble in water, easily soluble in alcohol sulphate B<sub>2</sub> H<sub>2</sub>SO<sub>4</sub>, fine needles, fairly soluble or cold water, disulphate BH, SO<sub>4</sub>, small crystalline groups, very slightly soluble in cold water, sulphocyanide B HCNS, small colourless

prisms, very slightly soluble in water Cusconine  $C_{23}H_{26}O_4H_2$ . The rough cusconine sulphate, obtained from the aricine acetate mother liquid (above), on precipitation with ammonia as the base and crystallising from ether, is obtained as white lamine. From alcohol or acetone larger crystals may be obtained The crystallised base contains 2H,O, which it loses at 80°, the anhydrous base melting at 110°. It has  $[a]_{D}^{15} = -54.3^{\circ}$  for a 2 p c solution in 97 p.c. alcohol The base dissolves in 35 parts of ether at 15°, more easily in alcohol or acetone, is very soluble in chlorotorm, but is insoluble in water. It gives the same colour reactions with H.SO4 and ammonium molybdate as arreine It is a feeble base, its salts having an acid reaction Most of the salts are gelatinous or amorphous Hesse (Annalen, 1878, 185, 296) prepared the following salts. aurichloride, dirty yellow amorphous precipitate readily decomposing; hydrobromide, white ın water, amorphous precipitate, soluble hydrochloride, uncrystallisable, but forms with mercuric chloride a pulverulent precipitate B·HCl  ${\rm HgCl_2,2H_2O}$ , hydrodide, pale yellow amorphous precipitate, freely soluble in water, platinochloride B2, H2PtCl6,5H2O, amorphous flocculent dark yellow precipitate; sulphate  $B_2H_2SO_4$ , lamine from alcohol, disulphate, gelatinous and uncrystallisable; thiocyanate B HCNS,2H2O, pale yellow amorphous powder

Cusconidine, an amorphous base precipitated from cusconine mother liquors with alkalis; it falls as pale yellow flakes which, after washing, mass together, and on drying form an amorphous mass (Hesse, Annalen, 1880, 200, 303)

Cuscamine. From an acetic acid solution of the total alkaloids of Cusco bark nitric acid precipitates insoluble cuscamine and cuscamidine nitrates. On conversion of the nitrates to oxalates, and washing with water, cuscamidine oxalate dissolves, leaving cuscamine oxalate The free base is obtained by treating with NaOH, and crystallising from ether and alcohol Cuscamine forms colourless prisms, m.p. 218°

bitter in flavour, but slightly astringent. It ether, moderately soluble in alcohol. It gives a vellow colour with concentrated H, SO4, turning brown on warming; on adding molybdic acid a bluish-green colour is obtained, turning brown on heating, and violet-brown on re-cooling With nitric acid a yellow colouration is obtained It readily yields crystalline salts (Annalen, 1880, 200, 304).

Cuscamidine is obtained by concentration of its oxalate solution obtained as above closely resembles cuscamine in chemical and physical properties, but its salts are more soluble

#### ASPIDOSPERMA BASES.

Paytine  $\rm C_{21}H_{24}ON_2$  is extracted from the white bark of Payta (Peru) by means of alcohol The alcoholic extract is diled, mixed with NaOH, shaken with ether, the ethereal solution extracted with dilute H<sub>2</sub>SO<sub>4</sub>, the acid liquor treated with animal charcoal and neutralised On adding KI solution ammonia until no more precipitation occurs, paytine hydrodide falls as a white precipitate, becoming dense, yellow, and crystalline. The free base crystallises in fine prisms containing IH,O, and is soluble in alcohol, ether, benzol, ligroin, and chloroform, slightly soluble in water; mp  $156^{\circ}$ ,  $[\alpha]_{j} = -495^{\circ}$  in 0 45 pc alcoholic solution Án alcoholic solution is alkaline to litmus
bitter flavour, but is not toxic

It gives curious characteristic colour reactions. With centrated  $\mathrm{HNO_3}$  it gives a colourless solution passing through gainet-red to yellow. Its hydrochloride yields with platinum chloride a dark yellow precipitate, dissolving in HCl to a reddish-brown solution, turning blue and giving a blue precipitate Bleaching powder produces in acid solution a dark red colour, turning blue and then pale yellow with precipitation Gold chloride gives a purple colour and precipitate; mercuric chloride a yellow amorphous precipi-It gives several crystalline salts, the chief being the hydrochloride B HCl, prisms, soluble in 16 6 of water at 15°. Heated with soda-lime it yields a non-nitrogenous body, paytone (Hesse, Annalen, 1870, 154, 287, 1873, 166, 259, 1882, 211, 280, Ber 1881, 13, 2308, Wulfsberg, Pharm Zeit 1880, 546, Arata, Gazz. chim. ital 1881, 11, 246).

Paytamine  $C_{21}H_{24}ON_2$  is an amorphous alkaloid precipitated from the iodide mother liquor of paytine hydriodide (see above) by alkalis It is readily soluble in other, gives a purple colour with gold chloride, but differs from paytine in yielding a soluble hydriodide, and by not giving paytone on heating with soda-lime B F H & O. C.

CINEOL v CAMPHORS, SANTONICA. For method of estimating cineol in volatile oils, see Dodge, Analyst, 1912, 461 For its solubility m water, see Earle, J. Soc Chem. Ind. 1918, 274 T.

CINNABAR. Native mercury sulphide (HgS), and the only ore of this metal. Its crystals are rhombohedral, with perfect cleavages parallel to the faces of the hexagonal prism; they are of interest crystallographically in presenting the same type of trapezohedral symmetry as quartz, 280 CINNABAR.

and, like this, they rotate the plane of planepolarised light. They are bright-red in colour, often transparent, and have a brilliant adamantine to sub-metallic lustre; the scarlet streak is characteristic. Sp gr. 8:1; hardness, 2-21. The refractive indices are high . for the ordinary ray 2.854, and for the extraordinary ray 3.201 for red light. The massive ore, which may be compact or earthy in texture, is of the same colour, but sometimes it is liver-brown or black. owing to the admixture of clay or organic matter, as in the varieties called respectively hepatic cinnabar and coral-ore (German, Korallenerz). Cinnabar is very sporadic in its distribution, and no mineral containing mercury has yet been found in the British Isles It is mined at Almaden in Spain, Monte Amiata in Tuscany, Idria in Carniola, New Almaden in California, in the provinces of Kwei-chou and Hunan, in central China, and in Mexico and

Cinnabar and two other crystalline modifications of mercuric sulphide have been obtained artificially by E T Allen and J L (Trenshaw (1912) Cinnabar is the stable form at all temperatures up to its sublimation point, about 580°.

L J. S.

CINNABAR, AUSTRIAN, v CHRQMIUM

CINNAMALDEHYDE, Cunamic aldchyde C.H. CH CH CHO, is contained, together with a hydrocarbon, in oil of cinnamon and oil of cassia. It may be extracted from oil of cinnamon by shaking the oil with a concentrated solution of sodium bisulphite, filtering off the crystalline bisulphite compound, washing the latter with alcohol and distilling it with dilute sulphuric acid, when the cinnamaldehyde passes over with the steam The cinnamaldehyde is extracted from the aqueous distillate with other, and, after expelling the ether, is purified by distillation under a pressure of from 40 to 50 mm (Peine, Ber 1884, 2109) It may be extracted from cassia oil by adding to it the barium salt of sulphanilic acid, filtering off the crystalline compound thus formed and steam distilling, whereby the compound is resolved into its components and cinnamaldehyde distils over (Ch. Fab. von Heyden Akt -Gesel D. R. P. 124229, Chem Zentr 1901, 11 903) It is chained by allowing a mixture of 10 parts of benzaldehyde, 15 of ordinary aldehyde, 900 of water, and 10 of a 10 pc solution of caustic soda to stand at a temperature of about 30° for from 8 to 10 days, shaking from time to

### $C_6H_5$ ·CHO+CH<sub>3</sub>·CHO= $C_6H_5$ ·CH CH CHO+ $H_2O$

The solution is extracted with ether and the ethereal extract treated as in the foregoing method (Krszysica, Ber 1884, 2117). It is best prepared by the condensation of benzaldehyde and ordinary aldehyde at a low temperature by means of a concentrated alkali solution. The alcoholic solution of the aldehydes, cooled to  $-10^{\circ}$ , is agitated with a 25–30 p c solution of caustic soda, previously cooled to the same temperature. Under these conditions the formation of resins is avoided (Bochringer and Sohne, Eng. Pat. 10003; J. Soc. Chem. Ind. 1897, 463). Also formed when a mixture of calcium cinnamate and calcium formate is distilled (Piria, Annalen, 100, 105).

It is a colourless oil with a pleasant aromatic smell of cinnamon. It decomposes when distilled under ordinary pressures, especially with access of air, but may be distilled without decomposition in a current of steam or under reduced pressure. It boils at 120°-130° under a pressure of 20 mm (Peine, Ber. 1884, 2110); at 209 5° under 250 mm. (Perkin, Chem. Sec. Trans. 1896, 1247) and solidifies at  $-7.5^{\circ}$  (Pictet, Compt rend. 119, 955); sp.gr. 1 0497  $20^{\circ}/4^{\circ}$  (Bruhl, Annalen, 235, 18).

By oxidation it yields first cinnamic acid and afterwards benzaldehyde and benzoic acid. Direct reduction does not lead to cinnamyl alcohol as the aldehyde polymerises. Reduction with the zinc-copper couple gives rise to hydrocinnamoin C<sub>2</sub>H<sub>2</sub>(OH)<sub>2</sub>(CH·CHPh)<sub>2</sub> (Thiele, Ber. 1899, 1296) It gives the usual reactions of the aldehydes The diacetyl derivative of the aldehyde, obtained by the action of acetic anhydride, can, however, be easily reduced by iron in acetic acid solution, and by subsequent saponification the alcohol is obtained (Barbier and Leser, Bull Soc chim 1905, 858)

Estimation.—To estimate cinnamic aldehyde in oil of cinnamon or oil of cassia, 10 c c. of the oil are heated on the water-bath, and a solution of sodium bisulphite added in small quantities, time being allowed for the solid to liquefy between each addition. The precipitate is filtered off and weighed (Schimmel, Chem. Zentr. 1892, 1. 92). Hanus (J. Soc. Chem. Ind. 1903, 1154) estimates cinnamaldehyde by means of its semioxamazone. See also-Burgess, Analyst, 29, 78.

It may be estimated colorimetrically by the reaction it develops on treatment with sulphuric acid and isobutyl alcohol (Jellenberg)

CINNAMEIŃ v Balsam of Peru, art

CINNAMIC ACID  $\mathrm{C_6H_5}$  CH.CH COOH (Acide cinnamique, Fr., Zimmtsaure, Ger.)  $\beta$ -Phenylacrylic acid. The separation of a solid acid from oil of cinnamon on keeping was first observed towards the end of the 18th century, but the acid was confounded with benzoic acid, until Bizio, in 1826, showed that it was a distinct acid. It was first investigated by Dumas and Peligot (Annalen, 14, 56).

Occurrence—In liquid storax, partly free, partly as cunnamyl cunnamate (styracin), in tolu and Peru balsams together with benzoic acid and benzyl cunnamate; in some sorts of gum benzoin, in Barbados aloes; and in the leaves and stalks of Globularia aliquim and G. vulgaris, in the leaves of Enkunthus, japonicus, and as esters in many varieties of guttapercha.

and as esters in many varieties of guttapercha Formation and Preparation—It is formed by heating benzaldehyde with acetyl chloride at 120°-130° (Bertagnini, Annalen, 100, 126):

 $C_6H_5$  CHO+CH<sub>3</sub>·COCl= $C_6H_5$ ·CH CH CO<sub>2</sub>H+HCl

Perkin showed that it might be more readily obtained by heating a mixture of benzaldehyde, acetic anhydride, and anhydrous sodium acetate

 $C_8H_5$  CHO+(CH $_3$ ·CO) $_2$ O= $C_6H_5$ ·CH CH CO $_2$ H+ $C_2$ H $_4$ O $_2$  (Chem. News, 32, 258, Chem. Soc. Trans. 1877, 388) Edeleano and Budishteano (Bull. Soc. chim 3, [3] 191) state that by heating 1 part of benzaldehyde, 1 part of acetyl chloride, and 3 parts of sodium acetate for 24 hours at 160°, and

subsequently extracting with alkali and precipitating the cinnamic acid with hydrochloric acid, the cinnamic acid is obtained in quantitative yield. The cinnamic acid employed in the preparation of artificial indigo was at first manufactured by this method; but the process was afterwards improved by Caro (D. R. P. 17467 and 18232; Frdl. 1. 26), who showed that cinnamic acid could be prepared by heating benzal chloride with dry sodium acetate, thus avoiding the use of the expensive acetic anhydride

 $\begin{array}{l} {\rm C_6H_5~CHCl_2 + 2CH_3~CO_2Na} \\ {\rm = C_6H_5~CH:CH~CO_2H + 2NaCl + C_2H_4O_2} \end{array}$ 

1 part benzal chloride, and from 2 to 3 parts of finely powdered fused sodium acetate (for which potassium acetate or a mixture of the potassium and sodium salts may be substituted) are heated at 180°-200° for from 10 to 20 hours in an autoclave furnished with a mechanical The melt is mixed with water, rendered alkaline with caustic soda, and steam-distilled to remove volatile oils, after which the solution in the retort is filtered hot, and the cinnamic acid is precipitated with hydrochloric acid, filtered off after allowing the solution to cool, pressed, and finally purified by recrystallisation from boiling water or alcohol A method patented by the Farbwerke vorm. Meister, Lucius und Bruning (D. R. P. 18064), in which lead acetate is substituted for sodium acetate, offers no advantages over the foregoing

Cinnamic acid may be prepared from benzylideneacetone C<sub>6</sub>H<sub>5</sub> CH CH CO CH<sub>3</sub>, which is readily obtained by the condensation of benzaldehyde with acetone under the influence of dilute caustic soda (Claisen, Ber 14, 2471) When this compound is oxidised by warming it with sodium hypobromite, it is converted into cinnamic acid (Farbwerke vorm Meister, Lucius und Bruning, D. R. P 21162; Frdl. 1 28)

By employing substituted benzaldehydes, benzal chlorides, or benzylidene-acetones in the foregoing reactions, substituted cinnamic acids may be obtained.

It may also be prepared from benzaldehyde and malonic acid in the presence of ammonia or amines; in the place of benzaldehyde the benzylidene compounds of certain amines, such as hydrobenzamide, may be used (Knœvenagel, Ber 1898, 2692, Chem Zentr 1898, ii 695; D R P 97735); or by heating benzylidene diacetate with glacial acetic acid and sodium acetate for 10 hours at 160°-180° (Nef, Annalen, 1897, 298, 309)

Cinnamic acid may be extracted from storax by boiling in a retort 15 kilos of storax with 2 litres of caustic soda of 24°B until no more oily drops distil over with the steam. In this process the styracın is hydrolysed, forming sodium cinnamate and cinnamyl alcohol, the latter being volatile with the steam. The aqueous liquid in the retort is separated and the residue repeatedly extracted with boiling water, after which the cinnamic acid is precipitated from the united aqueous solutions by hydrochloric acid and purified by recrystallisation (Beilstein and Kuhlberg, Annalen, 163, 123); Claassen (J. Soc. Chem Ind 1897, 932) uses sodium carbonate instead of caustic soda Precipitated cinnamic acid may be readily freed from adhering resin by recrystallising it from hot light petroleum.

Properties and Reactions -Forms slender needles or large transparent prisms melting at 133°. Sublimes in absolute vacuum at 108° (Liebermann, Ber. 1900, 33, 2402) Boils at 300° (corr) If rapidly distilled, it scarcely suffers any decomposition, but by slow heating it is broken up into stryolene C.H. CH. and carbon dioxide Sparingly soluble in cold, more readily in boiling water; easily soluble in alcohol. Forms crystalline salts closely resembling those of benzoic acid Oxidising agents convert it first into benzaldehyde (distinction from benzoic acid) and afterwards into benzoic acid, the final products when potassium permanganate is used being phenylglyceric acid, benzaldehyde, and benzoic and oxalic acids (Fittig and Ruer, When taken internally it Annalen, 268, 27) is oxidised to benzoic acid, and appears in the urine as hippuric acid. By fusion with caustic potash it yields a mixture of benzoate and It unites with nascent hydrogen to form hydrocinnamic (β-phenyl-propionic) acid; with bromine to form a dibromide, and with the hydracids to form 3-halogen-hydrocinnamic acids—thus \(\beta\)-chlor-hydrocinnamic acid C<sub>\(\beta\)</sub>H<sub>\(\beta\)</sub> CHCl CH, CO,H

Cinnamic acid condenses with hydrocarbons; thus with benzene and sulphuric acid, it forms phenylhydrindone (Liebermann and Hartmann, Ber 1892, 2124), with phenols, phenol itself yielding hydroxyphenylcoumarin (L and Hibid 1892, 957), and with sulphur to form diphenylthiophene For its detection, see Schenk & Burmeister, Pharm Zeit 1915, 60, 213; Analyst, 1915, 409

Esters. Methyl cinnamate White crystalline solid, m p 36°; b p 263° Ethyl cinnamate may be obtained direct

Ethyl cinnumate may be obtained direct from benzaldehyde by means of ethyl acetate and sodium (Farb vorm Meister, Lucius und Bruning, D R P 53671, Eng Pat 4969, J Soc Chem Ind 1891, 358; Claisen, Ber 1890, 976) It is a colourless liquid, boiling at 226° (corr) under 250 mm (Perkin, Chem Soc Trans. 1896, 1228) By heating 2 parts of ethyl cinnamate with 1 part of sulphur at 150°-160° for 8 hours, a yellow odourless compound C<sub>9</sub>H<sub>6</sub>S<sub>2</sub>O is formed, and is suitable for therapeutical purposes (Farb vorm F Bayer and Co Eng Pat 8425, D R P 87931; J Soc Chem Ind 1896, 293; Kuster, Ber 1897, 115)

Benzyl connamate v Benzyl benzoate Isomeric acids. Allocunnamic acid, m p 68°, dimorphous \*\*socinnamic acid, m p 42°/58°, have been described, but a discussion as to their constitution cannot be entered into here (Bulmann (Ber 1909, 182 and 1443) and Liebermann (\*\*shift 1027) Cf Stobbe (Ber 1911, 44, 2739), who has studied the transformations of allocand \*\*socinnamic acids in the fused and crystalline states

Substituted cinnamic acids. Of the substitution derivatives of cinnamic acid, the only one of industrial importance is orthontrocinnamic acid, which is prepared in the manufacture of orthontrophenylpropiole acid (v Indigo, Artificial). On a large scale cinnamic acid is first converted by heating with alcohol and concentrated sulphuric acid into ethyl cinnamate. The latter substance, which, being a liquid, is more easily manipulated in the nitration process than the solid cinnamic acid, is run in a thin stream into the calculated quantity of cold

nitrosulphuric acid. The mixture of ortho- and para-nitrocinnamic esters thus formed is dissolved in warm alcohol. On cooling, the paracompound crystallises out, whilst the ortho compound remains in solution. The two ethyl salts are hydrolysed by heating with sulphuric acid. The ortho- acid has also been prepared from o-nitro-benzylidene acetone by warming it with a 3 p c solution of sodium hypochlorite (Hochster, Farb D R P 21162, Frdl 1 29) In this process the two isomerides are formed in approximately equal quantity.

Orthonitrocinnamic acid

## CaHa(NO))CH CH CO2H

is insoluble in water, sparingly soluble in cold, more readily soluble in boiling alcohol, from which it is deposited in crystals melting at 240°

The para-compound melts at 285°-286°, and is very sparingly soluble even in boiling alcohol It cannot be used in the preparation of artificial indigo, and the attempt made to utilise it in the rosaniline manufacture has not proved industrially successful

CINNAMON. The inner bank of shoots of the Cinnamomum zeylanicum (Nees), nat ord Lauraceæ, or true laurels According to Percival, it is imported principally from Ceylon, but in part also from Madras, Tellicherry, and, rarely, from Java The bark-peelers select such branches as are 3 years old, and not more than 2 or 3 inches in diameter nor less than half an meh The back in drying rolls up into quills, many layers being enclosed in one quill It is used as a condiment, and yields a highly perfumed essential oil (q v), employed in the preparation of chocolate and for purposes of perfumery Both the back itself in its powdered state and the oil derived from it are frequently adulterated by cassia (r. Cassia).

The value of cinnamon depends upon its content of cinnamaldehyde rather than on the essential oil A method for the estimation of cinnamaldehyde depends on the colouration developed by treatment with sulphuric acid and isobutyl alcohol (v Fellenberg, Analyst,

1916, 274) CINNAMON BROWN v. Azo- COLOURING

MATTERS CINNAMON OIL v OILS. ESSENTIAL.

CINNAMON-STONE or Hessonite. A gemvariety of gainet of a warm reddish-brown colour (hence the name) and transparent It is essentially an orthosilicate of calcium and aluminium Ca3Al2Si3O12, containing, however, isomorphous replacements of iron, manganese, and magnesium Bulliant crystals are found in veins in serpentine at Ala in Piedmont, but material of the best gem-quality is found as pebbles in the gem-gravels of Ceylon

L J. S

CINNAMYL COCAINE v COCAINE AND THE COCA ALKALOIDS

CITARIN. Trade name for sodium anhydromethylene citrate

CITRAL v Terpenes CITRAMALIC ACID v Malic acid.

CITRIC ACID C6H8O, Occurrence -This acid commonly occurs in the juice of many fruits, and in the sap of many plants
Synthesis —The acid has been prepared

artificially by Grimaux and Adam (Compt rend.

90, 1252). A saturated solution of dichloracetonic acid was neutralised with sodium carbonate, and heated with two molecules of potassium cyanide. The resulting solution of dicyanoacetates was saturated with hydrochloric acid gas, and heated on a water-bath for 15 hours, the citric acid was then separated as calcium citrate by neutralisation with milk of lime Another synthesis has been effected by Lawrence (Chem Soc. Proc 1897, 65), who obtained ethyl citrate by heating together ethyl bromacetate and ethyl oxalylacetate in the presence of zinc

Properties -The crystallised acid of commerce has the formula C6H8O7, H2O. The crystals are large prisms belonging to the trimetric system. Their sp gr, according to Buignet, is system. Their sp gr, according ar, and in 1553 They deliquesce in damp air, and in perfectly dry air slowly lose the whole of their Different crystals (probably differently prepared) may lose water at very different rates (Warington, Chem Soc Trans. 28, 928, Gros-According to Marchand (J. jean, ibid, 43, 331) pr Chem 1841, 23, 60), crystals obtained from a saturated boiling solution have the formula 2(C<sub>6</sub>H<sub>8</sub>O<sub>7</sub>),H<sub>2</sub>O According to a later investigation by Sarandinaki (Ber 5, 110), the crystals from a solution long boiled are anhydrous Citric acid is optically mactive. The ordinary crystallised acid dissolves in about half its weight of boiling water Aqueous solutions of various strengths have, according to Gerlach (Zeitsch anal Chem 1869, 295), the following sp gr at

Acid p c	Sp gr	Acid p c	Sp gr
1	1 0037	34	1 1422
2	1 0074	35	1 1467

33	1·1378	66	1 3071

A 25 p.c. solution boils at 101 8°, a 50 pc. solution at 105 8° (Gerlach, J 1859, 48)

At 15° the solubility of the crystallised acid in alcohol is as follows.

> 100 of 80 p.c. alcohol dissolve 87 90 52 85 100 75 90

100 parts of anhydrous ether dissolve 9 l of the crystallised acid

According to Buchner (Ber. 1892, 1159), the ordinary hydrated acid melts between 135° and 152°, and the anhydrous acid at 153° Saltzer (Arch Pharm. 231, 514) finds that the finely powdered hydrated acid, if slowly heated, becomes anhydrous at 55°, and melts at 160° in this condition.

Decompositions —When heated to 175°, acetone and carbonic oxide are evolved, the residue is a conitic acid  $C_6H_6O_6$  , the same acid is formed in small quantity when a solution of citic acid is long boiled (Dessaignes) When heat is continued beyond 175°, an only distillate appears, which yields crystals of itaconic acid C5H6O4. By further heating, itaconic acid is transformed into an uncrystallisable oil, citraconic anhydride C<sub>5</sub>H<sub>4</sub>O, Heated with sulphure acid, carbonic oxide and acetone are given off, the intermediate stage in the reaction being the production of acetone dicarboxylic acid (v. Pechmann, Ber 1884, 17, 2542) This acctone dicarboxylic acid is also formed in the oxidation of citric acid by potassium permanganate and by the photochemical decomposition of citric acid in the presence of 1 p c uranium oxide

Solutions of citue acid are rapidly destroyed by fungi According to F Watts (J Soc Chem Ind 1886, 215), the action of Saccharomyces mycoderma on lime juice is to convert the citric acid into carbonic acid and water cording to I Macagno (Gazz chim ital 11, 443), an alcoholic fermentation in lemon juice does not affect the citiic acid, but under the influence of bacteria the citric acid disappears, and acetic

and propionic acids are formed

Salts — Citric acid is tribasic, and forms in consequence three classes of salts The salts with the alkali metals are readily soluble in water, the neutral salts of the alkaline earths are only sparingly soluble

Calcium citrate ('a<sub>3</sub>(C<sub>6</sub>H<sub>6</sub>O<sub>7</sub>)<sub>2</sub>,4H<sub>2</sub>O does not lose water at 100° When precipitated in a erystalline state its solubility in water is 1 in 1180 at 14°, and 1 in 1730 at 90°-100° When thrown down in an amorphous condition, the solubility is greater, 1 in 707 at 18°, and 1 in 1123 at 100° (Chem Soc Trans 28, 939)

When a solution of citric acid contains a ferrous, ferric, or aluminium salt, in not too great proportion, it may be made strongly alkaline with potash or soda without producing a picci-Such a solution may also be boiled with chalk without precipitating iron or aluminium, although a large part of the citric acid falls as calcium citrate. (With tartaric acid in the place of citric, iron is to a small extent precipitated by chalk in the cold, and entirely on boiling) If, however, the ferric salt bears a large proportion to the citric acid, the whole is precipitated by chalk, even in the cold (Chem. Soc Trans. 28,

Derivatives .- Methylenecitric acid is obtained

by heating citric acid with four times its weight of polymeric formaldehyde at 140°-160°, and allowing the melt to crystallise It is tolerably stable towards acids, but is decomposed by alkalis with elimination of formaldehyde Its di-sodium It is used as a salt is known as 'citarin.' disinfectant for the urinary passages (Ch. Fab auf Act vorm E Schering, US Pat 699422; J Soc Chem Ind 1902, 791).

Monophenetidenecitric acid is obtained by heating 42 parts of citric acid with 27 5 parts of p-aminophenetol for some hours at 100°. The product is dissolved in caustic soda, and the precipitated with hydrochloric acid Diphenetidenecitric acid is obtained similarly. They are medicinal substances, acting energetically as precipitants without producing secondary symptoms (Farb von Heyden-Nachfolger, Eng Pat 1254, J Soc Chem Ind 1895, 385)

Detection - ('itrie acid is best recognised when in a pure state by its yielding on heating an oily sublimate, which afterwards crystallises (itaconic acid) A solution of citiic acid, neutralised with ammonia, gives no precipitate in the cold with calcium chloride, except after long standing, but on boiling, calcium citrate is pre-cipitated. Calcium citrate, precipitated in the cold, is freely soluble in solution of ammonium chloride, and is precipitated therefrom on boiling Alkalı citiates do not reduce silver salts on boiling, as tartrates do, or only to a trifling extent

Kammerer (Zeitsch anal Chem. 8, 298) recommends the detection of citric acid by the To the formation of a crystalline barium salt free acid, or to the alkali salt, excess of barium acctate is added, and the whole heated on a water bath for several hours, the banum citrate

will then be found in microscopic monoclinic prisms.

Dèniges (Compt. rend 130, 32) adds to the solution to of its volume of a reagent obtained by dissolving 5 grams of mercuic oxide in 20 cc of cone, sulphuric acid, and 100 cc of water. The solution is heated to boiling, and, if citric acid is present, a white precipitate is obtained on the addition of a few drops of a 2 p c solution of potassium permanganate

Another method is to add potassium permanganate to the solution until it is pink. If a precipitate is formed, or a brown colour produced, ammonium ovalate is added until it is destroyed On adding bromine water a white precipitate is obtained, which, on the addition of alkalı, gives the characteristic smell of bromoform (Stahre, J. Soc Chem Ind 1896, 53, Wohlk, Zeitsch anal Chem 1902, 77).

The tests for adulteration will be given at the close of this article

Estimation -When the quantity of citric acid in a solution is determined by alkalimetry, phenolphthalem should be used as the indicator; in coloured solutions red-brown turmeric paper (Thomson, J Soc. Chem Ind 1887, 195) has been recommended. If neutral litmus paper is used, the alkalı must be standardised with citric The quantitative determination of citric acid by precipitation as calcium citrate will be described under the analysis of lemon juice.

Citric acid in milk and wine. Citric acid is

present in milk and wine, and as it occurs in small quantities in most wines, adulteration with a small quantity of citric acid cannot be detected (Hubert, Ann. Chim. anal. 1908, 139). It may be detected in milk by taking 10 c c. of milk, 2 c c ot soulum mecaphosphilis, mercuric sulphate solution, and filtering Half of the filtrate is mixed with 0 5 c.c of 10 p c.

To milk, 2 c c of sodium metaphosphate, 3 c.c. of this 4 drops of a 2 p c solution of potassium permanganate is added, and the solution again This is repeated, and the liquid decolourised by a drop of hydrogen peroxide precipitate or an opalescence indicates the presence of citric acid. This method may be used quantitatively (Denigès, Chem Soc Abstr. 1902, in 365, v also Scheibe, ibid 1891, 1276) It may be detected in wine by the method of Spica (Gazz chim ital 31, [2] 61) A portion of the wine is evaporated to a syrup and extracted with alcohol. This is nearly neutralised with alcoholic potash, and the potassium bitaitrate filtered off. The filtrate is then neutralised with more potash, and the precipitate is filtered off, dried, and heated in a small tube with sulphuric acid, until it goes It is then diluted, made alkaline with caustic potash, and sodium introprusside added A red colour indicates the presence of citric Favrel (J. Soc Chem. Ind 1908, 637) evaporates 100 c c. of wine to dryness, dissolves the residue in 7 cc of boiling water, and adds 35 e.e. of 90 p.e. alcohol A solution of calcium acetate (0 4 gram in 5 cc of water) is added, and the precipitate filtered When dry it is transferred to a test-tube, 3 cc of sulphuric acid added, and the whole heated to 80°-90° for 2 minutes The solution is cooled and extracted with ether White crystals are obtained, giving a violet-red colour with ferme chloride, the colour being discharged by mineral acids other methods and quantitative estimation, vWilliams, Analyst, 14, 25, Devarda, J. Soc. Chem. Ind. 1904, 273, Klinger and Bujard, Chem. Soc. Abst. 1893, 11–54; Schindler, Chem. Zentr 1902, II 1016; and Robin, Ann Chim anal 1904, 453)

Gowing-Scopes finds that a mixture of equal weights of mercuric nitrate, manganese nitrate and nitric acid reacts with citric acid, yielding a precipitate after prolonged boiling which is exactly six times the weight of citric acid present. The method gives good results in presence of tartane, succinic and other organic acids, but with malic and lactic acids the results are high (Analyst, 1913, 12)

3 , , ,

### RAW MATERIAL.

Citric acid is prepared from the fruit jurce of three species of Citrus—the lemon, bergamot, and lime, the first of these is the principal source of citric acid. Concentrated lemon jurce is chiefly imported from Sicily, a very little comes from Naples or Sorrento. Concentrated bergamot jurce is prepared in Calabria, and exported from Messina. Concentrated lime jurce is imported from Montserrat and Dominica. The lemon jurce from Sicily is prepared by pressing the inferior fruit, from which the rind has previously been removed for the manufacture of essence. The so-called 'single' jurce.

is then boiled down till its sp.gr. equals 60° on the citrometer (sp.gr. 1.24); it then forms a dark-brown, rather syrupy liquid.

Lemon juce has its greatest acidity early in the season (November). The juce of the fine fruit, exported as lemons, has a sp.gr. 103-104; it contains free acid equal to 11-13 oz. of citric acid per gallon. The inferior fruit pressed in Sicily yields a juice containing at the beginning of the season about 9 oz. of free acid per gallon, and at the end of the season a good deal less.

There are other differences between the juice of fine lemons pressed in England, and the Sicilian juice employed for the manufacture of eitric acid. The former contains very little combined organic acid, only about 2.5 p.c. of the total organic acid (free plus combined) present. In unconcentrated Sicilian juice the combined acid is about 7–9 p.c. of the total Again, the English pressed juice contains hardly any organic acid save citric, only about 1 p.c. of the total organic acid being unprecipitable as calcium citrate. In Sicilian juice about 8 p.c. of the total organic acid is unprecipitable as calcium salt.

The concentrated lemon juce from Siely is reckoned of standard quality when its sp gr is 124, and its acidity is equal to 64 oz per gallon of nominal citric acid. In dealing with trade analyses it must, however, be borne in mind that the 'crystallised citric acid.' of a trade certificate is not the crystallised acid of commerce, but an acid containing only half the actual amount of water, an acid, in fact, having the atomic weight 201 instead of 210:

## CaHaOz,HaO

No reason can be given for this practice, which should certainly be abolished. In the present article all quantities of citric acid will be expressed in terms of the common crystallised acid.

The concentrated lemon juice from Sicily contains pretty uniformly 7–8 oz per gallon of combined organic acid, equal to about 10 pc. of the total organic acid (reckoned as citric) present. Of the total organic acid about 10 pc. is not precipitable as calcium salt, and is therefore not citric acid; this proportion is, however, by no means constant. Purchases of lemon juice are unfortunately still made on the basis of acidity, and not on the amount of precipitable acid present. Analyses of 895 pipes of concentrated lemon juice by Grosjean have been published (Chem Soc Trans 43, 333). The average proportion of precipitable acid was 99 2 pc of the free acid, but the range of variation was considerable, individual parcels of juice giving 81 1, 85 %, and 103 6 pc.

giving 81 1, 85.8, and 103 6 p c.

Concentrated Bergam of juice has a similar spigr. to lemon juice, but a lower acidity; it generally contains free acid equal to about 51 oz of citric acid per gallon. The quantity of combined organic acid is apparently similar to that in lemon juice, namely, 7-8 oz. per gallon; but the proportion of combined to total is higher, 12-13 p.c.. The proportion of unprecipitable acid is about 13 p.c. of the total. Grosjean's analyses of 90 pipes of bergamot juice show a mean of 98.4 of precipitable acid for 100 of acidity, the extremes being 95.4 and 101.4.

The unconcentrated Lime juice of Montserrat has a mean sp.gr. of 1 036; it contains, according to Conroy (Pharm. J. 1883, 606), an average of 7 84 pc, or 12.54 oz per gallon of free acid. The extremes observed wore 6 70–10 05 pc., equal to 10 7–16 l oz. per gallon. The juice yields 0 43 pc of ash. It contains only a trace of sugar. Warington found the combined acid in two samples 5 pc of the total, 10 pc of the total acid was not precipitable

Concentrated lime juice is a viscid liquid, sp.gr 1 32, and with an acidity averaging about 94 oz of eitric acid per gallon. The combined acid is about 8-9 oz per gallon. The unprecipitable acid is about 10-14 p c of the total. The precipitable acid bears a lower proportion to the free than is the case with either lemon or bergamot juice, the published analyses showing a mean of 93 8 of precipitable acid for 100 of free.

The nature of the organic acids, other than citric, present in lemon, bergamot, and lime juce has not been determined. A little formic acid and acetic acid have been detected in concentrated juice, but the principal acids other than citric are clearly non-volatile and have soluble calcium salts. The acids most probably present are malic and acountic

Besides lemon juice, some clude Calcium citrate, prepared in Sicily by precipitating lemon juice with chalk, is exported into England.

It contains about 64 p c of citric acid

## METHODS OF ANALYSING JUICE AND CITRATE

1 Aculity —The commercial analysis juice is confined to the determination of acidity It is most important that the alkalı (sodium hydroxide) used should be actually standardised with citric acid, and the same indicator employed in standardising as in subsequent analyses. Powdered crystals of citric acid are taken, water carefully determined in one portion, while another is used for standardising the alkali determining water, the powdered acid should be heated for some hours at about 60° before exposing it to 100°, if this is not done, the acid will melt, and lose the rest of its water with great difficulty Warington recommended delicate litmus paper for determining the neutral point F Watts has since employed films of turmeric tincture on a white tile (J Soc Chem Ind. 1886, 214) Thomson recommends red-

brown turmeric paper
2. Combined organic acids—The juice is neutralised with a known quantity of standard alkalı, evaporated to dryness in a platinum basin, the residue gently ignited, the black ash treated with a known quantity (excess) of standard sulphuric acid, the whole boiled and filtered The amount of unneutralised acid is then determined with alkali We have now the neutralising power of the ash in terms of alkali; by subtracting the alkali added when neutralising the juice, we obtain the amount of alkali corresponding to the bases of the organic salts, which became carbonates on ignition the amount of these bases their equivalent in combined citric acid can be calculated.

3 Precipitable citric acid—This is for the manufacturer the only trustworthy method of analysis, but is, in fact, seldom adopæd. War-

ington proceeds as follows: 15-20 e.c. of unconcentrated juice, or about 3 cc. of concentrated juice, are exactly neutralised with sodium hydroxide, the solution (about 50 c c ) is brought to boiling in a salt-bath, and a measured quantity of calcium chloride solution, known to be rather more than sufficient for all the organic acids present added. After boiling for half an hour, the precipitate is collected on a small filter, and washed with hot water. The filtrate and washings are then concentrated to 10 cc and the solution finally neutralised with a drop of am-The second precipitate is collected on a monia very small filter, the filtrate being used for getting the precipitate on to the paper, which is finally washed about five times with a little hot water. The precipitates in their papers are then burnt at a low heat in a platinum basin, and the neutralising power of the ash determined with standard hydrochloric acid and alkali The amount of citric acid which the base is equivalent to can then be calculated, three molecules of base being reckoned as equivalent to one molecule of citric acid

4 Analysis of calcium citrate—The excess of chalk present is first determined by boiling about 4 grams with dilute standard hydrochloric acid in a covered beaker, and then adding standard alkalı tili feebly alkalıne Two grams of the citrate are then gently ignited in a covered platinum crucible, and the neutralising power of the ash determined by solution in standard hydrochloric acid and titiation with alkali By deducting from the neutralising power of the ash that due to the chalk previously determined, we find the amount of base which has to be calculated as citrate. This method presupposes that citrates are the only organic salts present If it is preferred, the citrate may be dissolved in hydrochloric acid, the solution boiled, neutralised with soda, the calcium citrate precipitated by boiling in the salt-bath, and its quantity determined as in the case of juice

The information here given respecting juice, calcium citrate, and the methods of their analysis, will be found in greater detail in Chem Soc Trans 28, 925, 43, 331, v also Ulpiani and Pairozzani (Chem Soc Abstr 1907, n 57), Shica (Analyst, 1910, 35, 519), Barboni (ibid. 1913, 65).

### PROCESS OF MANUFACTURE.

The manufacture of citic acid from concentrated lemon juice is extremely simple A proper quantity of whiting (levigated chalk) is mixed with water, and heated by steam in a wooden vat provided with a revolving agitator, the concentrated juice is then slowly pumped in, care being, of course, taken that the whiting is finally in small excess. The liquor never becomes neutral, however long boiling may be continued, or however great is the excess of whiting present, the adjustment of juice and whiting is therefore effected by ascertaining if the liquor effervesces with more whiting, or the precipitate effervesces with more juice. The amount of unneutralised acid is about 1-21 p.c of the original acidity of the juice. Pure citric acid is readily neutralised by whiting, malic and aconitic acids are not; the final acidity is thus possibly due to the presence of these acids. Citric acid, however, is not

neutralised by chalk if phosphates, and especially ferric phosphates, be present; this fact will also explain the result—It is not advisable to neutralise completely by the use of lime, as vegetable impurities are then thrown down which are afterwards difficult to separate

The precipitated calcium citrate is washed with hot water on a liter. It is next brought by the addition of water to the state of thin cream, and decomposed, with constant agitation, by the addition of a small excess of sulphunic acid (sp.gr. 1.7). The occurrence of an excess of sulphunic acid is known by the liquor affording a precipitate with a strong solution of calcium

chloride after some minutes' standing

The citric acid liquor is then separated from the gypsum, which is washed on a filter liquor is evaporated in shallow leaden baths by steam heat Much gypsum is at first deposited, from this the clear houor is run off and further concentrated When strong enough to crystallise, the hot liquor is run into a wooden tub provided with an agitator, and the liquor is kept in constant motion while cooling, by this process, known as 'granulation,' the citric acid is obtained as a crystalline powder. The mother liquor is again concentrated, and 'salt' again obtained by granulation. The process may be repeated a third time. The liquor is then too dark and impute for further crystallisation, and is known as 'old liquoi' The granulated citic acid when drained, and, if necessary, slightly washed, is redissolved, decolourised by heating with animal charcoal (previously freed from phosphates by hydrochloric acid), again concentrated to the crystallising point, and poured into leaden trays about 3 inches deep, the crystals here formed are the citric acid of commerce Citric acid thus prepared always contains a trace of lead, and often particles of metallic lead, probably due to the plumbers repairing the vessels. To free the and from lead, the process usually adopted is to pass sulphuretted hydrogen through the solution after the first crystallisation, filter, and then recrystallise the citie acid in lead-free vessels

The 'old liquor' is diluted with water, and the citic acid it contains precipitated with an excess of whiting, exactly as in the case of the examination. If iron or copper is present in original juice. The liquor is never neutralised any quantity, a drop of solution of potassium by the whiting, this may be either due to examination. If iron or copper is present in original juice is never neutralised any quantity, a drop of solution of potassium by the whiting, this may be either due to examination. If iron or copper is present in original juice is added before the ammonium sulphide acontic acid liquors, or to the presence of ferric reaction. The standard of purity suggested is or aluminic phosphate derived from the whiting is that lead is not to be present to a greater extent.

Any considerable excess of sulphuric acid in the liquors, or any overheating, must be avoided, as occasioning decomposition of citric acid The presence of non or aluminium in the whiting also occasions loss, as citie acid holding iron or aluminium in solution is not precipitated by calcium carbonate In consequence of the nonprecipitation of iron or aluminium from citrie solutions by whiting, the citric liquors of the factory remain nearly pure, however long the work may have been continued, a result very different from what happens in the case of tartaric acid; the purity of citric-acid liquors is however obtained at the expense of some loss of citric acid In a well-conducted factory the total loss during manufacture will amount to 12-15 p c of the citric acid in the juice.

A method has been patented (Fancheux and terated with tartaric acid. To detect adulteration,

Boissière, Eng. Pat. 11991; Fr. Pat. 338735, J Soc Chem. Ind. 1904, 680) by which the ciude calcium citrate is purified by passing hot gases over it, so as to roast it superficially

Citric acid is also produced by the fermentation of carbohydrates, glycerol, and analogous substances under the influence of certain fungi, named *ettromycetes* (Wehmer, Eng. Pat. 5620, D. R. P. 72957, J. Soc. Chem. Ind. 1894, 275). To prepare the organisms, a sugar solution containing 2 5 p.c. of citie acid is allowed to stand for a few days The growth formed on this solution is introduced into sterilised sugar where it develops. The pure culture prepared in this way is then introduced into large vessels containing sugar solution, in which are dissolved small quantities of ammonium nitrate, dipotassium phosphate, and magnesium sulphate, the liquid is then allowed to remain at the ordinary temperature for 8-14 days. At the expiration of that time, the liquid contains a certain amount of cities acid, so that it can be directly employed for lemon juice. The acid can be isolated, preferably as calcium citrate by adding calcium carbonate to the liquid Other moulds, such as Mucor proforms, which grows on putretying fruit, specially on pears and apples, may be employed (D R P 91891, v also Maze and Perner, Compt rend 139, 311).

Estimation of lead in eitric acid Forty grams of the sample are dissolved in water, pure strong ammonia added in slight excess, the hquid cooled and diluted to 120 cc. For a preliminary experiment 10 cc are taken, diluted to 50 c c. in a Nessler tube, and one drop of ammonium sulphide added, the colour determines what volume should be taken, it varies from 5 to 50 cc. Having repeated this with the volume of liquid thus indicated, the tint has to be matched with that from the pure solution. A volume of pure ammonium citrate solution identical with that taken of the acid under examination is mixed with a measured quantity of slightly acid lead nitrate solution, containing 01 gram metallic lead per litre A drop of ammonium sulphide is added, and various solutions are made up until the colour obtained matches that from the acid under examination If iron or copper is present in any quantity, a drop of solution of potassium which prevents them interfering with the reaction The standard of purity suggested is that lead is not to be present to a greater extent than 5 parts per million (Warington, J Soc Chem Ind 1893, 97, v also Tatlock and Thomson, Analyst, 1908, 173)

Another method is that of Buchet (J Soc. Chem Ind 1892, 848) To estimate the metallic lead, 200 grams of acid are dissolved in three times its weight of water, and a slight excess of ammonia added After 24 hours the liquid is docanted, and the residue collected on a filter, carefully washed and dissolved in nitric acid. The lead is then precipitated as sulphate, and estimated as such. To determine the combined lead, the ammoniacal solution is first acidified with hydrochloric acid, the lead precipitated as sulphide, converted into sulphate, and weighed as such.

Adulteration.—Citric acid is at times adulterated with tertaric acid. To detect adulteration

CLAY 287

Cailletet (Chem. Soc. Trans 36, 674) adds | I gram of the powdered acid to 10 c c. of a cold saturated solution of potassium dichromate the solution remains unchanged in colour for 10 minutes, tartaric acid is absent If tartaric is present, the solution becomes brown Pusch (J. Soc. Chem. Ind 1885, 552) places 1 gram of the acid in a test-tube with 10 grams of pure oil of vitriol. The test-tube is placed in a water-bath, and kept at 100° for I hour citric acid only is present, the colour is lemon-If tartaric acid is present, the colour brown Both these tests are very becomes brown delicate, and readily show 1 or 1 p c of adulteration Piñerua (Compt. rend 124, 291) puts 0 05 gram of the substance in a porcelain basin, and adds 10-15 drops of a reagent made by dissolving 0 02 gram of \beta-naphthol in 1 cc. of concentrated sulphure and 1f eithe acid alone is present, a blue colour is formed, unchanged on heating, which on dilution gives a nearly colourless or a slightly yellow liquid tartaric acid is present, the colour on heating changes to green, and on dilution to a reddishvellow Deniges adds a small quantity of the acid to a solution of resorcinol in dilute sulphuric acid, and heats to 115°-140°. If tartain acid is present, a violet-red colour is formed sugar is present, or other bodies blackened by sulphuric acid, the acid is precipitated as its lead salt, and then tested (J. Pharm Chim 1895, 1 586) Crismei (Chem Soc Abstr 1892, 546) adds 1 gram of the acid to 1 cc of ammonium molybdate solution (10 pc) and 2 to 3 drops of hydrogen peroxide solution (1 to 1 pc), and heats at 100° for 3 minutes. If citric acid alone is present, the yellow colour given by the molybdate is unaltered, whilst if tartain acid is present, a beautiful blue colour results test detects 1 mgm of tartaric acid in 1 gram of citric acid Spindler has modified Deniges' mercuric sulphate method (q v), and uses potassium dichiomate instead of permanganate If extric acid alone is present, a yellow precipitate is obtained; the presence of tartaile acid is indicated by a change of colour to green, due to reduction. Taitaile acid may also be detected by adding a little solution of potassium acetate to a strong solution of the citric acid, and stirring

The quantity of taitaric acid in an adulterated sample may be determined by adding 10 p c of potassium chloride to a strong solution of the acid, and precipitating the tartaric acid with citrate or acctate of potassium, with the precautions described under estimation of tartame acid

CITRIC ACID FERMENTATION v. FERMEN-TATION

CITROCOLL. Trade name for neutral aminophenacetin citrate

CITRONINES v Azo- colouring matters. CIVET. An odorrferous substance resembling musk or ambergris, obtained from the pouches situated between the anus and genital organs of Viverra civetta of N Africa, V Zibetha of Asia, and V. Malaccensis of Java. Is of the consistence of honey, and of a yellowish or brown

Pharm. 1824, 537) (For analyses of civet, see Charabol and Hébert, Bull Soc. chim 1910. 7, 687.) Civet melts at about 36°, and contains from 50 to 70 p c of fatty acids, and should have a saponification value of about 180°, and should have not more than 1 p c of ash.

It has been inferred that the musk aroma of ervet is due to a ketone, muskone, present in musk, but according to Sack (Chem Zeit 1915, 39, 538), it is caused by a specific ketone, Zibetone C<sub>17</sub>H<sub>30</sub>O, of a pleasant musk-like odour, which may be obtained pure by decomposition of the crystallised semicarbazone. Its oxime crystallises in white needles, in p 92°. See Musk

CLAY. (Argde, Fr; Thon, Ger) The term 'clay' is ordinarily used to denote certain earths, the chief characteristic of which is that of plasticity when wet, and which have the property of baking to a haid, stone-like mass when heated to full redness Clay is a heterogeneous mixture of certain hydrated aluminium silicates, with particles of quartz, felspar, mica, &c , resulting from the decomposition of various silicious minerals, the chief source being the felspars of granite rocks These hydrated aluminium silicates form the essential basis of all clays, and are known as clay substance or clay base. They are all decomposed by hot concentrated sulphuric acid (infra), whilst the other ingredients mentioned above are affected only slightly or not at all. The method of so-called 'rational analysis' is based on this action, and it has been found that when so treated, the great majority of clays give a clay substance approximately of the composition represented by the formula Al<sub>2</sub>O<sub>3</sub> 2SiO<sub>2</sub>,2H<sub>2</sub>O This corresponds with the composition of the rare crystalline mineral kaolinite, and, consequently, it has often been assumed that all clays contain kaolinite as their clay base It has, however, been shown that the clay substance, in some cases, does not correspond in composition with the above formula, and it is now generally accepted that other hydrated aluminium silicates may be present in clays, forming part, and in some cases the whole, of the clay base Various investigators have attempted to define these substances, and to show that they correspond in composition with certain silicates, such as allophane  $(Al_2O_3 \cdot SiO_2, 5H_2O)$ , pyrophyllite  $(Al_2O_1 \cdot SiO_2, 5H_2O)$ , halloysite  $(Al_2O_3 \cdot 2SiO_2, 2H_2O + Aq)$ , pholerite  $(2Al_2O_3 \cdot 3SiO_2, 4H_2O)$ , &c

It has been suggested by J. W. Mellor (Trans, Eng. Ceramic Soc. pt. 1, 8) that the term kaohnite should be restricted to the comparatively rare crystalline mineral, and that the amorphous clay substance of similar composition (Al<sub>2</sub>O<sub>3</sub>·2SiO<sub>2</sub>,2H<sub>2</sub>O) should be called clayite.

The same investigator points out that this latter substance occurs in clays in non-crystalline or amorphous granules, which, however, sometimes show faint polarisation phenomena. Practically all clays contain more or less free colour. Contains stearm, olem, mucus, resm, silica, undecomposed or partially decomposed volatile oil, and yellow colouring matter (J. felspar, and mica, and they vary in composition

through a wide range, differences in composition being brought about partly as a result of different origins, and partly by differences of deposition, &c. The commoner varieties of clay generally contain a considerable percentage of oxide or carbonate of iron, and small percentages of calcium, magnesium, and titanium salts.

According to Washington (J. Amer Ceram. Soc. 1918, 1, 405) clays are composed of four minerals corresponding to generalised formulas, viz kaolinite (Al<sub>2</sub>O<sub>3</sub>,2SiO<sub>2</sub>,2H<sub>2</sub>O), orthoclase (K<sub>2</sub>O,Al<sub>2</sub>O<sub>3</sub>,6SiO<sub>2</sub>), albite (Na<sub>2</sub>O,Al<sub>2</sub>O<sub>3</sub>,6SiO<sub>2</sub>), anorthite (CaO,Al<sub>2</sub>O<sub>3</sub>,2SiO<sub>2</sub>), limonite (Fe<sub>2</sub>O<sub>3</sub>, H<sub>2</sub>O) with, in some cases, muscovite (K<sub>2</sub>O,2H<sub>2</sub>O, 3Al<sub>2</sub>O<sub>3</sub>,6SiO<sub>2</sub>). The proportions of the several minerals may be calculated from the ultimate chemical analysis. The lime, soda, and potash are first calculated to the felspars, and the alumina and silica required for those are deducted from the total. The iron oxide is calculated as limonite. Any surplus alumina is calculated as kaolinite, and any surplus silica is regarded as quartz (see below)

Clays may be divided broadly into two classes: residual clays and sedimentary clays Residual clays are the insoluble residue left from the breaking down and decomposition of 10ck masses containing certain aluminium silicates (chiefly felspathic minerals), and they are found overlying or adjacent to the rock mass from which they are formed. These residual clays usually present a gradual change in mineral character from the finer or puter portion nearer the surface to the mixture of clay and undecomposed rock which lies in contact with the rock The decomposition of the mineral silicates may be brought about by carbonic acid in the surface waters; but many of them are acted on by water alone, and although this action proceeds very slowly, it may account for the gradual decomposition of the felspathic rocks and the formation of clay. The alkalis of the felspars combine with the free silica formed in the decomposition, and with the carbon dioxide contained in the percolating water, forming soluble salts which are more or less completely washed away. In some cases the decomposition of the mineral silicates may have been brought about by the action of gases, and it has been shown by J. H. Collins (Min Mag 1887, 7) that when felspar is exposed to the action of hydrofluoric acid, hydrated aluminium silicate is formed, mixed with soluble potassium fluoride, whilst silica is deposited on the sides of the tube in which the reaction takes place Residual clays, as a rule, contain a smaller percentage of oxide of non and organic matter than sedimentary clays, and are consequently lighter in colour both before and after baking

Sedimentary clays are formed by the transportation and redeposition in water of residual clays, and clays so formed may be again transported and redeposited in the same way, so that they may have no direct relationship to the rock formation on which they lie. Sedimentary clays belong to all geological ages, from the present to the Cambrian, and are of varying degrees of hardness, from the soft drift which may be dug with a spade to the hard clay shales of the older formations, which require to be blasted. These clays are always roughly

stratified in structure, and show considerable variations in general character and composition throughout their mass, owing to the varying conditions under which they were deposited. The harder varieties of clay are readily converted into the plastic form by grinding with water, or by weathering, and they are now largely used for the making of bricks, &c, where formerly only the softer surface clays were used. When breathed upon or moistened, clays usually emit a peculiar odour known as argillaceous. This characteristic is more marked in the sedimentary than in the residual clays, and may possibly be connected with the contained organic matter.

Plasticity is an essential property of all clays in the moist condition, but this quality The presence varies greatly in different clays of organic matter, finer grinding of the particles of the clay, 'ageing' in the most condition and 'weathering,' all tend to increase the plasticity, but no entirely satisfactory explanation of the cause of plasticity has yet been put forward. Clay loses practically the whole of its hygroscopic water when dried at 100°, and it contracts and loses its plasticity at the same time, becoming hard and brittle On being soaked or ground in water, however, it becomes soft and plastic again The chemically combined water is not driven off until the clay is heated to redness, the temperature of the dehydration, in the case of ordinary clay, being probably between 480° and 600°. Clay that has been heated to this temperature will not again become plastic on being ground with water, so that it is evident that the plasticity of a clay is dependent upon some physical or chemical condition, which is destroyed on heating to about 500° When clays are heated to a higher temperature (generally about 900°), they contract more or less and become hard, compact, and stone-like, and at higher temperatures still they become vitieous and ultimately fuse. The purest varieties of china clay (which approximate to the composition of kaolinite) fuse at a temperature of about 1830°, and other clays fuse at lower temperatures, according to the nature and percentage of the various impurities contained. The chemical impurities which chiefly affect the fusibility of a clay are the salts of magnesium, calcium, iron, sodium, and potassium first pointed out that chemically equivalent amounts of the oxides of these substances exert equal influences on the fusibility of a clay presence of free silica (quartz sand) tends to raise the fusion point of clays containing a considerable percentage of these bases, but it has an opposite effect on the purer china clays the manufacture of pottery ware of all kinds, the firing temperature depends upon the chemical composition of the clay (which determines the fusibility) and upon the result required. For example, in the manufacture of porcelain, where the resultant ware must be non-absorbent or vitreous, the firing temperature ranges from about 1250° to 1550°, according to the chemical composition of the clay mixture or body used, whereas in the manufacture of ordinary white earthenware, where a porous or non-vitreous ware is desirable, the firing temperature ranges from about 1150° to 1250°.

The colour of fired clay, i.e. clay that has

been heated to a temperature of over 900°, depends upon the impurities present, and upon the character of the firing gases. The purer the character of the firing gases. kinds of residual clays fire to a whitish mass. but all other clays become more or less strongly coloured, the tint being determined generally by the percentage of iron oxide present. Iron may be present in clays in various combinations, such as ferric oxide (Fe<sub>2</sub>O<sub>3</sub>), hydrated ferric oxide (2Fe<sub>2</sub>O<sub>3</sub>, H<sub>2</sub>O), ferrous carbonate (FeCO<sub>3</sub>), and more rarely magnetic oxide (Fe<sub>3</sub>O<sub>4</sub>), but in firing in the ordinary way all these salts are converted into ferric oxide Some clays contain a considerable amount of iron pyrites disseminated through the mass in small grains, and these clays are often troublesome in use, as the sulphide is not so readily converted into oxide in the ordinary firing process. Moreover, the sulphide on weathering with the clay gives rise to soluble sulphates which are detrimental. In the yellow and brown surface clays and red-firing shales, the iron is present in the form of ferrous carbonate, which, together with the organic matter present, produces the natural grey colour of these shales. In ordinary clays, and with an oxidising atmosphere, 1-2 pc of iron oxide produces a buff colour, 2-4 pc a salmon colour, and above 4 pc a red colour, which becomes darker as the percentage of iron increases presence of other impurities, however, modifies the colour produced by iron oxide considerably, and this is especially the case when a large percentage of lime or magnesia is present

Some clays (commonly called marls) contain from 15 to 30 pc of lime, and although they may also contain as much as 6-8 p.c of iron oxide, they fire to a light-yellow or buff colour. Such clays are largely used for making the wellknown yellow facing bricks, which were at first made chiefly from the marks of the Thames basin, the Paris basin, &c, and are now made from artificially prepared mixtures of clay or chalk and limestone The presence of certain soluble salts (chiefly sulphates of calcium or magnesium) in clays often produces serious discolouration on firing, owing to the deposition of these salts on the surface during the drying and firing of the ware To prevent this action, it is usual to mix with the clay barium carbonate, to combine with the whole of the sulphuric acid present, and so convert the soluble salts into When clays are fired in a insoluble ones reducing atmosphere, the red ferric oxide is converted into blue ferrous oxide, and the resultant ware is consequently bluish in colour. Blue bricks are made from certain clays, containing generally from 6 to 10 pc of iron oxide

by firing in this way

The presence of clay in soils exerts an important action on the growth of plants Ammonia is retained by clay in such a manner that it cannot be removed except by an excessive amount of washing; in fact, clay will remove ammonia and many organic substances from manure, and still retain them in a form readily available for plants.

Kaolinite Al<sub>2</sub>O<sub>3</sub> 2SiO<sub>2</sub>,2H<sub>2</sub>O A comparatively rare crystalline mineral which occurs in Anglesey, in Colorado, and a few other localities in the form of minute hexagonal plates, having a perfect basal cleavage, and belonging to the monoclinic system. Kaolinite was formerly

supposed to form the base of all clays, but this view is no longer held, and the term should be restricted to the crystalline mineral described

Kao-lin, China clay The Chinese term kao-lin' (literally meaning 'high ridge') was applied to the white earth from which porcelain was made, and it corresponds to the English china clay, so called because it is used for the making of 'china,' or porcelain. These terms are now applied to all the purer residual clays which contain a high percentage of hydrated aluminium silicate (Al<sub>2</sub>O<sub>3</sub>·2SiO<sub>2</sub>,2H<sub>2</sub>O), and which consequently give on analysis 33-40 p c. alumina (Al<sub>2</sub>O<sub>3</sub>), 45-60 p c. silica (SiO<sub>2</sub>), 11-14 p.c. water, with very small percentages of iron oxide, soda, potash, lime, magnesia, &c. Clays of this class are worked in Cornwall and Dovon, at St Yrieix near Limoges, Zettlitz in Bohemia, in the United States, in South Africa, As mined, the clay generally contains a large percentage of quartz-sand and mica, and it is refined by washing In Cornwall the china clay is usually the result of the weathering of pegmatite, and the felspar of the parent rock is often decomposed to a depth of 60 to 100 feet. In this condition it is known as china clay rock, and the workman breaks down the crumbling surface with a pick and then directs a stream of water over this to wash down the material, which is passed into tanks where the suspended matter settles out, the quartz, clay, and mica being deposited according to the sizes of the particles, and so separated from each other The china clay is allowed to dry to a stift paste in the tanks, and is then removed to the drying kilns, where it dies until it can be cut into blocks ready for shipment It is a soft, friable, seetile, white substance, showing irregularly shaped granules under the microscope, and possessing only a moderate plasticity when mixed with water Cf Coon, Trans Eng Coramic Soc 1910-1911, 10, 81 China clay is used in the manufacture of porcelain and white earthenware, in paper making, and the filling of calico, and also in the manufacture of alum, aluminium sulphate, and ultramarine The fine mica separated from the china clay in the washing is used for weighting coarse papers, paper boards, &c

Ball clay, Potter's clay The name given to certain sedimentary clays which fire to whitish or light-buff colour, and which possess high plasticity and tensile strength when in a moist condition. They are worked in Devon-shire and Dorset, and in some parts of the United States, &c., and are chiefly used in the manufacture of white earthenware. They are generally finer in grain than china clay, contain more organic matter and other impurities, and are consequently more plastic in a most state, and fire to a vitreous mass at a lower temperature. They usually also contain a higher percentage of silica than china

Pipe clay A rather loose term, which is applied to white clays which contain a relatively high percentage of silica, and which have been used without admixture for several hundred years for the making of tobacco pipes and also for common pottery. These clays are of various geological origins, and in some localities the

highly silicious clay found in pockets in lime stone formations, and resulting from the decomposition of argillaceous limestones and chert rock, is used in this way. Ball clay is also used for the same purposes, and is sometimes consequently

spoken of as pipe clay.

Plastic clay. This term has been specially applied to those beds of the Lower Tertiary or Eocene strata, which occur between the London clay and the chalk, and which may be recognised at Woolwich, Reading, Blackheath, Bognor, and in the neighbourhood of Paris, &c This clay is mottled red or purple, and fires to a red colour Some of our earliest pottery was manufactured from this clay, and it is still worked in Hampshire, in the lile of Wight, and elsewhere.

Slate clay occurs in Devon, Cornwall, &c., differing considerably in different districts. is massive, interspersed with mica, and of a greenish or greyish colour It is sometimes hard and slatey, being readily cleavable into slabs, whilst in another form, the killas of the Cornish mines, it has an earthy fracture, is soft and frangible, and weathers to a more or less plastic clay It is chiefly used for the manufacture of common bricks and tiles, and, when fairly free from lime, magnesia, and iron, for fire-

Common clay is the term often applied to the ordinary surface and drift clays which have been used for centuries for making common

pottery and bricks

Fireclays. As the name implies, these clays are of a very refractory nature, and although, strictly speaking, practically all the pure residual clays come under this head, the term 'fireclay' has been restricted in use to certain coal-measure shales which have a high fusion point, and which are used mainly for the manufacture of firebricks, gas retorts, glass pots,

furnace linings, &c

These fireclays usually underlie the coal seams, and are often worked in conjunction with Certain districts are particularly the coal noted for the quality of their fireclays, and in England the Stourbridge coal-measure shales have long been considered of the highest quality, and fireclay-mines are extensively worked in the Stourbridge district Good fireclays are also found and worked in the Lancashire and Yorkshire, Derbyshire, and Glasgow coal-fields. The fireclay shales are mostly greenish grey in colour, compact, dense, and of varying degrees of hardness On exposure to the weather they usually crumble down, and in time become converted into plastic clay

The weathering process may be greatly accelerated by grinding the shale, but this is only done when the clay is to be used for the more expensive fireclay goods Only those coal-measure shales which contain small percentages of oxide of iron, lime, and magnesia. are sufficiently refractory to be used as fireclays. and although no definite fusion point has been fixed, it seems advisable that no clay having a fusion-point lower than 1500° should be classed as a fireclay. In the manufacture of fireclay goods, the partially weathered or ground fire-clay is usually mixed with a certain proportion of 'ganister,' coarse sand, burnt clay, or other refractory material which produces in the fired ware a certain open texture, which enables it

better to withstand rapid changes of temperature. Certain silicious fireclays and other coalmeasure clays are used in the manufacture of salt-glazed drain pipes, and also for making common culinary ware, buff-coloured tiles, terracotta, glazed bricks, &c.

Chemical analysis of clay. From 1-2 grams of finely powdered clay, dried at 120°, are weighed into a platinum crucible, and mixed with about six times its weight of a fusion mixture consisting of potassium and sodium carbonates in equimolecular proportions mixing is best performed by first stirring together the clay with about the same bulk of fusion mixture by means of a dry glass rod, and then adding more and more fusion mixture with repeated stirring, until the whole is thoroughly mixed. The glass rod should then be rubbed in a little fusion mixture, which is added to the mass in the crucible. The covered crucible is gradually heated over a Bunsen burner (a Teclu burner may be advantageously used) until the whole mass is in a state of tranquil fusion crucible is allowed to cool, and afterwards the bottom is raised just to dull redness, twice successively, in order to facilitate the removal of the mass from the crucible. After cooling, a few drops of distilled water are added, and the crucible very gently warmed until the mass detaches itself. The contents of the crucible are then washed into a large platinum dish (a porcelain dish may be used without seriously impairing the accuracy of the estimation), covered with water, and then warmed until the fused mass is completely softened. Hydrochloric acid is then added, a few drops at a time, until all effervescence ceases The contents of the dish are evaporated on a water-bath, with constant stirring at the later stages, to ensure a fine powdery residue from which the last traces of hydrochloric acid are readily driven off. When cold, the contents of the dish are moistened with moderately strong hydrochloric acid, and allowed to stand for one hour, water is then added, and the dish again heated on the water-The clear liquid is poured through a filter, and the residue in the basin, which consists of silicic acid, is washed repeatedly by hot water until it remains white when moistened with hydrochloric acid. The residue is then transferred to the filter, and washed with hot water until the filtrate no longer gives a precipitate with silver nitrate solution The filter and contents are then placed in a platinum crucible and dried, and afterwards gradually heated, and finally ignited strongly until the paper is completely incinerated, and the weight constant. In order to ensure the complete separation of the silicic acid, it is necessary to evaporate the filtrate down to dryness, and treat exactly as before, and this process may be repeated again if very great accuracy is required. After filtering, the filter paper and residue are dried and added to the original silicic acid residue before ignition. The contents of the crucible are then weighed as silicon dioxide (SiO2) If the clay contains titanic acid (as many clays do), this will accompany the silica. In order to determine the former, the contents of the crucible are covered with strong hydrofluoric acid, a few drops of sulphuric acid added, and the crucible warmed on the water-bath until all the silicon

fluoride and the sulphuric acid have been driven off. The residue is then weighed as titanic oxide (TiO<sub>2</sub>), which should be identified by the violet-coloured bead with microcosmic salt.

The filtrate is made up to definite volume, and divided into two parts, one for the determination of the iron, and the other for the determination of the alumina, calcium, and magnesium. The iron is estimated as ferric oxide, and determined either by reduction with zine and titration with potassium permanganate solution,

or by the iodimetric method

The other portion of the filtrate is heated on the water-bath, and ammonia added drop by drop, with repeated stirrings, until there is a slight excess of ammonia present The liquid is then boiled for a moment and filtered. The precipitate is washed twice with hot water; washed back into a dish, and dissolved in hydrochloric acid; reprecipitated and filtered as before, and finally washed with hot water until the filtrate gives no precipitate with silver nitrate solution. The washing should be repeated immediately the previous washing has disappeared from the filter, and a jet of hot water should be directed into the precipitate so as to break it up as much as possible. The filter as to break it up as much as possible paper and contents are then dried, the residue removed into a platinum crucible, the paper separately incinerated, and then placed in the crucible, and the whole strongly ignited until the The contents are then weight is constant weighed as alumina (Al2O3) and ferric oxide (Fe<sub>2</sub>O<sub>3</sub>), the amount of ferrie oxide separately determined as above being deducted from the total, leaving alumina only (v art Aluminium) The filtrate from the alumina and ferric oxide is concentrated, and ammonium oxalate solution added while hot. The precipitate is filtered off, thoroughly washed with hot water, dried, strongly heated, and weighed as CaO filtrate from the above is then concentrated, and the magnesium precipitated by sodium phosphate and ammonia. The precipitate is filtered off, dried, and ignited until the weight is constant The ignited residue consists of Mg<sub>2</sub>P<sub>2</sub>O<sub>7</sub>, and the weight must be multiplied by 0 3624 to give the amount of magnesia (MgO)

Determination of the alkalis. The method introduced by Lawrence Smith (Amer. J. Sci. [2] 50, 269) is the most trustworthy, and is -based on the decomposition of silicates by fusion with calcium carbonate. In practice, the dried and finely powdered clay is mixed with its own weight of ammonium chloride, and four times its weight of calcium carbonate. These latter materials must be as free as possible from alkali The ammonium chloride used is prepared by subliming the commercial salt, and the calcium carbonate is prepared by dissolving the purest calcite obtainable in hydrochloric acid, and precipitating with ammonia and ammonium carbonate. The precipitation is carried out in a large porcelain dish, and, after settling, the clear liquid is poured off, and the precipitate washed by decantation until free from chlorides. A special platinum crucible is used for the fusion, about 8 cm. long, and 2 cm. diameter at the top, tapering to  $1\frac{1}{2}$  cm. at the bottom. About 0.5 gram clay is weighed out, and mixed by rubbing in an agate mortar

with the same weight of ammonium chloride, and afterwards 3 grams of calcium carbonate are added, and the whole thoroughly mixed The mixture is then transferred to the crucible. and the mortar is cleaned out with about 1 gram of calcium carbonate, which is added to the mix-ture in the crucible. The covered crucible is supported in an inclined position, and very gradually heated over a small Bunsen flame for about 15 minutes, until no more ammonia is given off, and then the temperature is raised until the lower three-fourths of the crucible is a dull-red, and this temperature is maintained for I hour The crucible is cooled and the contents removed (by tapping the inverted crucible) into a porcelain or platinum dish. If the sintered mass sticks to the crucible, a little water should be added, and the crucible gently warmed until the mass detaches itself, and the whole can be washed into the dish About 60 c c of distilled water are added, and the covered dish heated on a water-bath for 30 minutes, the water lost by evaporation being replaced, and the larger particles reduced by rubbing with an agate pestle. The clear liquid is decanted through a filter, and the residue washed by decantation four times, and then transferred to the filter and washed until the filtrate gives no precipitate with silver nitrate. The filtrate contains the alkalis as chlorides

The calcium is precipitated by the addition of ammonia and ammonium carbonate to the filtrate, which is heated and filtered. The residue, which contains some alkali, is dissolved in hydrochloric acid, again precipitated by ammonia and ammonium carbonate, and filtered. The combined filtrates are then evaporated to dryness in a platinum dish, and the ammonium salts iemoved by careful heating over a moving flame. The residue is dissolved in water, and any traces of calcium left are precipitated by the addition of ammonia and ammonium oxalate After standing 12 hours, the liquid is filtered off, evaporated to dryness in a weighed platinum dish, and gently heated. The alkali chlorides remaining in the dish are weighed, and the potassium determined by dissolving the chlorides in water and precipitating the potassium as platino-chloride The sodium is potassium determined by difference

Rational analysis of clay. To determine the relative amounts of clay substance, quartz, and undecomposed felspar, dry the clay to constant weight, and weigh about 5 grams of the dried and finely powdered clay into a porcelain dish, add 50 c c. of concentrated sulphuric acid and 100 c.c of water, and then heat the mixture for 3 hours on a water-bath, and afterwards on a sand-bath, until the acid commences to fume. After cooling add water, and decant the clear liquid into a 2-litre beaker To the residue in the dish add 10 c c. of Lunge's solution (100 grams crystallised sodium carbonate, and 10 grams sodium hydroxide, dissolved in 1 litre of water), boil for 5 minutes, dilute with water, and decant into the beaker. Treat the residue in the dish similarly with concentrated hydrochloric acid, and repeat the treatment with Lunge's solution and hydrochloric acid, diluting with water after each treatment, and decanting the clear liquid into the beaker. Then wash the residue on to a filter with

dilute hydrochloric acid. Stir up the contents in the beaker, and allow to stand for an hour. Decant off the clear liquid, taking care to retain the residue in the beaker. Wash the residue into the dish, and repeat the treatment with Lunge's solution and acid as above, and pass through the filter. Wash with dilute hydrochloric acid, dry and ignite the filter paper and contents in a weighed platinum crucible. This residue is reckoned as felspar and quartz, and the loss suffered by the clay in this treatment as clay substance.

To determine the quartz and felspar, add about 5 cc of water, 4 drops of sulphune acid, and 15 cc. of hydrofluoric acid to the residue in the crucible, and heat the whole carefully on a sand-bath until nearly dry. Add more hydrofluoric acid, and again heat as before. After cooling, dissolve the mass in water, wash into a dish, and add ammonium chloride and ammonium hydrate to precipitate the hydroxides of aluminium and iron. Filter, wash with hot water, heat and weigh. This weight is multiplied by 5 451 to obtain its equivalent in potash felspar, and the difference between this and the weight of the original residue is taken as quartz.

Many ceramic chemists calculate the rational constitution of the clay from the ultimate analysis, taking the potash as derived entirely from undecomposed felspar (reckoned as  $K_2O \cdot Al_2O_3 6SiO_2$ ), the alumina and iron as derived from felspar, and the clay substance (reckoned as  $Al_2O_1 \cdot 2SiO_2 \cdot 2H_2O$ ) and the silica as derived from the clay substance and quartz.

CLAYITE. A name suggested by J W Mellor in 1909 for the non-crystalline variety of kaolimte H<sub>4</sub>Al<sub>2</sub>Sl<sub>2</sub>O<sub>3</sub>, of which china-clay and most other clays are largely composed. The same name had been earlier used by W J Taylor, in 1859, for an uncertain alteration product (of tetrahedrite?) composed of sulphur, arsenic, antimony, lead, and copper.

CLAY SLATE v SLATE

CLAYTON CLOTH RED v Azo- COLOURING

CLAYTON YELLOW v PRIMULINE AND ITS DERIVATIVES.

CLEVEITE. A variety of uraninite, consisting of a uranate of uranyl, and oxides of lead and the rare earths Usually obtained from Norway and Sweden Hillebrand (Bull. U.S. Geol Survey, 78, 43, 83) found the percentage of rare earths to be about 13, and that on heating with sulphuric acid, over 2 p c of nitrogen was evolved. Ramsay (Chem. Soc. Trans 1895, 1107) proved that the gas evolved was not nitrogen, but helium (q v) Only half the helium is evolved by heat alone, and, moreover, in some cases the disengagement of the gas is accompanied by considerable evolution of heat (Proc Roy. Soc 1898, 64, 140). V BROGGERITE and PITCHBLENDE.

CLOVE OIL v. OII S, ESSENTIAL.

clover. The name by which several leguminous forage plants are known. The chief species are white clover (Trifolium repens, Linn); red clover (T. pratense, L.); alsike clover (T. hybridum, L.); crimson clover (T. incarnatum, L.), yellow suckling clover (T. dubium, Sibth.); mammoth red, or zigzag clover (T' medium, L.); hop clover, or hop trefoil (T. procumbens, L.) All the above belong to the true clovers, to the genus Trifolium. Also included as clover are yellow clover, or trefoil (Medicago lupulina, L.); Bokhara clover, or melilot (Melilotus alba, Desn.); Japanese clover (Lespedeza striata, Hook et Arn.); and Soola clover, or sulla (Hedysarum coronarium, L.). The following table gives the average composition of various clovers at the time of flowering (Kellner):—

White or Dutch clover is a low, creeping perennial plant, valuable for grazing Its growth in pastures is encouraged by phosphatic and potash manuring, but discouraged by introgenous manures. In America, it is said that its blossoms salivate horses, and that consequently much clover in pastures is an objection where horses graze. White clover furnishes most excellent pasturage for bees, the honey which it yields being colourless and of high quality.

Red clover or broad clover is usually grown as a bennial, but will sometimes stand longer. It is often grown as a hay crop, or for cutting for green forage. It is the variety most susceptible to 'clover sickness,' and on many soils can only be grown safely once in 10 or 12 years.

A variety of red clover, T pratense var. perenne, known as 'cow grass,' is not so prone to clover sickness, and lasts longer. It is, however, of slower growth, and usually yields but one crop per year of hay.

Alsike clover has whitish and pinkish flowers, and is a perennial; it is hardly susceptible to clover sickness.

Crimson clover, or 'trifolium,' is also a somewhat slow-growing crop, and is an annual.

Yellow suckling clover is a smaller plant than the other clovers, and is usually only grown in mixtures with rye-grass, &c. It is an annual.

Zigzag clover, known in America as mammoth red clover, ripens later than red clover, and is taller and ranker. Bokhara clover, or large white clover, is a biennial, with small white flowers. This plant is remarkable for its strong odour, more pronounced when dried, of coumarin; animals do not eat it readily until they become accustomed to it.

Soola clover is a perennial resembling red clover, but is richer in soluble carbohydrates

(v Scurti, Chem Zentr 1910, 1 1632).

As the table of analyses shows, clovers are remarkable for the large amounts of nitrogenous matter and of ash which they contain. Of the former, however, a considerable proportion is of a non-protein nature, particularly in the immature plants. In the case of red clover, for example, it has been found that about 40 p.c. of the total nitrogenous matter is present as amides in very young plants, and that the proportion diminishes with growth, until, when the plants are in full bloom, it is about 20 p.c., when fully ripe it sinks to about 12 p.c.

The ash of clovers is remarkable for its richness in lime and its poverty in silica (in which grasses and cereal straws are so rich).

The following are Wolff's analyses of various clover ashes:—

The very high ratio of lime to phosphorus pentoxide in the ash is noticeable.

Clover hay has proved very successful as a constituent of the rations of fattening oxen and

sheep

Out of about 200 feeding experiments with nearly 1000 cattle, conducted in Britain between 1833 and 1908, 17 included clover hay in the daily ration. The average daily increase in live weight per head of the whole was 1 803 lbs., while the consumption of total digestible matter per 1 lb. live weight gained averaged 9 lbs. In the 17 cases where clover hay formed a portion of the food, the figures are 2 1 lbs., and 7 47 lbs respectively (Ingle, Journ High and Agri Soc of Scotland, 1909)

With sheep, the results are equally significant 2390 sheep fed in various ways, between 1844 and 1909, gave an average weekly increase per head of 2 06 lbs, and consumed an average of 7 43 lbs total digestible matter per 1 lb increase in live weight; while 384 sheep receiving clover hay as part of their ration, gave an average weekly increase of 2.58 lbs. per head, and consumed only 6 20 lbs of total digestible matter per 1 lb. increase in live weight (ibid 1910)

CLOVER FLOWERS. It has long been known that clover flowers dye a yellow colour on aluminium mordanted fabrics, and in the past they have been employed to a minor extent for dyeing purposes. Three varieties have been chemically examined, viz. those derived from the Trifolium pratense, the T. incarnatum, and the T. repens.

Trifolium pratense—The flowers known as the 'common red clover,' according to Power and Salway (Chem. Soc. Trans. 1910, 97, 231), contain in addition to isorhamnetin (quercetin, monomethyl ether) and a glucoside of quercetin, melting-point 235°, numerous other phenolic substances, which, judging by their chemical

properties, appear to be closely allied to the colouring matters of the flavone group. These are described below.

 $Pratol\ C_{15}H_8O_2(OH)$  OCH 3, colourless needles, melting-point 253°, readily soluble in hot aqueous sodium carbonate and codium hydroxide with a pale yellow colouration, yields the acetyl compound,  $C_{15}H_8O_2(OC_2H_3O)$  OCH 3, and is probably a hydroxymethoxyflavone.

A yellow compound,  $C_{18}H_{10}O_{7}$ , thin yellow plates, melting-point about 280°, is soluble in alkalis with a yellow colour, and its solution in sulphuric acid exhibits a brilliant green fluorescence. It contains a methoxy group and gives an acetyl compound,  $C_{18}H_{6}O_{7}(C_{2}H_{2}O)_{4}$ , melting-

point 145°-147°.

Pratensol, C<sub>17</sub>H<sub>9</sub>O<sub>2</sub>(OH)<sub>3</sub>, is very readily soluble in alcohol, dissolves in alkali carbonates yielding yellow solutions, and its alcoholic solution gives with ferric chloride a greenish-black colouration Triacetylpratensol C<sub>17</sub>H<sub>9</sub>O<sub>5</sub> (C<sub>2</sub>H<sub>3</sub>O)<sub>3</sub>, colourless slender needles, melts at 189°.

A phenolic substance, C<sub>15</sub>H<sub>7</sub>O<sub>3</sub>(OH)<sub>3</sub>, colourless needles, melting-point 225°, is soluble in alkali hydroxides, and gives with alcoholic ferric chloride a dark green colouration. The acetyl derivative, silky needles, has melting-point 209°.

The glucoside trifolin  $C_{12}H_{12}O_{11}$ ,  $H_{2}O$ , pale yellow needles, melts and decomposes at about 260°. It is soluble in alkalis with an intense yellow colouration, and dissolves in sulphuric acid, forming a yellow solution, which rapidly develops a brilliant green fluorescence. When hydrolysed it yields thamnose and trifolitin  $C_{16}H_{10}O_{6}$ , melting-point about 275°, readily soluble in alcohol,

$$C_{22}H_{22}O_{11}=C_{16}H_{10}O_6+C_6H_{12}O_5$$

Alkalis dissolve trifolitin with an intense yellow colour, alcoholic ferric chloride gives a dark green colouration, and alcoholic lead acetate an orange-yellow lead salt. It contains no methoxy group, and is unaltered when heated for several hours with 30 p.c. aqueous potassium hydroxide. It does not appear to belong to the flavone group, and differs from the flavone compounds by the fact that it does not give an oxonium salt with sulphune acid, and only with difficulty a potassium compound by means of alcoholic potassium acetate. It may possibly consist of a tetrahydroxyphenylnaphthoquinone. The acetyl compound when rapidly heated melted at 116°, resolidified at a higher temperature, and finally melted at 182°.1

The glucoside isotrifolin  $C_{22}H_{22}O_{11}$ , isomeric with trifolin, consists of pale yellow needles, melting-point about 250°, and when hydrolysed yields similarly to the latter trifoliin,  $C_{16}H_{10}O_{6}$ , melting-point 275°. Though in general behaviour it is very similar to trifolin, it is much more soluble in alcohol, and does not appear to be identical with this glucoside.

identical with this glucoside.

In addition to these compounds the flowers contain salicylic acid, commaric acid, myricyl alcohol C<sub>31</sub>H<sub>63</sub>OH, heptacosane C<sub>27</sub>H<sub>56</sub>, hentriacontaine C<sub>31</sub>H<sub>64</sub>, sitosterol C<sub>27</sub>H<sub>46</sub>O, trifolianol C<sub>21</sub>H<sub>34</sub>O<sub>2</sub>(OH)<sub>2</sub>, palmitic, stearie, linolic, oleic, linolene, and isolinolenic acids.

Both in its melting-point and that of its acetyl derivative there is a marked resemblance between trifolitin and kaempferol.

Trifolium incarnatum.—A considerable difference is exhibited between the constituents of the 'carnation or crimson clover flowers' and those of the T. pratense or 'common red clover.'

According to Rogerson (Chem. Soc Trans 1910, 97, 1006) these flowers contain pratol C<sub>15</sub>H<sub>8</sub>O<sub>2</sub>(OH)(OCH<sub>3</sub>), free quercetin, and a glucoside of quercetin C<sub>21</sub>H<sub>20</sub>O<sub>12</sub>,3H<sub>2</sub>O, to which the name incarnatrin is applied. This latter crystallises in yellow prismatic needles, meltingpoint 242°-245°, dissolves in sulphuric acid with formation of a green fluorescent solution, and when hydrolysed yields quercetin and glucose according to the equation

$$C_{21}H_{20}O_{12}+H_{2}O=C_{15}H_{10}O_{2}+C_{6}H_{12}O_{6}$$

Incarnatrin is not identical with the quercimentum of Perkin (Chem. Soc. Trans. 1909, 95, 2181)

In addition to these substances the flowers yield furfuraldehyde, benzoic and salicylic acids, a trace of p-coumanc acid, incarnatyl alcohol  $C_{34}H_{69}OH$ , hentriacontane  $C_{31}H_{64}$ , a phytosterol C27H46O, and palmitic, stearic, oleic, linolenic, and isolinolenic acids

Trifolium repens -The flowers of the white clover, T. repens, according to Perkin and Phipps (Chem. Soc. Trans 1904, 85, 58), owe their tinctorial property to quercetin which is present as glucos:de. A G P.

CLOVES. The cultivation of cloves forms the most important industry of Zanzibar and of the island of Pemba In 1913-14 the total erop was 25,431,735 lbs of which 20,692,771 lbs came from Pemba, where about two-thirds of the total area, or about 35,000 to 40,000 acres, are under clove cultivation The crop is, however, very uncertain, the amount in some years not being above one sixth of the above yield. Large trees may furnish from 60 to 70 lbs of dry cloves, although the average yield is only about 31 to 4 lbs per tree per annum The cloves are picked by hand and dried in the sun The value of cloves depends upon the amount of essential oil present, the quantity of which may vary from about 6 to 20 p c Of this oil about 84 to 90 pc consists of eugenol (V Clove Oil in art Oils, Essential)
COAL v Fuel

COAL GAS v. GAS, COAL

COBALT. Sym Co At wt 58 97.

Cobalt usually occurs combined with arsenic or sulphur, and almost invariably associated with nickel and other metals Free cobalt occurs only in meteorites.

The most plentiful and important ore of cobalt is smalline or tin white cobalt, consisting of arsenide of cobalt, nickel, and iron It occurs abundantly at Schneeberg and many other localities where bismuth is found (v. BISMUTH), ın Bohemia, at Balmoral near Pretoria, near Sudbury in Ontario, very pure at Tunaberg in Sweden, and free from nickel in Colorado. triarsenide, it forms skutterudite CoAs3 Sulpharsenide of cobalt occurs as cobalt glance, grey cobalt, or cobaltine, abundantly at Vena (Sweden) and in Norway; in smaller quantities in Silesia and Cornwall As hydrated arsenate it forms cobalt bloom or erythrite Co3As2O8,Aq, found frequently as a peach-coloured incrustation on other arsenical ores, being produced by their decomposition. As sulphide, cobalt occurs

in small quantities in cobalt pyrites and in linnaeite.

Black earthy cobalt is a hydrated oxide of cobalt and manganese. It is essentially a variety of wad (hydrated manganese oxide), containing sometimes as much as 40 p.c. of cobalt. Surface deposits containing oxides and sulphides of cobalt and of nickel occurat New Caledonia, with veins of chrome ore and nickel and magnesium silicates, it is smelted on the spot and exported as a regulus to England Cobalt occurs in small quantities in many other minerals, in pyrites and in certain non ores, as oxide in black oxide of manganese, as arsenide in mispickel, sometimes to the extent of 10 p c., in selenide of lead, and in cerite, and in some peats and coals.

At the present time the most important source of cobalt, whence almost the whole of the cobalt of commerce is obtained, is the district surrounding Cobalt city, near the shores of Lake Temiskaming in North Ontario very rich silver ores are found, containing frequently 2000 or silver per ton, and sometimes as much as 60 p c These ores also contain a high percentage of cobalt and nickel, chiefly as arsenides, and, after extraction of the silver, are

sent to nickel and cobalt refiners.

Extraction —The methods adopted by manufacturers for the extraction of cobalt from the ores vary with the nature of the ores 
The ores are first concentrated by fusing with a suitable flux, whereby silicious matter and a portion of the iron are removed In the case of the Ontario ores, the speiss consists chiefly of arsenides of cobalt, nickel, iron, and copper The speiss is then calcined, the iron is oxidised to ferric oxide, part of the arsenic is removed, a little less being left than is required to combine with the iron. The mass is then dissolved in hydrochloric acid, and bleaching powder and lime are added, whereby the iron is precipitated as arsenate and hydroxide. The liquid is then treated with sulphuretted hydrogen to precipitate copper and other heavy metals, excess of the gas evaporated off, and the cobalt precipitated as oxide by the addition of bleaching powder The mekel in the solution is subse-

quently precipitated by potash or lime
In the case of New Caledonian ores, consisting chiefly of sulphides, the treatment of the concentrated ore is somewhat different The matt, consisting chiefly of sulphides, is carefully calcined at a moderate temperature, and converted into sulphates. These are dissolved in water, and the non precipitated by careful addition of the requisite quantity of sodium carbonate. The copper and heavy metals are separated by sulphuretted hydrogen, and after boiling off the excess, the cobalt is precipitated by sodium hypochlorite (bleaching powder cannot be used, owing to the sulphates in the solution), and the nickel in the remaining liquid

precipitated by sodium carbonate.

In Herrenschmidt's process for the treatment of New Caledonian ores, these are treated with a solution of ferrous sulphate, when cobalt, nickel, and manganese pass into solution, and iron remains in the residue. Copper is first separated, and then the cobalt, nickel, and manganese precipitated by sodium sulphide. The manganese is extracted by ferric chloride, the nickel and cobalt sulphides roasted to

sulphates, and converted into chlorides by calcium chloride. A part of the solution is treated with lime water, and the suspended precipitate oxidised by chlorine and added to the other portion, whereby the cobalt is precipitated and nickel chloride remains in solution.

Until of late years the only market for cobalt compounds was in the ceramic industry, in which it was employed for whitening the body of china and in the production of blue colour employed in the enamelling trade, the manufacture of blue-coloured signs, the colouring of glass and in the manufacture of pigments and

as driers for paints.

Metallic cobalt is not at present used to any extent in the arts, though its utility is becoming more fully recognised, especially in electroplating and in high-speed steels and in 'stellite, an alloy of cobalt, chromium and tungsten. Commercially it is always prepared by heating the oxide with charcoal, it then contains small quantities of carbon Pure cobalt is prepared by heating cobalt oxalate Co(CO2)2, when the carbon and oxygen pass off as carbonic anhydride, leaving the pure metal as a powder A button of the fused metal may be obtained by fusion of the oxalate alone, or of the oxide mixed with charcoal under a layer of powdered glass containing no lead or other reducible metal, the fusion is preferably performed in a lime crucible at the highest temperature of a furnace Pure cobalt may also be prepared by electro-deposition with platinum electrodes (Winkler, Zeitsch anorg Chem 8, 1) Cobalt is also produced as a grey metallic powder by igniting the oxide at a red heat in a current of hydrogen If too low a temperature has been used, the metal produced is pyrophoric, igniting and becoming reoxidised in contact with the air

Carbon monoxide rapidly reduces cobalt oxide at all temperatures above 600°, the reduction being complete at 900° With chair coal complete reduction takes place at 900°, the final product containing about 2 p c of earbon Reduction with aluminium by the thermit process gives a metal containing about 0.1 p.c. of aluminium or even less (Kalmus, J Ind Eng.

Chem. 1914, 6, 107).

Properties —Cobalt is a brilliant silver-white metal, with a slight bluish cast It is the most magnetic metal after iron, and retains its magnetism at high temperatures; above 1115°

it passes into a non-magnetic variety.

Pure cobalt is harder and more tenacious than iron, its breaking weight being about 50 kilos per sq millimetre Valenciennes states that cobalt, after fusion and annealing, may be rolled into spiral bands like good iron (Compt. rend. 70, 607). Cobalt melts at 1530° (Copaux), 1490° (Henning), 1478° (Kalmus & Harper), and boils at 2415°/30 mm. Its sp gr. is 88, and hardness, 5.5. Its specific heat (20°-100°) is 0.104, specific resistance, 55; and the temperature coefficient of resistance, 0 0055. According to Kalmus & Harper (J Ind. Eng. Chem 1915, 7, 6), pure cobalt prepared by reduction of cobalt oxide has  $D_4^{17}$  8·7918 (unannealed),  $D_4^{14}$  5·8·8105(annealed),  $D_{1}^{\overline{16}5}$  8 9253 (swaged); m p. 1478±1·1°; tensile strength, cast and unannealed, 34,400 lb.

per sq. in.; annealed 36,980 lb. per sq. in; and rolled, more than 100,000 lb. per sq. in.; compressive strength, cast and unannealed, 122,000 lb per sq. in, annealed, 117,200 lb. per sq. in., electrical resistance 89 64 ohms per cm 3, specific heat, from 0° to 890° 0.1058  $+0.0000457t+0.000000066t^2$ . The hardness of cast cobalt is considerably greater than that of either iron or nickel, being approximately 124 0 (load 3500 lb ) The presence of from 0 06 to 03 pc. of carbon in the metal increases the tensile and compressive strength, and the electrical resistance, but has little effect on the hardness. Pure cobalt may be machined in a lathe as readily as pure iron or nickel, but it is somewhat brittle, cobalt containing a small quantity of carbon machines like mild steel, and whilst pure cast cobalt cannot be rolled or swaged without developing cracks, cobalt containing carbon may be rolled or swaged down from cast bars to any extent provided that the metal is worked at a red heat (Chem Soc Abst 1915, ii 99). It is slowly soluble in hydrochloric and sulphuric acids, with evolution of hydrogen, quickly soluble in nitire acid; it is not attacked by hot or cold alkali, but if used as anode in the electrolysis of alkaline electrolytes, passes into a colloidal solution of cobaltous oxide It exhibits also the passive state, similar to that of iron and other metals, but the tendency to do so is slight Cobalt occludes from 60 to 150 times its own volume of hydrogen, the amount varying with the mechanical condition of the metal. The powdered metal combines, when heated, with chlorine, bromine, and rodine. It decomposes steam at a red heat, and, if finely divided, ignites when heated in oxides of nitrogen, and in a current of amimonia gas at  $500^{\circ}$  forms a intiide  $\mathrm{Co_4N_2}$ . When finely divided cobalt is heated to  $150^{\circ}\text{--}200^{\circ}$  in carbon monoxide at 100 atmos pressure, orangered crystals of cobalt carbonyl Co(CO), are formed, melting at 51°, soluble in alcohol or ether, but insoluble in water, and decomposing above 52°, yielding Co(CO)<sub>3</sub> which further decomposes (Mond, Chem. Soc. Trans. 1910, 798) (v. COBALT. CARBONYLS)

Cobalt may be deposited as a fine lustrous coating on metals by the electrolysis of a neutral solution of the double sulphate of cobalt and ammonium, using a current of about 6 amperes per sq foot of cathode surface, and an anode of cobalt (A Gaiffe, Compt rend. 1878) presence of ammonium chloride appears to hinder, whilstammonium sulphate assists, the deposition. The deposit of cobalt is harder, more tenacious, and of greater beauty than that of nickel (Troost).

(For the properties of cobalt containing other

metals, v Alloys of cobalt)

Detection —All ores and compounds of cobalt impart a blue colour to a bead of borax on fusion; if present in too great excess, the bead appears black. Heated on charcoal with reducing flux, all substances containing cobalt produce metallic particles which are attracted by a magnet (distinction from all other bodies except iron and nickel).

Salts of cobalt, when strongly heated with alumina before the blowpipe, give a fine blue colour (Thenard's blue) Sulphuretted hydrogen produces no precipitate in an acid solution, but gives a black precipitate of sulphide in

alkaline solutions, the precipitated sulphide being insoluble in dilute acids. In a solution containing free acetic acid, potassium nitrite produces a yellow precipitate of potassium co-baltimitrite  $K_3\mathrm{Co}(NO_2)_6$ , the whole of the cobalt being thus precipitated on standing in a warm place for some time If a mineral acid is present, it should first be neutralised by potassium hydroxide.

Potassium thiocyanate with cobalt salts gives a red colouration, and, on the addition of alcohol and ether, forms a deep blue ethereal layer.

Cobalt is also precipitated as a red precipitate by the addition of a solution of nitroso-βnaphthol to its alcoholic or acid solutions nickel is not thus precipitated, this forms a useful means of separation of the two metals, the sulphides being dissolved in aqua regia, evaporated to dryness, taken up with a little water and hydrochloric acid, and precipitated as above

Estimation —Ores containing cobalt are usually very complex; they almost invariably contain nickel and many other metals from which the separation is difficult. The following scheme will serve for the estimation of both cobalt and nickel in any mineral, though in the case of certain ores it may be somewhat simplified.

From 2 to 7 grams of the finely ground ore are roasted in a porcelain crucible in a muffle. The residue is boiled with hydrochloric acid containing a little nitric acid until the metallic oxides are dissolved; the solution is diluted, nearly neutralised with ammonia, and boiled with sodium acetate solution, whereby the iron and aluminium are precipitated as acetates containing the greater part of the arsenic (as arsenate of iron) and a little nickel and cobalt The solution is filtered, and the precipitate redissolved in hydrochloric acid and reprecipitated as before, the precipitate being this time free from nickel and The two filtrates are mixed, just neutraised with ammonia, and treated with sulphuretted hydrogen gas; cobalt, nickel, zinc, copper, bismuth, &c, are thus precipitated as sulphides, leaving the manganese and the alkaline and earthy metals in solution. The precipitate is filtered, washed, dried, and roasted, the oxides so produced dissolved in hydrochloric acid, and treated with sulphuretted hydrogen, the copper, bismuth, lead, &c, are thus precipitated and fil-

The solution is boiled till free from sulphuretted hydrogen, and the two metals coprecipitated by the addition of potash to the boiling solution; the precipitate is filtered and washed, nearly dried, and separated as far as possible from the filter. The precipitate is digested in a dish with dilute hydrocyanic acid, then with potash solution, and again with hydrocyanic acid, and warmed until no further solution A minute quantity of residue is left, consisting of paracyanogen and a small quantity of the oxides of nickel and cobalt, it is added to that still remaining on the filter paper, and the whole washed, dried, heated, and weighed.

The solution containing the two metals is boiled to expel the excess of acid, and consists of cobalticyanide of potash and double cyanide of nickel and potash. Precipitated yellow mercuric oxide is added, and the solution boiled for some time. The nickel is thus precipitated, is filtered, washed, dried, heated, and weighed as nickel protoxide NiO. The filtrate is nearly neutralised with nitric acid, and a neutral solution of mercurous nitrate added in excess. cobalt is thus precipitated as mercury cobalticyanide, which is washed, dried, and heated in an open crucible until of constant weight. The product consists of Co<sub>3</sub>O<sub>4</sub>.

From the proportions of cobalt and nickel thus found, the amount of each in the residue on the filter paper, &c., which has been weighed may be calculated, and added to the amounts

directly determined.

In other methods, the copper, &c, are first precipitated by sulphuretted hydrogen, non by ammonia, and the nickel and cobalt precipitated as sulphides. The sulphides are redissolved, and in (1) the total nickel and cobalt estimated by electro-deposition, in (2) the cobalt is first precipitated and the nickel alone determined.

The cobalt in the above solution may also be determined by precipitation as potassium cobaltinitrite, dissolving the precipitate in warm dilute sulphuric acid, evaporating nearly to dryness, and electrolysing after addition of ammonium oxalate and excess of ammonium carbonate

(Copaux, Bull Soc chim iii 29, 301)

The solution containing the sulphides of nickel and cobalt may also be estimated after freeing from excess of acid by boiling with barium carbonate, and adding excess of bromine After 10 minutes the cobalt is completely separated as sesquioxide (Taylor, Proc.

Man Phil Soc 46, 1).

Various volumetric methods have been suggested, but none appears to be perfectly satisfactory

Alloys of Cobalt. Cobalt unites with incandescence on fusion with antimony or arsenic,

forming brittle iron-grey alloys.

With arsenic the freezing-point curve indicates the existence of compounds, Co,As,; Co<sub>2</sub>As, and Co<sub>3</sub>As<sub>2</sub>. Smaltine CoAs<sub>2</sub> forms tin-white octahedra, and skutterudite CoAs<sub>3</sub> occurs as greyish-white octahedra The arsenides are attacked by oxidising agents, and all containing over 38 p.c arsenic are non-magnetic.

Antimon $\hat{y}$  and cobalt are completely miscible in the liquid state. Three classes of alloys exist: magnetic alloys with less than 67 pc. antimony; alloys of from 67 to 80 27 pc, which on heating form CoSb; and alloys above 80 27 pc, which by acids yield a compound, CoSb<sub>2</sub>, as a grey crystalline powder (Ducellicz, Compt rend. 147, 1048)

Cobalt has a marked effect on the electrical properties of copper; 35 pc. gives an alloy with a temperature coefficient of the resistance of only 0 00077. Two series of mixed crystals appear to exist, 0-10 p.c, and 95-100 p.c copper, and alloys within these limits consist of conglomerates of the two sets of mixed crystals Some of the alloys are very ductile. As in many of the cobalt alloys at high temperatures, the cobalt is present as a non-magnetic form  $(\beta)$ , which changes to the magnetic (a) form on cooling. Alloys containing 99 p.c of copper are stated to be magnetic (Sahmen, Zeitsch anorg Chem 57, 1).

Tin and cobalt are perfectly miscible as liquids, and, according to Ducelliez (Compt. partly as cyanide and partly as sesquioxide. It | rend. 148, 562), all alloys are mixtures of CoSn

and Co<sub>3</sub>Sn<sub>2</sub> with one another, or with either of the components. Below 57 6 p.c tin, the alloys are magnetic and brittle; above 66.8 pc tin, the alloys are less brittle and non-magnetic; all are much harder than either component. A compound Co<sub>2</sub>Sn of m p 1151° has also been described

With gold a brittle alloy is produced, that containing 1 part gold and 17 parts cobalt is dark-yellow and very brittle, all the alloys are magnetic. With platinum a fusible alloy is produced, and a silver-white magnetic amalgam

with mercury is used in dentistry.

Alloys with aluminium containing less than 68 5 p.c. cobalt are non-magnetic, the freezingpoint curve indicates a compound CoAl. Cobalt and nickel do not appear to form a compound, the freezing-point curve is almost straight, the composition of the solid being almost identical with that of the liquid in all cases

Addition of iron has no appreciable effect on the melting-point of cobalt, the curve being almost horizontal to 5 pc. cobalt, the crystals having the same composition as the fused mass. Two series of non-magnetic, which transform into four series of magnetic crystals, appear to exist (Tammann, Zeitsch anorg. Chem 45, 205) Steels containing up to 60 pc cobalt show perlitic structure, and the mechanical properties are only slightly affected by the cobalt.

Lead, silver, or bismuth are only partially miscible with cobalt when molten, and no definite

alloys appear to be formed.

With silicon in the electric furnace, steel-grey metallic-looking silicides are formed, Co2S1 and CoSi2. Both are stable and hard, and attacked by hydrofluoric acid and aqua regia. A very hard magnetic bonde is prepared in a similar manner; and by the action of phosphorus on cobalt chloride at a low red heat a hard brittle phosphide, Co, P3, not affected by heat or acids, is produced.

It is possible to combine cobalt or nickel with manganese with the production of valuable alloys. For this purpose commercial manganese or ferro-manganese may be used, the presence of iron not being injurious From 2 to 5 pc. of the manganese is added in small portions to the molten metal, much gas is evolved after each addition, and the metal is poured into moulds when tranquil (v. Hunting-

don, J. Soc Chem. Ind 1882, 258)

It is stated that when in the molten condition cobalt and nickel take up both carbon and oxygen, but evolve the greater part of the latter substance on cooling, leaving a porous metal containing carbon A method has been patented whereby this carbon is said to be eliminated. The porous cubes of metal are immersed in a 4 p.c solution of alkaline manganate or permanganate, dried and melted in a crucible at a high temperature The carbon is said to be thus oxidised and removed, and the metal takes up a small quantity of oxygen As soon as the metal flows easily, a little black flux and charcoal. or a small quantity of aluminium, or the calcium zinc produced in Caron's process, is added, and the oxygen thus removed (Dingl. poly J. 1884, 254-315).

Oxide of cobalt is used for the preparation of the salts of cobalt and of smalt, and by enamellers and porcelain manufacturers for the production of the finest blue glaze and colour on porcelain, glass, and other vitrifiable substances. The presence of  $z_0 \bar{b}_{00}$  of this substance imparts a bluish tinge to clear glass.

The presence of other oxides has an injurious effect on the colour produced by this substance (v Smalt), it is therefore necessary, for the more delicate work, to ensure its complete freedom from such impurities.

When heated strongly with magnesia, it pioduces a pink mass, with alumina, a fine blue (Thenard's blue); and with zinc oxide, a green (Rinmann's green) Zaffre consists of a very impute oxide of cobalt, produced by roasting the ore. It is usually mixed with 2 or 3 parts of fine sand or ground quartz, and is used for the same purpose as smalt for the coarser work.

Cobalt blue, Cobalt ultramarine, Thenard's blue, Azure blue. The composition of this pigment varies considerably, according to the It consists sometimes method of manufacture of the oxides of cobalt and aluminium, at other times it contains phosphate or aisenate of cobalt

It may be prepared by first precipitating a solution of a cobalt salt, usually the nitrate, free from iron and nickel, with potassium or sodium phosphate, or with sodium arsenate gelatinous violet precipitate is thoroughly washed and well mixed with 3-5 volumes of freshly precipitated, well-washed alumina (when cobalt arsenate is employed, a larger proportion of alumina may be added), precipitated from a solution of alum free from iron by the addition of sodium carbonate The mixture is dried until it becomes brittle, and calcined at a cherryred heat for 30 minutes in a well-covered clay crucible When the desired blue colour has been developed, the mass is ground with water and dried In order to prevent the possibility of entrance of reducing gases, which much injure the value of the product, Regnault recommended the addition of a little mercuric oxide This becomes decomposed before the ignition and evolves oxygen, which effectually prevents reduction, while the mercury escapes as vapour (Regnault, Cours Elém de Chimie, 3, 150)

A similar but less fine colour is produced by the simultaneous precipitation of the oxides of cobalt and aluminium by the addition of sodium carbonate to a mixture of cobalt nitrate and alum, the mixed precipitate is washed and

treated as above

According to the process recommended by Binder (Technologiste, 5, 55), the oxide of cobalt is precipitated by the addition of the requisite quantity of ammonia to a solution of pure cobalt chloride The washed precipitate is mixed with alumina as before, dried, and calcined at a red heat in a clay crucible for two hours

According to Hedvall the fusion of cobaltous oxide and alumina is best made in presence of potassium chloride as a flux When the cobalt oxide is in excess the resulting product can be obtained pure by treatment with water to remove the flux and with hydrochloric acid to remove the excess of cobalt oxide At 1100° the blue aluminate  ${\rm CoO\cdot Al_2O_3}$  is formed, at temperatures above 1100° a green aluminate 4CoO,3Al<sub>2</sub>O<sub>3</sub> is produced. McEachern has pointed out that alumina and cobalt oxide alone do not produce a satisfactory colour, but that additions of sodium or magnesium salts greatly improve it. Wagner and Vanino found

that cobalt sulphate could be used instead of phosphate, and that the alumina was most suitably introduced as ammonium-alum To 25 pts. of alum were added 25 to 5 pts cobalt sulphate, 03 pt. magnesium or zine sulphate; the mixture is melted in its water of crystallisation and constantly stirred until dry, when it is heated to the required temperature (Vanino, Chem Zeit 1911, 35, 497).

Thenard's blue is of a fine ultramarine colour; the presence of excess of cobalt imparts a somewhat greenish tinge. It has, however, the disadvantage of appearing violet by gaslight It is one of the most permanent blue pigments, being unaltered by acids or alkalis, and is largely used as an oil and water colour, but works better as water colour. It is non-poisonous, and has the advantage of miscibility with other pigments without alteration.

Correleum, Coline, Bleu céleste, is a corresponding colour containing oxide of tin and usually calcium sulphate—Its general composition is said to be oxide of tin, 49 66; oxide of cobalt, 18 66; calcium sulphate and silica, 31 68, and a pigment of this nature is obtained by precipitating a solution of cobalt intrate with sodium stannate, and heating the precipitate as

above.

It is a fine light-blue pigment of slightly greenish tinge, of greater density than Thenard's blue, and retains its colour in aitificial light

New blue. A blue pigment of shade varying from a pale-greenish blue to a deep-turquoise blue, largely used for enamels, consists of aluminates of cobalt and chromium produced by the action of alum on carbonates and hydroxides of cobalt and chromium

Cobalt green, Rinmann's green. The constitution of this pigment corresponds with that of Thenard's blue, with the substitution of zinc oxide for alumina

It may be prepared by mixing a solution of pure cobalt sulphate (or nitrate) into a paste with zinc oxide, and heating in a muffle furnace for 3 or 4 hours, until the desired colour is obtained. Pigments of a more uniform nature are produced by the precipitation of a mixture of solutions of zinc and cobalt salts, by means of sodium carbonate, phosphate, or arsenate, drying and heating the precipitate. The phosphate is said to give a purer and brighter green than the carbonate

R. Wagner (Technologiste, 18, 409) gives the composition of fine green pigments as varying from 71.68 p.c. zinc oxide and 11.62 p.c. cobalt oxide, to 88.04 p.c zinc oxide and 11.52 p.c. cobalt oxide, the quantity of phosphoric oxide also varying greatly

According to Hedvall (Arkw Kem Min Geol

According to Hedvall (Arkw Kem Min Geol 1913, 5, No. 6, 1), Rinmann's green is not a definite substance, but rather a series of solid solutions of its component oxides in isodimorphic

crystals.

Rinmann's green is a fine permanent pigment; its colour varies through many shades, according to the proportion of zinc present, the darker greens containing less of that substance It is non-poisonous and unacted upon by dilute acids or alkalis, but is attacked by ammonia. It has also the advantage of not affecting or being unaffected by other pigments. Rinmann's green, on account of its high price, and

the number of other permanent greens, finds little use as a pigment. Another permanent green pigment used in porcelain painting is said to be prepared by the calcination of a dried mixture of the following proportions of the freshly precipitated substances; 20 cobalt carbonate, 40 alumina, 20 chromium oxide

Cobalt bronze is a phosphate of cobalt and ammonia, of a violet colour, with a bronze-like

metallic lustre

Cobalt silicates. A cobalt silicate is produced by the addition of sodium silicate (soluble glass) to a cobalt salt—It produces a blue pigment well suited for painting on glass and porcelain

Smalt. Bleu d'azur, Bleu de Saxe This important substance consists of a silicate of cobalt

and potash

In the preparation of smalt in Saxony, smaltine is principally used. In Norway and Sweden the principal ore is cobaltine. The general process is identical for both ores.

The selected one is powdered, freed from the lighter earthy impurities by washing, and placed, in charges of about 3 cwt, in a layer of 5 or 6 inches thick on the bed of a reverberatory furnace or in a muffle. It is then roasted, and the sulphur and arsenic expelled as oxides, the latter being condensed in chambers through which the fumes are passed The roasting must be discontinued when only sufficient arsenic is left to combine with the less oxidisable metals, especially copper and nickel, while the greater part of the cobalt is converted into oxide order to ascertain whether the roasting has proceeded sufficiently, a small portion is occasionally tested and the process stopped when the The material finest tinted glass is produced. is then ready for fusion for 'smalt'

The fluxes used consist of powdered quartz and potassium carbonate. They must be of great purity, as the presence of lime and many other substances impairs the beauty of the colour. The quartz is first heated to redness, plunged into water, and, thus disintegrated, is powdered in a mill. It is then suspended in water and allowed to subside for a short time, and the liquid, which contains most of the iron and other impurities still suspended, is poured off; this operation is repeated until a pure quartz

powder is obtained

The proportions of the ingredients used vary extremely according to the richness of the ore and the colour required. The potassium carbonate used generally amounts to about one-third of the weight of ore and quartz together. White arsenic is usually added to oxidise any ferroussalt, and thus prevent the injurious effect of that substance on the smalt, and to otherwise heighten the colour of the product. The exact amount of each of these substances is found by a test fusion and comparison with a smalt of the required colour.

The smalt furnace is similar to a glass oven; it usually contains eight crucibles. The pots are of very refractory clay, free from lime, and capable of holding \( \frac{3}{4} \) cwt. When charged, they are strongly heated, and the mass fuses in about 8 hours; it is frequently stirred to render it homogeneous, and to break the crust which forms on the surface. At a white heat combination occurs, the quartz and potash react with the production of fusible potassium

COBALT. · 299

silicate, which dissolves the cobalt oxide, forming the blue 'smalt,' while the mixed arsenides of nickel, copper, and iron, with the small quantity of cobalt arsenide which is always present, fuse and form a brittle metalliclooking speiss beneath the smalt. This usually contains about 3 p c. of cobalt and a considerable quantity of nickel, and is used for the preparation of the latter substance and of cobalt oxide. The mass is left at a white heat for some time without stirring, to allow the speiss to settle, and is ladled out with long-handled iron ladles into vessels of cold water It is thus rendered granular, brittle, and easy to pulverise When nearing the bottom of the crucible, the ladle contains both speiss and smalt, the former, being much more fusible, is poured first from the ladle, from beneath the smalt, into a niche in the side of the furnace, whence the dense fumes of arsenic, &c., which it evolves pass up the chimney

The blue glass is next powdered with gramte stampers, or ground between gramte nullstones under water, and the product passed through a series of depositing vats. In the first vat it remains for a short time only, thence it passes to a second for a somewhat longer time, to a third for about 15 minutes, to a fourth and fifth for a corresponding period, and finally to a sixth vat, where it is allowed to deposit completely. The deposit in the first vat is returned to the mill and re-ground, that in the second and third is the best marketable smalt, whilst in the fourth and fifth vats a lighter-coloured deposit, sold under the name eschel, is produced. The deposit in the last vat is not marketable, and is

usually resmelted

The marketable deposits are again washed, deposited, dried, powdered, and sifted. About three-fifths of the glass taken from the pots is thus available. The presence of other oxides than those of cobalt and potash, even in small quantities, exerts a powerful influence on the colour of the small. Baryta produces an indigotinge; sodium, calcium, and magnesium produce a reddish shade; iron, a blackish green, very prejudicial to the brighter-coloured smalts; manganese violet, nickel violet, but less intense, copper, zinc, bismuth, and antimony, dull shades.

The composition of smalt varies considerably; the silica is usually from 56-70 p.c.; potash, 12-22 p.c., and cobalt, 6-16 p.c. The following analyses by Ludwig (J. pr. Chem. 1850,

51, 129) are typical -

Smalt is a very permanent blue pigment, largely employed for the production of blue colours with vitreous substances and in painting, both for delicate and coarse work. It was formerly much used for colouring starch, paper, &c., but for this and many other purposes it is now almost superseded by the far less permanent artificial ultramarine.

Cobalt yellow consists of potassium cobaltimitrate, prepared by the addition of potassium intrite to a solution of a cobalt salt acidulated with acetic acid. Its composition varies with the proportions used and the strength of the solution. Erdmann and Sadtler state that when precipitated from a solution containing much acetic acid it consists of  $K_3({\rm 'o(NO_2)_6})$  with a variable amount of water

Cobalt yellow is a bright yellow crystalline powder, very free from impurities, unacted upon by cold water or cold acids, and but slowly blackened by sulphuretted hydrogen.

It forms a fine pigment for artistic purposes. When used for painting porcelain it produces the usual blue colour on baking, which, on account of the purity of the substance, is of great beauty

Salts of cobalt. The soluble salts of cobalt are prepared by solution of the oxide, carbonate, or metal in the various acids. They are generally pink and deliquescent, forming pink solutions when dilute, but when dired, or in concentrated solution, they are blue. For this reason, solutions of initiate and other salts of cobalt are used as sympathetic inks, such writing being almost invisible until brought near a fire, when the letters appear blue. They gradually reabsorb moisture and again become invisible. They are largely used for neutralising the yellow colour of porcelain, and giving a pure white body, the porous clay being for this purpose soaked in solution of cobalt salts.

When ammonia is added to a solution of a cobalt salt, oxygen is absorbed, giving rise under various conditions to many complex series of salts containing ammonia and different oxides of cobalt.

Cobaltous hydroxide is obtained by adding an alkali to a solution of a cobalt salt either as a blue or red piccipitate depending upon the proportion of alkali. The red modification is more reactive than the blue compound they are regarded by Hantzsch as 'chromo-isometic' modifications (Zeitsch. anorg. Chem. 1912, 73, 304).

Cobaltous chloride CoCl<sub>2</sub> is prepaied by dissolving the oxide or carbonate in hydrochloric acid, and evaporating the solution According to the temperature at which it crystallises, it may contain 6, 4, or 2 molecules of water of crystallisation, the latter at the higher temperatures.

Cobaltous chloride is soluble in water or alcohol A strong solution, or a weaker solution containing strong hydrochloric acid, is of a blue colour.

Cobaltous sulphate CoSO<sub>4</sub>,7H<sub>2</sub>O is prepared by solution of the oxide or carbonate in dilute sulphuric acid It crystallises in red crystals, isomorphous with magnesium sulphate, soluble in 24 parts of cold water.

Cobaltous nitrate Co(NO<sub>3</sub>)<sub>2</sub>,6H<sub>2</sub>O is a red deliquescent crystalline salt prepared by dissolving the oxide in nitric acid. It is very soluble in water, the solution being used as a

reagent in blowpipe analysis.

Combinations of cobalt, as resinate, cleate or linoleate, tungate, oleo-resinate and resinotungate, are employed as driers. (See Krauss, 8th Int. Cong Appl. Chem. 1912, 12, 127; Journ. Soc Chem Ind 1912, 31, 938.)

Cobalt Carbonyls. Cobalt forms two carbonyls the tetracarbonyl Co<sub>2</sub>(CO)<sub>8</sub>, and the

tricarbonyl Co(CO)3.

Cobalt tetracarbonyl. This compound is prepared as follows. cobalt oxalate is carefully heated until completely converted into the ovide It is then washed free from traces of chlorides which hinder the formation of the carbonyl, and dried at 120°. The oxide is placed in the apparatus described under 'carbonyls,' and reduced to cobalt by means of hydrogen, at a temperature of 300° and a pres sure of 5 atmospheres After the reduction, the hydrogen is displaced by carbon monoxide, the pressure being increased and the temperature lowered For the production of the carbonyl, a minimum pressure of 40 atmospheres and a temperature of 150° is needed, and at pressures up to 250 atmospheres and temperatures between 150° and 250°, varying quantities of the carbonyl are collected in a tube attached to the outlet of the apparatus, and immersed in a freezing mixture.

The tetracarbonyl forms orange-coloured crystals of sp gr 1.73, which melt at 51°, and

decompose above that temperature.

The molecular formula is Co<sub>2</sub>(CO)<sub>8</sub> The compound is insoluble in water, but is soluble in most organic solvents, and in nickel tetracarbonyl It is not attacked by aqueous acids but concentrated acids and the halogens decompose it, forming the corresponding salt, carbon monoxide, and hydrogen

$$Co(CO)_4 + H_2SO_4 = CoSO_4 + 4CO + H_2$$

In contact with air a deep violet-coloured compound is formed, which is most probably a hydrated basic carbonate. The crystals are best preserved in a sealed tube in an atmosphere of hydrogen or carbon monoxide.

When the tetracarbonyl is heated at 60°, one quarter of the carbon monoxide is evolved at a regularly decreasing rate, leaving a compound having the formula Co(CO)<sub>3</sub> in the form of black cobalt and carbon monoxide, no intermediate

product being formed

When the tetracarbonyl is heated at 100°, one quarter of the carbon monoxide is evolved almost instantaneously, the rest coming off very irregularly and comparatively slowly (Mond, Hirtz, and Cowap, Chem Soc Trans. 1910, 97, 798)

COBALTITE (or Cobalt-glance). Sulpharsenide

of cobalt, CoAsS, containing Co 25–35 p.c. with Fe 2–5 p.c It frequently occurs as well-developed crystals, fine specimens coming from Tunaberg and Håkansboda in Sweden and Skutterud in Norway; these are cubic with parallel hemihedrism and with the same characteristic form as crystals of the isomorphous mineral iron-pyrites. Gianular and compact masses also occur The colour is tin-white with a reddish tinge and a brilliant metallic lustre; the streak is greyish-black Sp gr. 6.2, hardness 5½ A bed of pure cobaltite averaging 0.2 metre in thickness occurs at Dashkessan, govt Tiflis, Caucasus In the Cobalt area of Ontario massive cobaltite and small crystals are present with the more abundant smalter. Under the name sehta the mineral, found at Kheit in Rajputana, is used by the Indian jewellers for producing a blue enamel on gold and silver.

COCAINE AND THE COCA ALKALOIDS. The coca leaves of commerce are derived from Erythroxylon coca (Lam) (Bolivian or Huanuco), E coca var novogranatense (Morris) and Etruxillense (Rusby) (Peruvian or Truxillo coca).

Coca was introduced into Ceylon in 1870, and later into India, but whilst production in Ceylon attained considerable proportions, the Indian supply was never of commercial importance Subsequently, cultivation was taken up in Java where, after considerable initial difficulties, production attained large proportions constituting about 45 p c of the world's supply, the remainder being produced in South America, Cultivation was stopped in Ceylon in 1915 by order of the Government

Coca leaves contain alkaloids of four types:—
1 Cocaines; alkyl acyl derivatives of ecgo-

Cocames; alkyl acyl derivatives of ecgonine.

2 Acvlecgonines, acyl derivatives of ecgonine

3  $\psi$ -tropeines, acyl derivatives of  $\psi$ -tropine

4 Hygrines

The first and second types can be used as commercial sources of cocaine, since on hydrolysis they yield ecgonine which by benzoylation and methylation yields cocaine. The coca leaves derived from South America contain up to 1 p c of ether-soluble alkaloids (mostly cocaine), whilst Java leaves contain up to 1 5 p c, or sometimes more ether-soluble alkaloid of which little or none is cocaine.

Estimation of total alkaloids in coca leaves.-The following process is given in the United States Pharmacopæia, 8th ed. . 10-grms. of coca leaves in No 60 powder are mixed with 50 c.c. of a mixture of chloroform 1 vol, ether 4 vols., in a stoppered Erlenmeyer flask and set aside during 10 mins. Two cc of ammonia solution, diluted with 3 c c. of water, are then added, and the flask shaken at intervals during 1 hour. small glass percolator with the lower end obstructed by a wad of cotton wool is then placed in the neck of a separating funnel containing 6 cc of N-sulphuric acid, diluted with 20 cc. of water, and the contents of the flask poured into the percolator. When all the liquid has passed, the contents of the percolator are packed in firmly by means of a glass rod, and then the flask is rinsed out with 10 c.c. of the chloroformether mixture, followed by several successive washings with 5 c.c. quantities of the same mixture, the percolation being continued with

this liquid until 50 c.c. have been used in all. The separator is now shaken during one minute, the acid liquid drawn off, and the extraction repeated twice, using each time 10 c.c. of acid (6 c.c. N-acid with 20 c.c. of water); the combined acid liquors are made distinctly alkaline with ammonia solution and the alkaloids extracted with successive portions of other (25, 20 and 15 c.c.). The other is allowed to evaporate spontaneously, and the residue dissolved in 4 c.c. of N/10 sulphuric acid, and the excess of acid determined by N/50 potassium hydroxide using cochineal or iodeosin as indicator. This process gives the amount of other-soluble alkaloids in the drug. No satisfactory process is yet available for the estimation of cocaine in the 'total alkaloids'

Estimation of Ecgonine in total alkaloids.— The total alkaloids from 15-grm. of leaves are boiled for 1 hour with 30 times their weight of dilute hydrochloric acid, the mixture is cooled, extracted with other, evaporated to dryness and the residual ecgonine hydrochloride weighed (Greshoff, Pharm Weekb 1907, 44, 961)

Cocaine C<sub>17</sub>H<sub>21</sub>O<sub>4</sub>N occurs to a variable extent in the different varieties of coca leaves

(see above)

Preparation —The coca leaves are exhausted by maceration and agitation with a mixture of aqueous sodium carbonate and petroleum, whereby the cocaine with cinnamyl cocaine, &c, passes into solution in the petroleum The latter is shaken with dilute hydrochloric acid, when cocaine hydrochloride crystallises out and is collected, pressed and dried. This crude salt is purified by solution in water, liberation of the free base by ammonia, and solution of this in alcoholic hydrogen chloride, when the hydrochloride crystallises out. The motherliquors contain the other coca alkaloids Java coca leaves are used, the coca alkaloids other than cocaine alone are obtained, and these and the residual coca alkaloids referred to above are converted into cocaine by heating with boiling hydrochloric acid and pouring into water, when trustlic and cinnamic acids separate and may be filtered off The filtrate is concentrated until ecgonine hydrochloride crystallises out The ecgonine is recovered and then benzovlated and methylated in turn to produce cocaine

The crude cocaine manufactured in Peru and imported to Europe for the preparation of cocaine salts is obtained by extracting the leaves with 0.5 p.c. sulphuic acid, making the filtrate alkaline with sodium carbonate and extracting with petroleum. The latter is again shaken out with dilute sulphuric acid and the crude alkaloid precipitated from this as a white, bulky powder by sodium carbonate. The powder is washed with water and dried by ex-

posure to air for export

Properties — Monoclinic prisms, mp 98°; at higher temperatures it sublimes with decomposition. Lavorotatory [a]p—158°; sightly soluble in cold water, more soluble in hot water, by which it is slowly hydrolysed. Soluble in alcohol, ether, benzene, light or heavy petroleum, or carbon disulphide. The aqueous solution is alkaline to litmus, has a bitter taste and produces a tingling and numbness of the tongue and lips, or, more generally, local anæsthesia of the surface to which[it is applied.

On this account it is largely employed in minor surgical operations, although in recent years it has been replaced to some extent by synthetically prepared anæsthetics, such as benzamine (β-eucaine), stovaine, novocaine, &c alkaloid also causes dilatation of the pupil of the eye, but is not so powerfully mydriatic as some of the solanaceous alkaloids. When administered internally in small doses it acts as a stimulant, and diminishes the feeling of fatigue consequent on muscular exertion Coca leaves have long been known to possess this property, and in places where the plant is abundant, a mixture of lime and coca leaves is chewed by the natives before engaging in severe excition. Larger doses of the alkaloid are poisonous

The ordinary salts of cocaine are crystalline. The hydrochloride, which is the salt used in medicine, forms white micaceous scales, possessing a characteristic lustre, or as white needles, readily soluble in water. The chromate B H<sub>2</sub>(10<sub>4</sub>, H<sub>2</sub>O is thrown down, as a pale-yellow precipitate when potassium chromate is added to an acid solution of the hydrochloride. This salt is very slightly soluble in cold water, in p. 127°. The aurichloride B HAu(1<sub>4</sub> is crystalline and spatingly soluble in water. When aqueous mercuire chloride is mixed with a solution of cocaine hydrochloride a bulky precipitate of the mercurichloride. B HCl Hg(1, 2H<sub>2</sub>O is formed this salt may be crystallised from alcohol, in p. 124°.

d-Cocaine, mp. 46°, was obtained by Liebermann and Giesel (Ber. 1890, 23, 508, 926) from coca leaves, but was probably formed by the racemisation of 1-cocaine by the action of alkalis, it has been synthesized from d-ecgonine dd-cocaine, mp. 80°, was prepared from decgonine by Willstatter and Bode (ibid. 1901, 34, 1457)

Detection —In isolating cocaine, the aqueous solution should not be heated for any length of time, and not at all in the presence of acids For the liberation of the alkaloid or alkalıs from its salts, ammonia, and not caustic alkalis, should be employed Cocaine may be detected by its characteristic action on the tongue (see above) The following reactions are useful for the detection of the alkaloid: One c c of a 3 p e solution of potassium permanganate gives a violet precipitate with 0.01 grm of the hydrochloude dissolved in two drops of water (Chem Zeit 1886, 10, 71; Amer J Pharm 1911, 83, 195-201, 265-268). The hydrochloride heated with alcoholic potash gives off an odour of methyl benzoate When moistened with nitric acid, the mixture evaporated to dryness and alcoholic potassium hydroxide added, a characteristic peppermint odour is produced.

The most important criteria of purity of cocaine hydrochloride are the mp, the permanganate test, and the ammonia test

The mp. of cocame hydrochloride varies with the rate of heating. When inserted into a bath previously heated to 195° and the temperature then slowly raised, it melts at 201°-202°; when 3 drops of N/10 solution of potassium permanganate are added to 0·1 grm. of cocame hydrochloride in 5 c.c. of water containing 3 drops of dilute sulphuric acid a purple colour is produced, which should show no diminution in shade in half an hour. If 0·1 grm. is dissolved

in 100 c.c. of water, 0.25 c.c. solution of ammonia added and the mixture set aside 15 minutes, the side of the beaker being occasionally gently rubbed with a glass rod, a crystalline deposit should be formed leaving the supernatant liquid clear (limit of amorphous alkaloids).

Reactions and Constitution —Cocaine exhibits most of the general reactions of the vegetable alkaloids When boiled with water it is gradually hydrolysed into methyl alcohol and 1-

benzoylecgonine (see below)

 $C_{17}H_{21}O_4N+H_2O=C_{16}H_{19}O_4N+CH_3OH$  (Paul, Pharm J. 1887-1888 [III] 18, 781; Einhorn, Ber. 1888, 21, 47), and the same change gradually occurs if the alkaloid remains in contact with an alkaline liquid With alkalis or mineral acids methyl alcohol and benzoylecgonino are first formed, but the latter undergoes further hydrolysis into benzoic acid and 1-ecgonine (see below)

$$C_{17}H_{21}O_4N + 2H_2O_4$$

=CH<sub>3</sub>OH+C<sub>7</sub>H<sub>6</sub>O<sub>2</sub>+C<sub>9</sub>H<sub>18</sub>O<sub>3</sub>N Natural cocaine is therefore methylbenzoyl-

1-ecgonine

i-Eegonine C<sub>9</sub>H<sub>18</sub>O<sub>3</sub>N This base does not occur as such in coca leaves, but is the ultimate basic product of hydrolysis of cocaine, cinnamyl-cocaine, the truxillines and benzoyleegonine fit crystallises from dry alcohol in monoclinic prisms with 1H<sub>2</sub>O, mp 140°, or 198°-199° (anhydrous); lævorotatory It is readily esterified by alcohols yielding a series of alkyl esters, and by acid chlorides or anhydrides, giving the acyleegonines from which the corresponding 'cocaines' are obtained by alkylation

Ecgonine is now known, principally as the result of the researches of Einhorn, Liebermann, Willstatter and their collaborators (see below), to be closely related to tropine, the ultimate basic hydrolytic product of atropine and hyosoyamine, and may be regarded as tropine-β-carboxylic acid Ecgonine and its most important derivative 1-cocaine may be represented by the following formula:—

Some of the chief papers bearing on the constitution of ecgonine are: Einhorn, Ber 1889, 22, 399, 1890, 23, 1338; 1893, 26, 324; 1894, 27, 2823; Annalen, 1894, 280, 96; Liebermann, Ber 1890, 23, 2518; 1891, 24, 606; Willstatter, *ibid* 1897, 30, 702, 1898, 31, 1546, 2500, 2655, 1901, 34, 519; Annalen 1903, 326, 79.

1-Benzoylecgonine  $C_{16}H_{19}O_4N$  is the first product of the hydrolysis of cocaine; it occurs in coca leaves from which it was isolated almost simultaneously by Skiaup (Monatsh 1885, 6, 556), and by Merck (Ber. 1885, 18, 1594). The base crystallises from water in needles, mp 86° (anhydrous 195°), and is hydrolysed by hydrochloric acid to benzoic acid and ecgonine. On methylation it furnishes cocaine.

1-Cinnamylcocaine  $C_{19}H_{23}O_4N$ . This alkaloid is now known to occur in all varieties of cocalcaves, but is found in largest proportion in the Java leaves, whence it was isolated by Giesel

(Pharm. Zeit. 1889, 34, 516). It forms needles, m.p. 121°, from benzene on addition of light petroleum Lævorotatory. On hydrolysis it furnishes cinnamic acid, methyl alcohol, and lecgonine, and is therefore methylcinnamyl-1-ecgonine. The d-isomeride has been prepared (Einhorn and Deckers, Ber. 1891, 24, 7)

Truxillines  $C_{38}H_{46}O_8N_2$ . Two of these,  $\alpha$ - and  $\beta$ -, occur in coca leaves, the former is methylatruxillyl-1-ecgonine, and the second the corresponding  $\beta$ -truxillyl compound (Hesse, Pharm. Zeit 1887, 32, 407, 668; Liebermann, Ber. 1888, 21, 2342; 1889, 22, 130, 680) They are amorphous, and, according to von Liebreich, are heart poisons, and exert no local anæsthetic action

Tropacocaine (Benzoyl  $\psi$ -Tropeine)  $C_{15}H_{19}ON$  was isolated by Giesel (Ber 1891, 24, 2336) from Java coca leaves. It crystallises from ether, has mp 49°, is optically inactive, distils unchanged. The salts are crystalline, the hydrochloride melting at 283° and the aurichloride at 208°. On hydrolysis tropacocaine furnishes benzoic acid and  $\psi$ -tropine, and it may be prepared synthetically by the benzoylation of  $\psi$ -tropine (Liebermann, ibid 1891, 24, 2336, 2587, 1892, 25, 927), the latter is a physical isomeride of tropine, and has been synthesised by Willstatter (Ber 1896, 29, 936; 1901, 34, 129, 3163), who assigns to it the same structural formula as to tropine, and states that since tropine and pseudotropine are optically inactive the isomerism appears to be of the cis-trans type, a view subsequently confirmed by Barroweliff and Tutin (Chem Soc Trans 1909, 95, 1970). Tropacocaine, like the pseudotropeines as a class, is almost devoid of mydriatic action, but like cocaine is a local anæsthetic, though the effect is more transitory

Hygrines.—These secondary alkaloids were discovered by Lossen in Peruvian coca leaves (Annalen, 1862, 121, 374; 1865, 133, 352), and mvestigated by Liebermann and collaborators (Ber 1889, 22, 675; 1891, 24, 407, 1893, 26, 851; 1895, 28, 578; 1896, 29, 2050; 1897, 30, 1113), who showed that Lossen's supposed homogeneous material contained two liquid alkaloids, one boiling at  $193^{\circ}-195^{\circ}$  and having the formula  $C_8H_{16}ON$ , which makes it isomeric with tropine, and a second having the composition  $C_{14}H_{24}ON_2$ , bp.  $215^{\circ}$ , under 50 mm. pressure The low boiling alkaloid is that now known as hygrine Willstatter and Ettlinger's synthesis of hygrine acid shows that hygrine probably has the following constitution (Annalen, 1903, 326, 91):—

$$\begin{array}{c} \text{Me N} \\ \begin{array}{c} \text{CH}_2 \\ \\ \text{CH(CH}_2 \text{ CO Me) CH}_2 \end{array} \end{array}$$

From 'cusco' leaves Liebermann and Cybulski isolated a third substance of this type, viz. cuscohygrine  $C_{17}H_{24}ON_2$ , b p. 185° under 32 mm. pressure, which forms a crystalline hydrate B,3 $\frac{1}{2}H_2O$ , m p 40°. It probably has the constitution (L a C, Ber. 1895, 28, 578)—

COCAETHYTIN. Trade name for the ethyl ester of benzoylegonine.

COCATANNIC ACID v. TANNINS.

COCCINE v. AZO- COLOURING MATTERS.

α-COCCINIC ACID, COCCININ, v. COCHINEAL.

COCCULIN v. PICROTOXIN. COCCULUS INDICUS or INDIAN BERRY 18

the fruit of the Anamrta paniculata (Colebar), [A Cocculus (Wight and Arnott)] nat ord Menispermaceæ, a tree growing upon the coasts of Malabar, Ceylon, &c The berry is about the size of a large pea and of a dark-grey colour It possesses strong poisonous and narcotic qualities from the fact of its containing about one-fiftieth part of its weight of piciotoxin, and has been employed to increase the bitterness as also the mebriating effect of beer It is, however, exceedingly deleterious to health, and the use of it for this purpose has been prohibited by the Legislature under heavy penalties

Besides picrotoxin, Schmidt and Lowenhardt (Bull Soc chim 14, 817) obtained from the seeds cocculin C19 H26O10, crystallising in white needles, sparingly soluble in hot water, insoluble in cold water, alcohol and ether. It is probably identical with Barth and Kretschy's anamutin C19H21O10 which they regarded as a constituent of piero-

Cocculus indicus berries contain menispermine, paramenispermine, and picrotoxin (v Picrotoxin).

COCCUS CACTI, C. ILICIS, C. LACCAL, v. COCHINEAL.

COCHIN CHINA WAX v WAXES.

COCHINEAL. This important natural dyestuff, which, in its native country, Mexico, was used as a dye and cultivated by artificial means at a remote period of history, was for a long time considered to be of vegetable origin Cochineal, however, consists of the dried body of an insect, the Coccus cacti, which lives upon a species of cactus (the Nopalea coccinellifera (S -Dyck) or Nopal), a plant which is found in the wild condition, but which, for the sake of the insect, is cultivated in gardens which are termed Nopaleries. The collection of the insects takes place before the commencement of the rainy season, and they are then brushed either into straw baskets or into basins of tinned iron A number of insects are left upon each plant, and a new generation is produced, which is again gathered at a suitable period The insects are killed by immersion in boiling water, or are enclosed in a linen bag and placed in an oven; by the latter process the peculiar white down covering the insect is preserved, but in the former case is lost.

In Mexico and Central America two varieties of cochineal are known-the home-grown, or fine cochineal (grana fina), and the wild, or forest cochineal (grana silvestra). The former is more valuable than the latter, and is richer in colouring Since 1830 the cultivation of cochineal was introduced into Spain and the Canary Islands, Algeria, and Java, but the most productive of these newer plantations were those Since the discovery of the coal-tar of Java colours, the consumption of cochineal as a dyestuff has gradually decreased, and at the present time it is only employed in a minor degree. According to Liebermann, cochineal contains about 10 per cent. of colouring matter (Ber. 18, 19).

Carminic acid, the colouring matter of cochineal, was first isolated by Pelletier and Caven-

tou (Ann. Chim Phys (2), 8, 250), and was subsequently examined by Preisser (Annalen, 52, 375; J. Pharm. Chim (3), 5, 191) and Arppe (Annalen, 55, 101); but Warren de la Rue (ibid 64, 1) was the first to isolate this substance in a pure condition, and described it as a purplebrown mass, which, on grinding, yields a bright-red powder, easily soluble in water and alcohol, but not in ether. The mean of his analyses gave 54 13 p.c. of carbon, 4 62 p c of hydrogen, and 41 25 pc of oxygen (by difference), and from these figures he deduced the formula  $C_{14}H_7O_8$  or  $(C_{14}H_7O_8)_2$  Schutzenberger (Ann. Chim Phys (3) 54,

52), on the other hand, was the first chemist who succeeded in obtaining carminic acid in a crystalline condition. He precipitated the colouring matter, from an aqueous cochineal extract, in the form of its lead compound, suspended this in water, and decomposed it with sulphuretted The carminic acid thus liberated dissolved in the water and was recovered from this solution by evaporation at a low temperature. The product, dissolved in alcohol, was treated with ether to precipitate certain impurities, and the liquid partially evaporated, when, on cooling, a crystalline mass was obtained, which Schutzenberger considered to consist of two substances, carminic acid,  $C_9H_8O_8$ , and oxycarminic acid,  $C_9H_8O_8$ , the latter being distinguished by its solubility in ether

Schaller (J 1864, 410), who prepared carminic acid by the same method, assigned to it,

however, the formula CoH,O,

The work of Hlasiwetz and Grabowski (Annalen, 141, 329) indicated that carminic acid was a glucoside which could be decomposed into a sugar and a new colouring matter, carmine red-

$$\begin{array}{c} {\rm C_{17}H_{18}O_{10}} + 2{\rm H_2O} = {\rm C_{11}H_{12}O_7} + {\rm C_6H_{10}O_8} \\ {\rm Carmine\ acid} \end{array}$$

but according to Liebermann (Ber 18, 1969; Will and Leymann, ibid. 18, 318; and Von Miller and Rohde, ibid. 26, 2647), this is incorrect

Coccinin, according to Hlasiwetz and Grabowski, is produced when carminic acid is fused with caustic potash It crystallises from alcohol in straw-yellow needles or leaflets, dissolves in alkalis with a yellow colour, which, by air oxidation, develops first a green, then violet, and, finally, a purple tint. The analyses of this substance were in agreement with the formula C14H12O5.

Ruficoccin—By heating carminic acid with sulphuric acid to 130°-140°C, Liebermann and van Dorp (Annalen, 163, 105) obtained a new colouring matter ruficoccin, C<sub>16</sub>H<sub>10</sub>O<sub>6</sub>, and this consisted of a bright-red powder, sparingly soluble in hot water and ether, with a greenishvellow fluorescence. On distillation with zincdust, it yielded a colourless crystalline hydrocarbon,  $C_{16}H_{12}$ , melting-point 183°-188°C, from which, by oxidation, a quinone melting at 250° C. could be produced.

Furth, somewhat later (Ber. 16, 2169), prepared the same hydrocarbon by the distillation of both cochineal carmine and coccinin with zinc-dust.

Ruficarmine, C<sub>16</sub>H<sub>12</sub>O<sub>6</sub>, can be obtained, according to Liebermann and van Dorp, by heating carminic acid with water in a sealed tube at 200°C. It consists of a carmine red

powder, easily soluble in alcohol

In view of the uncertainty existing as to the percentage composition of carminic acid, Schunck and Marschlewski (Ber 27, 2980) submitted this substance to an elaborate process of purification, and, using in their operations as low a temperature as possible, obtained a product which crystallised from alcohol in red prismatic needles. Their analyses agreed closely with that required by the formula  $C_{11}H_{12}O_6$ , and the percentage composition approximately with the figures given by Warren de la Rue, and also by Schutzenberger

On the other hand, analyses by Miller and Rohde (Ber 30, 1762) pointed to the formula  $C_{12}H_{11}O_7$  or  $(C_{12}H_{11}O_7)_2$ , but according to the more recent work of Liebermann, Horing and Wiedermann (Ber 1900, 33, 149), it now appears that the correct formula for carminic acid is

 $C_{22}H_{22}O_{13}$ The most simple method of purification of Rohde. A solution of the crude colouring matter in five times its weight of water is diluted with four times its volume of acetic acid. filtered liquid, on standing over sulphuric acid, gradually deposits the carminic acid in a crystalline condition

Carminic acid crystallises in red prisms, easily soluble in water and alcohol, with a purple-red colour. It possesses no melting-point, but darkens at 130°, and at 250° becomes quite black.

By the action of alcoholic potassium acetate, carminic acid (Perkin and Wilson, Chem Soc Trans 1903, 83, 139) yields two potassium salts,

Monopotassium carminate C22H21O13K, which is red coloured; and

Dipotassium carminate  $C_{22}H_{20}O_{13}K_2$ , soluble in water with a violet-red colouration

Hexabenzoylcarminic acid C22H16O13(C7H5O)6, obtained by digesting carminic acid with benzoyl chloride (Liebermann, Horing and Wiedermann), is an orange-coloured powder, easily soluble in benzene

Octacetylearminic acid  $\rm C_{22}H_{14}O_{13}(C_2H_3O)_8$ , crystallises in golden-yellow needles, meltingpoint 155°-165°, and is readily prepared by the action of acetic anhydride in presence of zinc chloride or sulphuric acid on carminic acid (Miller and Ronde)

Constitution of Carminic Acid —Nitrococcussic acid was obtained by W de la Rue from carminic acid by the prolonged action of boiling nitric acid It was subsequently studied by v Kostanecki and Niementowski (Ber 18, 250), and was found to be identical with the trinitrocresotime acid, of the following constitution :-

When carminic acid dissolved in 50 pc acetic acid is treated with an excess of bromine, and the solution digested at the boiling heat, two substances, known as  $\alpha$ - and  $\beta$ -bromearmines, are produced (Will and Leymann, Ber. 18, 3180).

ingly soluble substance, crystallises in colourless needles, and melts at  $247^{\circ}-248^{\circ}$ , with decomposition. When oxidised with potassium permanganate in alkaline solution, it gives dibrommethylhydroxyaldehydobenzoic acid-

and dibrommethylhydroxyphthalic anhydride-

$$\begin{array}{c}
\operatorname{Br} & \operatorname{CH_3} \\
\operatorname{OH} & \operatorname{CO} \\
\operatorname{OH} & \operatorname{CO}
\end{array}$$

On treatment with hot caustic soda solution. a-bromearmine yields, in addition to a purplered colouring matter, dibrommethylhydroxyphthalic acid, and bromoform (Miller and Rohde). As a result of this reaction, these authors assigned to a-bromcarmine the constitution of a methylhydroxytetrabromdiketohydrindene-

for Zincke (Ber 20, 3227, 21, 2388) had previously shown that dibromdiketohydrindene itself-

under similar treatment yields both phthalic acid and biomoform

B-Bromcarmine C11H5B13O4 is obtained as a yellow amorphous powder, easily soluble in alcohol (Will and Leymann), and is best purified by means of its potassium salt Crystallised from acetone, it separates in orange needles, melting at 232° (Will and Leymann) or 288° (Miller and Rohde). By the action of bromine in the presence of 50 p c. acetic acid solution, it is converted into a-bromcarmine. As a result of their investigation, Miller and Rohde ascribed to  $\beta$ -bromcarmine the constitution of a methyldihydroxytribrom-a-naphthaquinone, possessing one of the following formulæ

This suggestion was supported by the fact that bromoxynaphthaquinone (1), on treatment with bromine and caustic soda solution, is converted into dibromdiketohydrindene (2) (Zincke, loc. cit)-

Additional support for this view was obtained a-Bromcarmine C<sub>10</sub>H<sub>4</sub>Br<sub>4</sub>O<sub>3</sub>, the more spar- by a study of the behaviour of \$\beta\$-bromcarmine

with zinc-dust in alcoholic solution. Thus the acetyl compound of the reduction product, melting-point 206°, gave, on analysis, numbers agreeing with those of the acetyl derivative of methyldibromdihydroxynaphthahydroquinone, possessing the following formula:

From a consideration of the points above enumerated, Miller and Rohde considered that the constitution of carminic acid could be represented by one or other of the following expressions :-

As, however, such formulæ require C=64 7 p c, H=3.92 p c, figures which are much higher than those given by the analysis of carminic acid itself, these authors suggested the addition of two molecules of water of hydration, as shown below-

A substance of this constitution would require C=55 p c , and H=5 p c Somewhat later, Liebermann and Voswinkel

(Ber 30, 688) studied the oxidation of carminic acid with alkaline potassium permanganate at the ordinary temperature, and in this way

succeeded in producing two important acids.

Cochenillic acid, C<sub>10</sub>H<sub>8</sub>O<sub>7</sub>, crystallises in colourless needles, which melt at 224°-225° with evolution of CO. It is tribasic, and at 260° is converted into hydroxymethylphthalic anhydride (1). When heated with water in a sealed tube at 210° it yields symmetrical cresotinic acid (2)-

and in the same manner at a lower temperature, 170°, gives a-coccinic acid or m-hydroxyuvitic acid (3) The constitution of cochemille acid is therefore as follows:-

VOL II -T.

a-Coccinic acid CoH &Os, the second product of the oxidation, which, as already indicated, can also be prepared from cochemilic acid, proved to be identical with the hydroxyuvitinic acid of Oppenheim and Pfaff (Ber. 7, 929) It consists of colourless needles, melting-point 239°.

Liebermann (ibid 30, 1731), whilst agreeing with the diketohydrindene constitution which had been assigned to α-bromcarmine by Miller and Rohde, considered that \$\beta\$-bromcarmine was an indone rather than a naphthoquinone derivative, and could be better represented as follows .---

It was probable, indeed, that carminic acid itself was a hydrindene or bishydrindene derivative, and the following constitutions were at the time suggested for it-

In a subsequent paper, however, Liebermann and Voswinkel (Ber. 37, 3344) consider that carminic acid is possibly a tetrahydrate of adimethyldihydroxynaphthacenequinonedicarboxylic acid-

$$\begin{array}{c|c} \operatorname{CH_3} & \operatorname{CH_2} & \operatorname{COOH} \\ \operatorname{COOH} & \operatorname{CH} & \operatorname{CH_2} & \operatorname{CH_3} \\ \operatorname{OH} & \operatorname{OH_2} & \operatorname{OH_2} \end{array}$$

and it was observed that the dimethyltetrahydroxynaphthacenequinone-

prepared by these authors not only possessed weak tinctorial property of a cochineal-like character, but in several respects closely resembled carminic acid itself

Rohde and Dorfmuller (Ber. 1910, 33, 1363) further examined & bromo-carmine, and obtained results which support the naphthoquinone constitution assigned to it by Miller and Rohde (loc cit.), but disprove Liebermann's contention that it is a derivative of indone By reduction with zinc-dust and acetic acid and subsequent acetylation,  $\beta$ -bromo-carmine gives the compound  $C_{17}H_{14}O_8Br_2$ —

colourless needles, m.p. 208°C.

Simultaneous hydrolysis and oxidation converts this into the substance

orange prisms, m.p.  $258^{\circ}\mathrm{C}$ , and it thus appears that by the latter treatment an hydroxyl has entered the quinone nucleus. The diacetyl derivative melts at  $233^{\circ}\mathrm{C}$ . When distilled with zinc-dust, this product, and also  $\beta$ -bromo-carmine itself, give naphthalene.

A valuable contribution to the subject was made by Dimroth (Ber. 1909, 42, 1611), who studied the oxidation of carminic acid with potassium permanganate at 0° in presence of sulphuric acid. The solution thus obtained gave nothing to ether, but on heating for three-quarters of an hour at 90°, it evolved carbon dioxide, and ether then extracted carminazarin

Carminazarin crystallises from water in gainet-red needles, decomposing at 240°-250°. It possesses the constitution (1), and is very similar to isonaphthazarin (2)—

Its alkaline solution when treated with a stream of oxygen, is quickly decolourised with formation of 5.6-dicarboxy-4-hydroxy-o-lolylgly-oxylic acid—

A further point of resemblance of caiminazarine to isonaphthazarine is shown by its behaviour with nitric acid in glacial acetic acid, for whereas the latter gives tetraketotetrahydronaphthalene, the former yields the analogous Carminizarinquinone crystallising in colourless prisms—

and which, when heated with water or acetic acid, passes back to carminazarin

The intermediate product formed by the oxidation of carminic acid with permanganate at 0° insoluble in ether, and which, on heating, is transformed into carminazarin, is termed by

Dimroth carminoquinone. The constitutions assigned to this substance (1) and tentatively to carminic acid (2) are given below—

Carminic acid was, therefore, not a symmetrical compound, and the nature of the group  $C_{10}H_{15}O_7$  was not then determined. At the time, Dimroth considered that the coccurum (see above) of Hlasiwetz and Grabowski, and which is prepared by fusing carminic acid with potassium hydrate, had probably the constitution of a tetrahydroxymethylnaphthalenc—

Later, Dimroth (Annalen, 1913, 399, 1) reexamined this product in detail, preparing it by fusing carmine acid with caustic potash at  $170^\circ$ – $200^\circ$ C. To it he gave the formula  $C_{17}H_{14}O_{6}$ , and described the pale yellow crystalline *tetra-acetyl derivative*,  $C_{17}H_{10}O_{6}(CH_{3}CO)_{4}$ , m.p.  $242^\circ$ – $244^\circ$ C.

When coccinin was oxidised by means of air, or oxygen, in alkaline solution (6 p c NaOH), the colour changes above described occurred, and when the pure violet colour had been obtained, acidification with hydrochloric acid yielded a substance coccinone, C<sub>17</sub>H<sub>12</sub>O<sub>7</sub>, which forms dark brown glistening crystals and decomposes at 250°C; it yields a tri-acetyl derivative, C<sub>17</sub>H<sub>19</sub>O<sub>7</sub> (CH<sub>3</sub>CO)<sub>3</sub>, orange-red crystals, m.p. 210°C, and also forms three different barium salts (one of which has a composition analogous to the sodium hydrogen salt of 2.6-dihydroxyles-methyl-a-naphtho-quinone-3:5-dicarboxyles-dickled coccinines in the content of the other hand, alkaline oxidation by means of hydrogen peroxide below 20°C, gives rise to two products, (1) cochenilic acid, and (n) an unexamined acid

Dimroth now formed the opinion that coccinin and coccinone are derivatives of anthranol and anthraquinone respectively, and the position of one of the hydroxy, methyl, and carboxyl groups in coccinone is made clear by the production from it of cochenillic acid. To coccinone Dimroth ascribes the structure—

and to coccinin either the structure-

or

When heated with water at 200°—or dilute sulphuric acid at 170°C.—coccinone loses carbon dioxide, yielding decarboxy-coccinone to which the structure-

is given, it forms red-brown crystals, and dissolves in alkalis to form purple red solutions and in concentrated sulphuric acid with a blue colour which becomes violet on addition of boric acid

Not only coccinin, but carminic acid itself, has been further examined by Dimroth (loc cit.), and as a result he considers that this substance is also a derivative of anthraquinone He has oxidised carminic acid by means of hydrogen peroxide in aqueous caustic soda, using cobalt sulphate as catalyst, and in this way obtained in the first instance carminoquinone, but the reaction proceeded further with the formation, after acidification with 80 pc acetic acid, of a yellow crystalline compound, C<sub>26</sub>H<sub>13</sub>O<sub>16</sub>Na<sub>3</sub>, 5H<sub>2</sub>O, which, when triturated at 0°C. with dilute hydrochloric acid, yielded 2 · 6-dihydroxy-8-methyl-a-naphthoquinone-3 5-dicarboxylic acid. pale yellow, hygroscopic crystals-

trisodium salt. C<sub>13</sub>H<sub>5</sub>O<sub>8</sub>Na<sub>3</sub>,4H<sub>2</sub>O, orange needles

The orientation of this acid has been established by Dimroth by comparison of its colour reactions with those of 2 6-dihydroxy-anaphthoquinone, synthetically prepared by Dimroth and Kerkovius, as also by its conversion into carminazarin by treatment with acid permanganate Moreover, the structure previously assigned by Dimroth to carminazarin, viz 2:3:6-trihydroxy-8-methyl-a-naphthoquinone-

5-carboxylic acid, has been supported by conversion of carminazarin-quinone—the oxidation product of carminazarin—into a diphenazin,  $C_{24}H_{14}O_3N_4$ , by treatment with an alcoholic solution of o-phenylene-diamine. The product

crystallises in yellow needles, and yields an acetyl derivative,  $C_{26}H_{16}O_4N_4$  When 2 · 6-dihydroxy-8-methyl- $\alpha$ -naphthoquinone-3 : 5-dicarboxylic acid—the oxidation product of carminic acid referred to above—is warmed with water, carbon-dioxide is eliminated with the production of 2: 6-dihydroxy-8-methyla-naphthoquinone-5-carboxylic acid: brown-yel-

low needles-

potassium salt, C12H2O6K, lemon-yellow crystals; dipotassium derivative, C12H6O6K2, orange-red crystals.

This compound when brominated in glacial acetic acid at 40° yields a monobrom derivative, yellow needles, m p. 240°-244°.

which on treatment with hydrobiomic acid yields a-bromo-carmin, whilst with bromine in cold methyl alcohol, the product is \$\beta\$-bromocarmin (Will and Leymann), which proves that this body has the structure

assigned to it by Miller and Rohde.

Beyond the above-mentioned decomposition products of carminic acid, Dimioth has obtained a 5 pc yield of hydrocarbons of the anthracene series by distillation with zinc-dust in an atmosphere of hydrogen After · oxidation of the mixture of hydrocarbons he isolated anthraquinone, and possibly a-methyl-anthra-

By treatment of carminic acid with boiling dilute sulphuric acid, Dimioth has also obtained a 10 pc yield of trihydroxy-methylanthraquinone carboxylic acid (C16H10O7), needles, melting-point above 300°, and this acid when heated with water at 230°-240°, passes into trihydroxy-methyl-anthraquinone by loss of carbon dioxide.

Dimroth considered the possibility that the anthraquinone nucleus is produced during the reactions described above, but concluded that this is not the case, and that it is present as such

both in carminic acid and coccinin. Dimroth formulates carminic acid thus—

$$C_{22}H_{22}O_{13} = HO \longrightarrow \begin{pmatrix} CH_3 & O \\ OH \\ OH \\ OH \\ OH \end{pmatrix}$$

On the other hand, C and H. Liebermann (Ber 1914, 47, 1213) bring forward arguments, chiefly the smallness of the yield of anthraquinone or anthracene derivatives obtained by Dimroth, in favour of the view that the anthracene nucleus is formed during the degradation reactions.

These authors have also re-examined the 'ruficoccin' of Liebermann and van Dorp (see above), and conclude that it consists of a mixture of trihydroxy-methyl-anthraquinone carboxylic acid, and trihydroxy-methyl-anthraquinone, which is confirmation of the work of Dimroth. Incidentally they described carmine anhydride,  $C_{22}H_{20}O_{12}$ , prepared by heating carmine acid with thionyl chloride—vivid red powder, resembling carminic acid, though less soluble It is reconverted into the latter by the action of aqueous alkalis.

Technical Preparations of Cochineal -Ammoniacal Cochineal - When a solution of carminic acid in ammonia is allowed to stand for some time, there is formed a new compound, which appears to consist of carminic acid in which one of the hydroxyls has been replaced by an amino group The formula assigned to this substance by Schutzenberger was C. H. NO. This reaction, long known, has been utilised for the production of a new colouring matter termed ammoniacal cochineal, or carminamide, and this comes into commerce either as cakes or in the form of a paste

The first variety is usually prepared by allowing one part of cochineal to stand in a closed vessel for three months with three parts of ammonia. The clear liquid is decanted, treated with about half its weight of gelatinous alumina, evaporated, and when the mass has become thick, it is cut up into cakes and dried

The paste is manufactured in a somewhat similar manner, the ammonia, however, being only allowed to react for eight days. The clear liquid is then evaporated to about one-third its bulk without addition of alumina (Crookes, Dyeing and Calico Printing).

Ammoniacal cochineal dyes much bluer shades than cochineal itself, and it is sometimes employed in conjunction with the latter. Its use is now very limited, but it finds some application in the blueing of bleached cotton

Dyeing Properties of Cochineal—Cochineal has been little employed in cotton dyeing, but was very largely used in silk and wool dyeing It has now been practically replaced by the azo-scarlets.

Two shades of red are obtained upon wool with cochineal, namely, crimson, which is produced by means of aluminium sulphate, and a very fiery scarlet, for which stannous and sometimes stannic chlorides are employed

For crimson, wool is mordanted with aluminium sulphate and tartar, and is then dyed

Dimroth in a separate bath with cochineal. The employment of calcium salts in the dyeing operation is not beneficial. Fairly good shades of crimson can also be obtained by mordanting and dyeing in a single bath with aluminium sulphate, oxalic acid, and cochineal For scarlet, wool can be mordanted with stannous chloride and tartar, and dyed in a separate bath with cochineal. single-bath method, employing stannous chloride, oxalic acid, and cochineal, has, however, been very largely used for this purpose On the other hand, preparations of stannic chloride, known as 'tin spirits,' 'scarlet spirits,' and 'nitrate of tin,' are and have been much employed by division of stannic chloride. ployed by dyers of cochineal scarlet. Though, when used alone, stannic (hloride does not give such brilliant shades as the stannous mordant, a mixture of both is considered to be beneficial. For very yellow shades of scarlet, yellow colouring matters can be added to the cochineal dyebath, and of these 'flavine' has been employed to a considerable extent

> Cochineal red on wool possesses considerable fastness to light, but has the defect that weak alkalis and soap cause it to acquire a duller or more bluish shade

> Wool mordanted with potassium dichromate gives with cochineal a good purple colour, whereas with ferrous sulphate and tartar, purplish, slate, or lilac colours can be produced. These mordants, however, are not employed in practice. A good erimson shade is produced by mordanting silk with alum, and dyeing with an extract of cochineal. In scarlet dyeing, silk is preferably first dyed yellow, then mordanted with 'intromuriate of tin,' and finally dyed in a second bath with the assistance of cream of tartar. Silk can also be dyed in a single bath with cochineal, stannous chloride, and oxalic acid.

COCHINEAL CARMINE v. Lakes. COCHINEAL RED, SCARLET v Azo- col-OURING MATTERS.

cochineal wax and FAT. The wax is obtained by extracting the cochineal with benzene, and consists almost entirely of a substance to which Liebermann gave the name coccern. After the removal of the coccern, the fat is extracted with ether; it consists of myristin and an oil containing fatty acids. The following are the percentages of coccern in various samples of cochineal (extracted whole with benzene):

Silver cochineal . 1.0 p c

Mexican silver cochineal . 1.7 ,,

Teneriffe silver cochineal . 2.0 ,,

Zaccatille . . . 0.5 ,,

Teneriffe black cochineal . 0.7-1.0 ,,

Mexican black cochineal . 1.5 ,,

Granilla . . . 4.2 ,,

By powdering the cochineal before extraction, the percentage is increased by about one-half, except in the case of Granilla, where the granules are exceedingly small. The percentage of myristin is on the average about 15-20, and of fluid fat and fatty acids 4.0-60, so that the average total quantity of wax and fat contained in a silver cochineal is about 12 p.c. After recrystallising from benzene or acetic acid, coccern forms thin glistening plates of meltingpoint 106°. It is sparingly soluble in all cold

COCOA. 309

solvents, and nearly involuble in alcohol and ether. It has the constitution  $C_{30}H_{60}(C_{31}H_{41}O_3)_2$ . On saponification with alcoholic potash, it gives cocceryl alcohol  $C_{30}H_{60}(OH)_2$  and coccerc acid  $C_{31}H_{62}O_3$ . The alcohol forms a white crystalline powder of mp  $101^\circ-104^\circ$  The acid melts at 93°, and is soluble in hot alcohol, benzene, &c; its ethyl ether melts at about 70°. The myristin  $C_3H_5(OC_{14}H_{27}O)_3$  forms colourless crystals of mp  $55^\circ$ , easily soluble in warm alcohol, &c; on saponification it gives glycerol and myristic acid  $C_{14}H_{25}O_2$  of mp.  $54^\circ$ , and b p.  $248^\circ$  at 100 mm (J Soc Chem. Ind 4, 585).

COCHINEALIC ACID v COCHINEAL

COCINIC ACID v. Hendecatoic acids. COCOA. The cocoa tree is an evergreen shrub, indigenous to Mexico and the tropical regions of Central America, whence it was introduced into Europe by the Spaniards. It belongs to the natural order Sterculaceæ, and comprises several species, that most highly valued and cultivated being the Theobroma cacao, so called by Linnæus, from  $\theta\epsilon \delta s$  (god) and  $\beta\rho\hat{\omega}\mu\alpha$  (food), in allusion to the esteem and almost veneration in which the beverage of Čentral America, and 'cacao,' the name by which it was originally known. The seeds were

used as a kind of money even down to the time

of Humboldt's visit to Mexico.

The tree grows to a height of from 12 to 40 feet, the average being about 25 feet, but in plantations it rarely exceeds 18 feet. It flourishes best in a moist and warm climate, in latitudes between 25° north or south of the equator, and at altitudes up to 1000 feet. It is now cultivated more or less extensively in Brazil, Caraccas, Central America, Ecuador, Essiquibo, Grenada, Guayaquil, Peru, Trinidad, Venezuela, and in the West Indies (particularly Jamaica, Dominica, and St Lucia); also in Ceylon, the East Indies, the Philippines, Mauritius, Madagascar, San Thomé, Gold Coast, Cameroons, and to some extent in Australia

The cocoa tree begins to bear fruit when 3 years old, and attains its full productiveness when 7 or 8 years old, but a healthy tree will bear for 40 or 50 years. Fruit is produced all the year round, but harvesting usually takes place only twice a year—from February to April, and again in October and November.

The fruit consists of an elongated pod, in shape between a melon and a cucumber, measuring from 5 to 12 inches in length, and from 2 to 4 inches in diameter, with a thick pericarp varying in colour from yellow or red to purple, according to the variety. There are from 20 to 40 or more seeds in a pod (though the number is smaller in the West Indian varieties) arranged in 5 longitudinal rows, and embedded in a rose-coloured mucilaginous pulp fresh they are usually white (some varieties purple), and have a bitter taste, but after drying and exposure to the air and light they acquire a yellow, red, or brown colour, and become hard, brittle, and less bitter They are ovate, compressed, and about the size and shape of harroot beans or olives.

After removal from the pods, the seeds or beans are either freed at once from adhering pulp and dried in the sun (or occasionally by artificial means), to produce 'unformented'

cocoa,' or they are removed to the 'sweating' or curing house to undergo a process of fermentation before drying Unfermented cocoa is distinguished by its pale skin, which separates with difficulty from the kernel Owing to its bitter taste, it is suitable only for use in cocoa mixtures containing starch and sugar. It is quite unfit for chocolate making, and commands a lower price than fermented cocoa.

To produce fermented cocoa, the beans were formerly buried in the ground, or in trenches covered with plantam leaves, but in order to avoid the consequent adherence of earthy matter, they are now generally buried in casks or boxes, or heated in piles in sheds, and turned over once or twice daily. The temperature rises considerably during fermentation, and the process requires great care and skill, as on it the commercial value of the finished beans chiefly

depends In the fermentation—for which the optimum temperature is 35°-40°-alcoholic fermentation is succeeded on the second or third day by acetic fermentation; during the subsequent drying, oxidation of the astringent constituents The market value of the seeds varies occurs inversely as their tannin content When the seeds contain over 20 pc of moisture butyric fermentation often occurs and causes mouldiness Oxidation is most rapid at 50°-60°, but must not be allowed to proceed too far, or loss of aroma occurs For observations on the fermentation of cocoa, see Brill, J. Soc. Chem Ind 1917, 36, 1245

The objects arrived at in the 'sweating' operations are the loosening of the adherent pulp, the removal or modification of the bitter principle, the development of an agreeable aromatic odour, and the colouration of the beans to a rich mahogany tint. The fermentation process generally lasts from 2 to 7 days. In some parts, as Trinidad and Jamaica, red earth is often employed to assist in the removal of the mucilage from the beans, which are afterwards rubbed clean and dried. Occasionally Venetian red is used to impart a uniform red tint to the finished beans.

As the fermentation process produces considerable change in the composition of the nibs it has recently been replaced by treatment with a 1 p c solution of sodium carbonate for 10 minutes at 45°, whereby the beans are 'stabilised' and sterilised. Cocoa prepared in this way is perfectly stable, and contains no pre-formed sugar. Theobromine is not present in the free state, but is formed together with sugar and tannin by hydrolysis (v infra).

In the drying operation the beans are spread out in trays and systematically turned so as to expose every part of the bean to the light, and, when thoroughly air-dried, are in a suitable

condition for shipment

The preliminary processes of manufacture consist in (a) sifting out sand, dust, and small stones; (b) picking out by hand the empty beans and foreign matter, as larger stones, grass, wood, &c; (c) roasting; and (d) cleaning, by breaking up the beans and removal of the husks or shells. Berhardt (Chem. Zeit. 1889, 32) has found, from the results of actual factory work, that the losses in these operations amount to 2 or 3 pc in sifting; nearly 1 p.c. in picking; about

310 COCOA.

5 p.c. in roasting; and 12 or 13 p.c. in cleaning, making a total loss of over 20 p c.

The roasting process, which requires great care, skill, and experience on the part of the operatives entrusted with it, is conducted in rotating cylinders heated by coke fires or by means of superheated steam in pipes lining the cylinders, to a temperature varying from 500° to 600°F (160° to 315°C.) Uniformity of roasting is facilitated by grading the beans in the same operation to a uniform size. The beans are then cooled, gently crushed in a 'kibbling mill,' to fracture the crisp husk and break down the kernel into its natural angular fragments or 'nibs,' after which the nibs, husks, and hard rod-shaped germs are separated by winnowing and sieving, and the nibs graded into different classes according to size

The object of roasting is to develop to the fullest extent the characteristic aroma and flavour of the cocoa. This is probably due to the development of a volatile principle in the nature of an essential oil, somewhat analogous to the caffeol of coffee (v. infra, Coca-red)

The roasted husks or shells constitute on an average about 12 or 13 p c of the weight of the whole bean, varying from 7 or 8 p.c. in the thin-walled beans of Ceylon and Java to 18 p c in those of Trinidad and the West Indies, which The shells form a have a much thicker shell low-priced product extensively used, after grinding, in the cheaper grades of cocoa and chocolate, and occasionally, under the name of 'cocoa tea,' as a beverage which has the taste and flavour of weak cocoa Cocoa shells have proved to be a useful addition to feeding stuffs, especially for milch cows, and gave good results on the experimental farms of Canada when used as manure. (For analysis of cocoa shells, see table below)

The nibs enter into commerce as such, but although in this form the consumer may be assured of the purity of the article, yet, owing to the large proportion of fat in them (about half their weight) and the difficulty of disintegrating them even by boiling water, they are hardly suitable for popular use as a beverage.

For the manufacture of the various forms of prepared cocoa, the nibs are ground by means of millstones or steel mills so constructed as gradually to reduce the cocoa to the finest and smoothest possible condition If the cocoa is to go into consumption as ground nibs in powder, the stones or rollers are kept cool during the operation, but if, as is usual, the ground cocoa is afterwards to be made up into any of the numerous forms of prepared cocoa or chocolate, the stones or rollers are usually kept heated during the grinding. This causes the fat to melt, and the whole is reduced to a liquid mass, which is run into moulds and cooled so as to form blocks, which are sold as such or kept as stock for subsequent conversion into prepared cocoa or chocolate

The leading types of manufactured cocoa are flake cocoa, rock cocoa, and cocoa powders sold under such names as 'soluble' cocoa, and 'extract' or 'essence' of cocoa. Flake cocoa is prepared simply by grinding the whole beans or the nibs only in steel mills somewhat resembling those used for grinding coffee Rock cocoa is

made in the form of a paste by grinding in a mill with heated stones or rollers, and with the addition of sugar and starch.

The admixture of starch or other gelatinising substance tends to mask the presence of the fat and to render the cocoa more readily miscible with boiling water. These mixtures, sold under such names as 'homeopathic,' 'Iceland moss,' &c., are frequently described as 'soluble cocoa,' but this is a mismomer, since the absence of a sediment in the cup is due, not to solution of the cocoa, but to the formation of an emulsion, which holds the cocoa in a finely divided state suspended in the liquid. In some of these, as 'granulated cocoa,' 'cocoatina,' &c, sugar is added as well as starch.

The large proportion of fat (about 50 pc), being found by many to be difficult of digestion, is reduced in preparations intended for use as a beverage, not only by the addition of sugar and starch (which incidentally reduces the proportion of cocoa present), but also by the actual abstraction of fat to form the so-called 'essence' or 'extract' of cocoa

The partial extraction of the fat is accomplished by submitting the pure cocoa paste enclosed in strong canvas bags to a pressure of 1200-1400 lbs per square inch in hydraulic presses heated to 70°-80°. The cocoa butter flows out through a special orifice, and is afterwards solidified into blocks or slabs ready for use in surgical and pharmaceutical preparations, for soap making, and in the manufacture of chocolate confectionery. The commercial value of cocoa butter just before the war was twice that of the raw bean, and this no doubt was an inducement to its removal, in addition to the alleged purpose of making the cocoa more directible.

digestible
To prepare the so-called 'essence' or 'extract' of cocoa, the cakes of compressed cocoa, now containing only about 25 pc of fat, are turned out in a nearly dry condition, and ground to a fine powder Some cocoa powders are said to be rendered more digestible by treatment with alkalis, which soften the cellulose tissue and act upon the fat so as to produce a more perfect emulsion than that obtained by other 'soluble' cocoas prepared with starch; also there is less tendency to separation of the melted fat in the cocoa bever-Another method is to soften the tissue by heating in closed vessels with or without water to a temperature of 150°. In some preparations, as 'solidified cocoa,' the fat is not removed, whilst as preparation of cocoa practically free from fat is obtained by extracting the roasted and ground beans with ether or benzene ordinary flavouring materials are vanilla and cinnamon, but other spices and artificial vanilla are occasionally used.

The principal constituents of cocoa are fat ('cocoa butter'), alkaloids, albuminoids, starch, tannin, cocoa-red, and mineral matter.

The fat, cocoa butter, or cacao butter, oleum theobromæ, is the principal food constituent of cocoa, and forms from 45-55 p c. of the husked bean It has a pleasant taste and odour, suggestive of chocolate At ordinary temperatures it is a yellowish-white, somewhat brittle solid, melting below the temperature of the body, viz 28°-33°, and solidifying at 21°-23°;

COCOA. 311

sp gr. from 0.95 to 0.97 at 15°, and 0.856 at 100°; rodine number from 33 to 38; saponification value, 193-195; refractometer reading (Zeiss) at 40° is 46-478; and index of refraction, between 1.4565 and 1.4578 at 40°. It is readily soluble in ether, chloroform, turpentine, and boiling alcohol, from which it crystallises out almost completely on cooling Chemically, it is a mixture of the glycerides of stearic, palmitic, oleic, and arachidic acids (Benedikt, Analyse der Fette und Wachsarten). It is sometimes adulterated with such substances as coco-nut oil, cotton seed, and sesamé oils, stearin, tallow, and paraffin way Illipé oil is often used as a substitute for cocoa butter (which it closely resembles in certain respects) in the manufacture of chocolate

Alkaloids — Theobromine C<sub>5</sub>H<sub>2</sub>(CH<sub>3</sub>)<sub>2</sub>N<sub>4</sub>O<sub>2</sub>, or dimethylxanthine, is the principal alkaloid in cocoa, and is closely related to the alkaloid of tea and coffee, caffeine (trimethylxanthine), which is also present to a small extent in cocoa Theobromine crystallises in white microscopic needles, having a bitter taste, and is present in cocoa to the extent of about 15 pc The published analyses show variations from 0 4 to 3 3 p.c., due to the different methods of analysis employed. One of the best methods is that of Decker, as modified by Welmans and Fromme (Pharm. Zeit 47, 789, and 858; and Apoth Zeit 18, 68) The caffein is usually included with the theobromine, from which, however, it can readily be separated by means of cold benzene, in which caffeine is soluble, but theobromine practically insoluble The amount of caffeine varies from 0 1 to 0 3 p c. (see art. Theorrowine).

According to Kreuz, the proportions of theobromine hithorto shown in published analyses represent only free theobromine. He maintains that part of the alkaloid is combined and is not extracted until the cocoa has been subjected to hydrolysis By this method Kreuz found from 2 8 to 5 1 p c. of theobromine in cocoa beans (Zeitsch. Nahr. Genussm. 1909, 17, 526-7).

Albuminoids.—These have been but little studied, but Stutzer (Zeitsch. angew. Chem

1891, 368) has classified the nitrogenous constituents of cocoa as follows:—

(1) Non-proteids, substances soluble in neutral water solution in presence of coppes hydroxide (theobromine, ammonia, and aminocompounds)

(2) Digestible albumen, insoluble in neutral water solution in presence of copper hydroxide, but soluble when treated successively with gastric juice and alkaline pancreas extract

(3) Insoluble and indigestible nitrogenous substances

According to Stutzer's analyses, the proportion of albuminoids in cocoa powder manufactured without chemicals is between 17 and 18 p.c., of which 10 p.c. is soluble or digestible albumen, the remainder (over 40 p.c. of the whole) consisting of insoluble and indigestible substances. Forster, however, maintains that the proportion of digestible albuminoids reaches as high as 80 p.c., his experiments being made on the human subject, whilst Stutzer's were conducted under laboratory conditions (Hyg. Rundschau, 1900, 314)

Starch, as in oleagmous seeds generally, is not very abundant. It has been variously estimated from 2 to 20 pc of the nib, but many of the results are too high, owing, no doubt, to the conversion of cellulose into sugar when the acid method for the starch conversion is employed. The diastase method is preferable in the presence of cellulose. The average amount of starch is from 4 to 5 pc, or about 8 pc calculated on the fat-free bean. The starch grains are nearly spherical, with a very indistinct nucleus. They have a tendency to unite in small groups of 3 or 4, and rapidly lose the colour imparted by ioding. The average size is about 0.005 mm.

Tannin —An astringent principle resembling tannin exists in the raw bean, but, according to Mitscherlich and Bell, it is rapidly oxidised to 'cocoa-red,' to which the characteristic colour of cocoa is due Bell (Foods, 1 79) states that this astringent principle is different from the tannin of tea and coffee, and that its rapid change to cocoa-red, even during the process of analysis, renders its quantitative estimation difficult. It is precipitated by basic acetate of lead, and can be obtained after removal of the lead by sulphuretted hydrogen. It gives a green precipitate with ferric chloride not unlike caffeic acid under similar treatment.

Cocoa-red is not present in the fresh seeds, which are nearly white, but arises from the oxidation of the natural tannin of the seed. It consequently appears in different quantities in different kinds of cocoa. On hydrolysis it decomposes into glucose, tannin, and a resinous substance. By many the peculiar taste and aroma of cocoa are associated with the formation of cocoa-red, which increases in amount during the process of fermentation, drying, and roasting, simultaneously with a corresponding increase in flavour, thought to be due to the development of a volatile principle or essential oil. Details of methods for its extraction and estimation are given in Zipperer (Die Schokoladen Fabrikationen) and Blyth (Foods).

tionen) and Blyth (Foods).

Mineral matter—The ash in cocoa nibs varies from 2 5 to 4 5 p.c., the average, according to Zipperer, being 3 6 p c. in raw, and 3 9 p.c. in

312 COCOA.

the roasted kernels. The shells contain two or three times this amount. Approximately half the ash (which is rich in potash and phosphates) is soluble in water. The ash is naturally lower than the average when starch or sugar has been added, and higher when fat has been abstracted, or when the cocoa has been adulterated with husks or coloured with pigments The shell is rich in alkaline carbonates and silica as compared with the nib A high alkalinity in the ash of cocoa powders indicates treatment with alkalis as described in the preparation of the so-called 'soluble' cocoas The composition of the ash of cocoa nibs and husks is shown in the table given below.

Whilst cocoa ranks higher than tea or coffee as a nutritious beverage, its value as a substitute for solid food has been greatly exaggerated. In its content of alkaloid and tannin substances, it stands midway between tea and coffee, and, like them, it should be considered a stimulating beverage rather than

a true food.

The tables on p 313 will serve to show the composition of cocoa nibs, shells, the ash, and

several kinds of commercial cocoas

Adulterants —Besides sugar and starches (which have come to be considered as essential ingredients of certain proprietary cocoa preparations), the usual adulterants are foreign fats (particularly coco-nut oil) to replace the abstracted cocoa butter, farmaceous substances, ground cocoa shells, and pigments such as ferric oxide, ferruginous earth, &c For the estimation of cacao shell, see Knapp & McLellan, Analyst, 1919, 2, which contains a bibliography on the subject

COCO-NUT OIL GROUP. Under this heading is grouped a number of vegetable fats which differ from all other vegetable fats by having high saponification values in conjunction with high Reichert-Meissl values The considerable proportion of volatile fatty acids which the fats belonging to this group contain, brings them into relationship with the milk fats of mammals. They differ essentially from the latter, however, in that they do not contain any The high proportion of volatile butyric acid fatty acids contained in the members of these groups differentiates them from other fats which are also characterised by high saponification values, but do not contain volatile acids.

The fats belonging to the coco-nut oil group are the following: (a) Muriti fat, from Mauritia vinifera (Mart); Acrocomia vinifera (Oerst);
(b) mocaya oil, from A sclerocarpa (Mart); Cocos sclerocarpa, C. aculeata (Jacq); Bactris minor (Gart); (c) cohune oil, from Attalea cohune (Mart), (d) maripa fat, from Palma (Attalea) maripa (Aubl), (e) aouara-kernel oil, from Astrocarpum vulgare (Mart); (f) palm-nut oil, from the kernels of Elons gumeensis (Linn; Jacq); (g) coco-nut oil from Cocos nucifera (Linn) and Cocus butyracea (Linn); (h) fat from Cocos acrocomordes.

It may be pointed out that aouara-kernel oil and palm-nut oil differ considerably from the corresponding fats contained in the fruit flesh surrounding the seeds (see Palm oil)

All these fats are derived from trees belonging to the palm family The two most important

latter will be described subsequently (v. PALM KERNEL OIL).

Coco-nut oil is the fat obtained from the kernels of the coco-nut, especially from those of the two species Cocos nucifera (Linn.), and C buturacea (Linn).

Cocos nucifera grows on all coasts and islands of the tropics; in fact, it may be considered a cosmopolitan of the tropical coast-lines in both hemispheres. The coco-nut tree is indigenous to the islands of the Malayan Archipelago, whence the nuts were carried by sea currents towards the east to the Pacific Islands and the coasts of ('entral America, and towards the west to Ceylon and the east coast of Africa.

Being well protected by the 'coir' (fibres), the seeds are able to germinate on all shores (islands and even coral reefs) where they may be

deposited.

The coco-nut tree forms large forests, especially on the coast-line of Ceylon, Java, and the Philippines. On account of its manifold uses, the tree has been cultivated early in the history of mankind, and the fruits were, therefore, gathered, as it were, on a commercial scale, not only in the localities named, but also in the South Sea Islands, Madagascar, Mauritius, Ceylon, Zanzıbar, the east and west coast of Africa, the Antilles, and the coast-lines of tropical South America

Cocos butyracea is indigenous to Brazil, and yields, together with Cocos nucifera (as also with the other cocos species mentioned above), the chief quantities of coco-nut fats which are consumed locally The coco-nut oil which is exported to Europe is mainly derived from

Cocos nucrfera

The coco-nut tree flowers when about 6 or 7 years old, and begins to bear fruit from an age of 8 years up to an age of 60 years. The nuts contain a fleshy endosperm, built up from a The nuts milky juice, rich in oil At the period of maturity of the fruit the milky juice has disappeared almost completely, and the endosperm forms the well-known coco-nut kernel, inside which the remainder of the milky juice, coco-nut milk, The kernel contains from 30 to is enclosed 40 pc of fat, and about 50 pc of moisture

Since the earliest times in the history of mankind, the kernels have been used by the natives of the South Sca Islands, and especially of India, as one of their chief articles of food. The mode of preparing the oil, as practised centuries ago, was of the most primitive kind The kernels were cut into small pieces and exposed in piles to the sun, when the oil would run off spontaneously Improved methods consisted in converting the kernels into pulp, placing the latter in vessels perforated with holes, and exposing them to the sun, when the oil would run through the holes. The oil was then collected and carried in bamboo sticks to the market, a practice which up till a few years ago still obtained in the outlying parts of the Philippines. In order to render the process independent of the heat of the sun, as in the rainy season, the kernels were, at a later stage of evolution laid on hurdles, formed from bamboo staves and coco-nut leaves, and dried over a slow fire, the fuel for which was derived from the shell of the kernels. In India, where fats are coco-nut oil and palm-kernel oil. The the nuts became at an early date an extensively

used food product, the nuts were split into | dried kernels were then triturated and expressed, halves by a blow with a sharp instrument, the coco-nut milk was poured off, and the halves exposed to the sun to dry, whereby the kernels became readily detachable from the shell. The used as cattle food ('coco-nut poonac') This

process was carried out with special care at Cochin and the coast of Malabar. Hence the reputation of Cochin coco-nut oil for best quality has been maintained to this day.

As large proportions of moisture left in the kernel readily lead to putrefaction, a further step in the preservation of the fat was found in drying the kernels thoroughly, so as to remove the bulk of the water. The absence of moisture rendered the growth of fungi impossible, and thus prevented excessive hydrolysis and subsequent rancidity. The process of producing the dried kernel—copra—developed into a manufacturing process.

Coconut oil became first known in Europe in the 18th century, but was not imported in any notable quantities before the year 1820. At present three qualities of oil are distinguished in commerce (1) Cochin oil; (2) Ceylon oil,

(3) Copra oil.

(1) Cochin oil represents the finest and whitest quality, and, is obtained as stated above, by boiling the kernels with water and

skimming off the oil.

(2) Ceylon oil is prepared in a similar manner in the plantations of Ceylon. This oil is not of such high quality as Cochin oil, owing mainly to the want of care on the part of the natives, as compared with that exercised by the natives of the Malabar coast. Hence Ceylon oil represents, as a rule, a second quality of coco-nut oil, and is characterised by a somewhat higher percentage of free fatty acids than is found in Cochin oil. At present, however, in some plantations in Ceylon, managed by Europeans, the same care is exercised as in Cochin, and some brands of Ceylon oil are now imported which yield little in quality to Cochin oil

(3) Copra oil is the oil prepared in modern factories in Europe, United States, Australia, from copra (i.e. the dried kernels), which are imported in enormous quantities into these countries. The conversion of the kernel into copra must not only be looked upon as a convenient method for reducing the cost of freight, but, as pointed out above, is pre-eminently a cheap process for preserving the coco-nut oil

as far as possible

In the Manila market copra oil is sold as 'Cebu sun-dried,' 'fair marketable Manila,' and 'Laguna,' but the distinction between the

different grades is not well marked

At present great care is bestowed on the preparation of copra, it is used in growing proportions for the production of edible coco-nut oil (see Edible oils), and coco-nut stearin (see CHOCOLATE FATS) In commerce we differentiate 'sun-dued copra' and 'kiln-dried copra' The sun-dried copra was considered the better quality, as it gives a white coco-nut oil, with only a slight yellow tinge, and could be readily converted into an edible oil Kiln-dried copra is obtained by a more rapid process, the kernels being dried over a bamboo grating heated by burning underneath it the shells. In these primitive kilns, the fumes obtain ready access to the copra itself, and not only burn it occasionally, but impart to the copra a peculiar empyreumatic smell and a dark colour Hence copra thus dried yields a yellowish oil which proves refractory in the refining process. At present, however, notable improvements are being

introduced in the kiln-drying process (rotary driers, vacuum driers), so that it may be expected that in the near future kiln-dried copra will take its place next to, or rank equally with, sun-dried copra. Sun-dried copra contains on an average 50 pc of fat; in kiln-dried copra the percentage rises to 63 and even 65 pc. Copra dried by means of hot air contains even as much as 74 p.c.

Its acidity (as oleic acid) should be less than 1 p.c. By reducing the amount of moisture to about 6 p c immediately after opening the nuts the action of moulds is checked and a better

yield of oil of good quality is obtained

The copra is treated in oil mills in a similar manner to that in which oleaginous seeds generally are worked up. The meal is expressed twice at a temperature of 55°-60°. The practical yield varies from 63 to 66 p.c., according the content of oil in the copra. The expressed oil contains a notable quantity of free fatty acid, the amount depending on the quality of the raw material

Copra press-cake is used for fertilisers and feeding-stuffs for cattle, but by separating the oil by appropriate methods a press-cake suitable for human food may be obtained. A meal suitable as a substitute for wheat flour and laid in pastry had the following composition: water, 7.35, oil, 32.14, ash, 4.05, crude fibre, 37.12; and proteins 20.34 p.c. (Parker and Brill, Philippine

J Sci, 1917, A, 12, 87)

In our climate coco-nut oil is, at the ordinary temperature, a solid white fat of bland taste, having the peculiar, though not unpleasant, odour of coco-nut. The odorous substances in coco-nut oil consist chiefly, according to Haller and Lassieur (Compt rend 1910, 151, 697), of methylheptylketone and methylnonylketone These two ketones, together with certain undefined volatile substances, are removed in the process of refining coco-nut oil for edible purposes. In order to obtain coco-nut stearin (chocolate fat), the liquid glycerides are removed by expression in hydraulic presses, when 50-80 pc of the liquid glycerides are expressed Inferior copra oils also are frequently subjected to the same process, and thus a commercial coconut stearin is obtained, which, on account of impurities, can only be employed in the manufacture of composite candles and night-lights The lower qualities of coco-nut oil are used in enormous quantities in the manufacture of soap, whilst the best grades are used for margarine

Coco-nut oil contains large proportions of myristin and, especially, of laurin, small quantities of palmitin, stearin, and triolein, and of

caprin, caprylin, and caproin.

Elsdon (Analyst, 1913, 38, 8), using the method of alcoholysis, found coco-nut oil to contain glycerides of the following fatty acids in approximately the proportions named: caproic, 2, caprylic, 9; capric, 10; lauric, 45; myristic, 20; palmitic, 7, stearic, 5; and oleic acid, 2 p.c. Methods for the detection of coco-nut oil in butter are based on the large proportion of lauric and myristic acids in the fat (Shrewsbury and Knapp, Analyst, 1910, 35, 385; 1912, 38, 3).

The saponification value of coco-nut oil lies between 246 and 260; the Reichert-Meissl value

of the oil is 7-8; its iodine value about 8-10; and its Hehner value 88 to 90 Owing to its peculiar chemical composition, coco-nut oil is not readily saponified by weak caustic leys. It requires for saponification alkaline leys of high strength, which, however, so easily convert it into soap, that it is only necessary to stir the fat and caustic alkali together at 30°-35°, and allow the mixture After a short time saponification takes place, with liberation of heat (Soapmaking by the 'cold process.') Soaps so formed are very hard, and combine with a large amount of water without becoming soft The soaps are further distinguished by their remarkable property of requiring large quantities of salt to throw them out of their aqueous solution. Hence they are used as 'marine soaps'

COCOSITOL v Inositol. CODAMINE v Opium CODEINE v OPIUM

CODEONAL. Trade name for a mixture of 1 part of medinal and 2 parts of codeine-veronal

COD LIVER OIL is obtained from the liver of the cod, Gadus morrhua (and of the dorsch, the young of G. morrhua, formerly considered a separate species, G callarius). The cod appears annually at certain times in enormous shoals on the coasts of the northern seas, chiefly on the coasts of Norway, Scotland, Newfoundland, the east of the United States and of Canada, the west coast of the United States and the coasts of Japan and Siberia The best-known and oldest fishing-grounds are those of Norway, where the fish make their appearance at regular

intervals of the year

In the early years of the manufacture of cod liver oil, the livers were heaped up in barrels and allowed to undergo a process of spontaneous putrefaction, whereby the liver cells burst and the oil exuded The oil so obtained was contaminated with decomposition products of the liver, and possessed that rank odour and nauseous taste with which even nowadays popular prejudice associates medicinal cod liver Of late years the manufacture of cod liver oil has been carried out in a scientific manner, and the best oil is at present obtained by steaming the livers in the freshest state obtainable The livers are washed immediately they are taken out of the body of the fish, and are placed in jacketed vessels in which they are heated to a temperature of 70°-80°, when the cells burst and the oil flows off This oil is known as 'raw medicinal oil,' and is consumed as 'congealing oil' in those countries where the Pharmacopeia The British Pharmapermits congealing oils copœia prescribes, however, a non-congealing oil, which will not 'set' at the freezing-point is prepared by expressing the fresh liver at a temperature not exceeding 85°, cooling the crude medicinal oil below zero, and filtering it at a temperature of about - 5°. The 'stearme' is sold as fish stearm of best quality for soapmaking purposes All unsound livers, and those which have been exposed for some time to the atmosphere, are then worked up for brown oil.' This oil is, of course, a genuine cod liver oil, but is (or should be considered) unfit for consumption, and is mostly used up in leather industries, under the name 'brown cod oil 'or 'cod oil.

light yellow, and the best qualities have a slight fishy odour only, and a by no means unpleasant taste Such oil has a sp gr of about 0 922-0 93 at 15°, and a saponification value of 175-192, and an iodine value of 140-175. The best qualities have an iodine value of about 175, for the longer the livers have been exposed, the lower will be the iodine value, so that this value alone may indicate, preliminarily, a good medicinal oil. The chemical composition of the cod liver oil glycerides is not yet completely Small quantities of palmitin occur in the oil, and are the cause of the separation of 'steame' The older statement that small quantities of lower saturated fatty acids, such as those of acetic, butyric, valeric, and capric acids occur in cod liver oil must be rejected, these statements being due to the fact that the cod liver oil in which those volatile fatty acids were found had already undergone decomposi-The greater number of the liquid fatty acids in cod liver oil have not been identified. Among the unsaturated fatty acids there occurs undoubtedly therapic acid, this can be identified and isolated by means of its octobromide, C<sub>17</sub>H<sub>36</sub>O<sub>2</sub>Br<sub>8</sub>, which does not melt at 200°, and decomposes, with blackening above that temperature

Japanese cod liver oil has a similar composition to that of the European oil Specimens examined by Tsujinioto (Chem Rev Fett Ind. 1913, 20, 70) had sp gr 0.9263-0.9290, saponification value 183 8-188 l; and iodine value 159 1-160 8 The fatty acids yielded 34 4-

36 17 p.c. of therapic octobromide.

The therapeutic value of cod liver oil which was attributed to the organic bases occurring in badly rendered cod liver oil must (in the author's opinion) be ascribed rather to the easy manner in which cod liver oil is digested than to any specific constituent, for the purest cod liver oil practically represents a mixture of pure glycerides with a small amount only of cholesterol and other unsaponifiable substances.

Like all liver oils, cod liver oil may be identified by the colour test which it gives with concentrated sulphuric acid in a solution of carbon tetrachloride or carbon disulphide better the quality of cod liver oil the fainter is the sulphuric acid colour test, this points to the fact that the colour test is due to small quantities of foreign substances which are dissolved by the oil from the tissues of the liver This is borne out by the fact that when completely hydrogenated, cod liver oil no longer gives any colour reaction with sulphuric acid A specimen of such fully hydrogenated oil prepared by Man-nich and Thiele (Ber. deut Pharm. Ges. 1916, 26, 36) melted at 65°, and had iodine value 1.2, and saponification value 186 2

CŒLESTIN v. STRONTIUM

CŒLINE, CŒRULEAN BLUE, CŒRULEUM v. Cobalt; also Pigments

CŒRULEIN, Anthracene green (v Alizarin AND ALLIED COLOURING MATTERS).

CŒRULIGNOL C<sub>3</sub>H<sub>7</sub> C<sub>6</sub>H<sub>3</sub> (OH)OCH<sub>3</sub>. A colourless oil of a burning aromatic taste, and a smell resembling creosote, obtained from beech pine and fir tars. Boils at 240°-241°; sp gr. 1.0564 at 15°. It is somewhat soluble in water, toil or cod oil. freely soluble in alcohol, ether, and acetic acid, The pure medicinal oil is pale yellow or It is coloured red by sulphuric acid, and

dark-brown by potassium hydroxide in contact with the air In alcoholic solution it gives with barium hydroxide a characteristic deep-blue colouration. Ferric chloride in alcoholic solution gives a green, in aqueous solution a deepred, colouration Carulignol is decomposed on treating with hydrochloric acid at 145°, according to the equation

 $C_{10}H_{14}O_2 + HCl = C_9H_{12}O_2 + CH_3Cl$  **CŒRULIGNONE** (Cedriret)  $(CH_3O)_*C_6H_9 \cdot O \cdot O \cdot C_6H_9(CH_3O)_9$ 

A steel-blue crystalline solid obtained by oxidising pyrogalloldimethylether in acetic acid solution with potassium dichromate (Hofmann, Ber 11, 335) It combines with primary amines to give deep-blue dyestuffs (Liebermann and Flatau, *ibid* 1897, 234, Moir, Chem Soc. Proc. 1906, 110, 1907, 307) (v CEDRIRET).

COFFEE. The beverage known as 'coffee' is prepared from the seeds (dried, roasted, and ground) of Caffea arabica (Linn), an evergreen shrub, indigenous to North-East Africa, and The use of coffee has been known from time immemorial in Abyssinia, whence it spread to the neighbouring Mahometan countries (where its use was at various times forbidden as being an 'intoxicating' beverage), and subsequently to all parts of the civilised world lt did not find its way into Europe, however, until the beginning of the 17th century It was introduced into England in 1652, and rapidly spread in popular favour in spite of heavy taxation and attempts to suppress the 'coffee houses,' for political reasons, until its importation reached a maximum of 371 million lbs ın 1847 Since then the consumption has declined, due, no doubt, chiefly to the greatly extended use of tea, and partly to the introduction of coffee substitutes At the present time the consumption of coffee in the United Kingdom is less than 30 million lbs, or less than I lb per head In the principal coffeedrinking countries of the world the consumption of coffee per head of the population is as follows Holland, from 14 to 15 lbs , United States of America, 12 lbs , Scandinavia, nearly 12 lbs ; Germany, 7 lbs , and France, 4 lbs

· The coffee tree belongs to the natural order Cinchonacea, which embraces, according to Lindley and Paxton, two species, C arabica and C paniculata (Aubl.) Other botanists distinguish many other species, as C microcarpa, C umbellata, C acuminata, C subsessilis, C laurina, C. racemosa, C bengalensis, C indica, &c. Some of these are probably only varieties However this may be, four species distinct from each other are now grown. (1) Arabian or Mocha coffee, having short upright branches with a brittle leaf, and seeds usually single in the (2) Jamaica coffee, bearing longer and more phable branches, a tougher leaf, and seeds almost always double in the berries. (3) East India or Bengal coffee, of which the leaf is smaller than the Jamaica variety, and the berry (4) Liberian coffee (C liberica) is very small taller and has larger leaves and fruit than the preceding varieties, but owing to its coarse flavour, it was not until recently of much commercial use It has, however, rapidly attained importance on account of its hardy habit and

power of resistance to disease, and is now largely cultivated by grafting on to its stem the more delicate and highly esteemed Arabian coffee. Trees growing wild in the Cingalese jungle attain a height of 14–18 feet; but under cultivation and subjected to systematic pruning, the plant rarely exceeds 6–9 feet. Within the tropics the coffee tree succeeds best at 1200–3000 feet above the sea-level, but grows at a height of 6000 feet. When the mean temperature is about 70°, it may be grown as far as lat. 36°. It is cultivated in the West Indies, Mexico Central America, Brazil, and Cayenne, in Western Africa, Egypt, Mozambique, and Natal; in Arabia, India, Ceylon, Siam, Sumatra, Java, Celebes, and other parts of the Eastern Archipelago, Fiji, and the islands of the Pacific. At the present time more than three-quarters of the world's supply comes from Brazil

The coffee consumed in the United Kingdom comes principally from Costa Rica and British India as regards the finer qualities, and the

inferior grades from Brazil

The manner of forming plantations varies somewhat in different countries The surface soil should be good and the subsoil not too stiff. Perhaps the best soil is that known in Brazil as 'terra roya,' a topsoil of red clay 3 or 4 feet thick, with a subsoil of gravel Virgin forest land is as a rule found very suitable from wind is most important, and a wet soil is Steep slopes are unsuitable owing to sh The loss due to this cause should be fatal repaired by good manure, well-rotted dung and ground bones being the best The young plants may be reared in nurseries, whence they are transplanted to their permanent position, or they may be gathered out of the old plantations; the age at which this is done varies, as in Brazil where the shrub is usually two years old on its removal, or as in the West Indies where it is planted out at 6 months Fruit is produced in the fourth year, and continues to be gathered for several years

The tree blossoms and bears fruit practically all the year round, and the fruit takes about 4 months to upen. There is thus in some places an almost perpetual crop, but, as a rule, there are two principal harvest seasons in the

vear

The coffee fruit consists of a bilobed berry somewhat resembling a small elongated cherry (by which term it is described commercially) The fleshy pericarp changes colour, as the fruit ripens, from green through yellow and red to a deep crimson When dried, it blackens and becomes hard and brittle, resembling a shell or Beneath the skin of the pericarp is a saccharine and somewhat glutinous pulp containing the seeds, which are usually double, lying face to face, but sometimes occurring singly. Each seed or 'bean' is enclosed in two membranous coverings—an outer, consisting of tough buff-coloured tissue, technically known as parchment,' which becomes loose and readily separates on drying; and an inner film of thin white tissue, closely adherent to the bean, and known as the 'silver skin.'

The principal methods in vogue for gathering and preparing the coffee berries for commerce are as follows—In Arabia, Egypt, and the Antilles, the berry is left on the tree till completely dried,

when it is easily shaken down and the dry outer envelope and the parchment removed by pounding in a mortar, beating with a flail, or simply rubbing in the hands. In many other places the berries are gathered by hand as soon as ripe but not dry, and are spread out on the ground in layers from 4 to 6 inches deep. These are exposed to the sun's heat for 3 or 4 weeks, with frequent turning by means of spades, when the bean becomes easily removable from the fruit by gentle trituration. As this process of drying sometimes imparts to the coffee a disagreeable flavour owing to putrefactive changes in the pulp, recourse is frequently had to artificial heat. The most modern method is to 'pulp the berries by crushing between rollers so as not to injure the beans, which are then subjected to a fermenting process in tanks, with or without the addition of water, after which they are separated from the pulp by 'washing,' and dried, either by the sun or by artificial means. Coffee beans in the form of 'cherry' rarely enter into commerce, but frequently retain the parchment and silver skin, which, however, before roasting, are removed by rollers and separated by winnowing They are then graded into different sizes by special machinery, which also separates the round or 'pea-berries' from the ordinary flat-faced beans. The colour of coffee beans varies from a pale-yellow passing through various shades of green to a slatey grey. The following table will indicate the variations ın sıze:-

Coffee undergoes important changes in the process of roasting, the object of which process is to develop its aroma and to destroy its toughness so that it may easily be reduced to powder Great care is necessary to ensure an equable roasting of all the beans, and to attain the exact point at which torrefaction should cease the one hand, rawness is not removed, the flavour of the bean is not developed, and the coffee is hard to grind, on the other hand, if too much heat is permitted, carbonisation takes place, and a strong empyreumatic flavour is produced, whict renders the coffee infusion nauseous

The roasting process is conducted in cylinders (preferably of strong wire gauze to permit of the escape of steam and other volatile products as fast as they are formed) heated by coke fires or gas. The loss in weight is from 15 to 18 pc, of which about one-half is due to moisture, and the rest chiefly to volatile products derived from the fat, and from the sugar during the conversion of the latter into caramel. There is also some loss of caffeine. At the same time, an empyreumatic oily substance is developed, known as caffeol, which, in spite of its small amount, imparts to roasted coffee much of its characteristic aroma. The most favourable temperature for developing the maximum aroma during roasting is a little above 200°. After roasting, it is most important that the beans should be rapidly cooled, and this is effected by spreading them on a large sieve through the meshes of which they cannot pass, but through which the air is forcibly drawn by means of a powerful exhaust connected with a closed chamber immediately below the sieve. Since the essential oil rapidly escapes after the bean is broken up, coffee should not be ground until required for infusion

Bernheimer (Wien Akad 81, [2] 1032, 1042) found that during the roasting of coffee, water vapour is first given off, then suddenly an evolution of carbonic anhydride, and distillation of volatile substances commences The distillate consists of an aqueous liquid and a solid part. The former contains caffeine, caffeol, acetic acid, quinol, methylamine, and acctone, the latter consists of fatty acids, chiefly palmitic Pyrrol escapes during roasting Of fatty acids, 0.48 p c of the coffee employed was volatilised, of caffeine, 0.18 p.c., and of caffeol, 0 05 р с.

Erdmann (Ber 1902, 35, 1846) attributed the aroma of roasted coffee to traces of acetic acid furfural, valeric acid, an unstable nitrogenous compound and a phenolic body resembling creosote Various samples of roasted coffee yielded from 02 to 025 grm of pyiidine per kilo (Bertrand and Weisweiller, Compt rend

1913, 157, 212)

Bernheimer found that raw coffee beans (50 kg) roasted in a revolving drum yielded a liquid distillate (5 lities) and a solid portion (680 grams) floating thereon The uncondensable vapours contained carbonic anhydride, and, on passing them through dilute hydrochloric acid, a resinous body was deposited, having the ap-

pearance of pyrrol-red.

A Liquid distillate -The crude liquid distillate filtered from solid particles has a yellow colour and the fragrant odour of coffee. On agitating it with ether, and evaporating the ethereal extract over the water-bath, a dark heavy oil was obtained, smelling like coffee, and yielding, on redistillation, first a few drops of liquid having the odour of acetone, afterwards, for the most part, acetic acid and water. The thermometer then 10se quickly to 200°, above which point there passed over an oil smelling like coffee, the temperature at the same time rising to 300°. Above this point there passed over a very small quantity of liquid, which immediately solidified to a mass having the buttery aspect and rancid odour of the higher fatty acids This portion, and the liquid which passed over from 200° to 300°, were neutralised with sodium carbonate, whereupon a thick darkcoloured oil was thrown down, which was separated from the supernatant liquid by means of a tap-funnel, and washed with water rendered very

slightly alkaline by potash.

The alkaline wash waters contained no fatty acids, but, when acidified with sulphuric acid and agitated with ether, they yielded a substance

which, after evaporation of the ether, filled the liquid with a pulp of crystals, and after precipitation crystallised in colourless needles, exhibiting the characters of quinol (m.p. 171°), converted into quinhydrone by the action of ferric chloride.

The oil above mentioned, designated by Bernheimer as caffeol, was dried over calcium chloride and fractionally distilled, the greater part passing over from 195° to 197°. The distillate smells very strongly of coffee, is apparently insoluble in cold water, but imparts to it the characteristic odour, slightly soluble in hot water, very slightly in aqueous potash, very casily in alcohol and ether, the alcoholic solution giving, with ferric chloride, a red colouration, which does not disappear on addition of sodium carbonate. Analysis led to the formula  $C_8H_{10}O_2$ . Caffeol is oxidised by chromic acid mixture, without formation of any definite products. By fusion with potash it yields salicylic acid. The portion of the crude liquid distillate

not taken up by ether, when concentrated over the water-bath, yielded groups of needle-shaped crystals, exhibiting the composition and properties of caffeine  $C_8H_{10}N_4O_2$  (0.28 p.c. of the coffee). The mother liquor was found to contain methylamine and trimethylamine.

B Solid distillate —The black mass floating on the crude liquid distillate was found, by a preliminary examination, to consist of a mixture of the higher fatty acids. By saponification, and treatment of the product by Heintz's method of separation, this mixture yielded, as chief constituent, palmitic acid melting at 60°, and a very small quantity of another acid having a melting-point a few degrees higher than that of lauric acid.

The chemical composition of coffee has been investigated by many chemists with various results. The following table gives analyses by O Levesic (Arch Pharm [3] 8, 294) of some of the principal commercial varieties of coffee:—

The principal constituents of coffee are alkaloids (caffeine and caffearine), caffetannic acid, cellulose, fat, gum, protein, sugar, water, and mineral matter.

Caffeine  $C_5H(CH_3)_3N_4O_2$ , trimethylxanthine, is identical both chemically and physiologically with theme, the alkaloid of tea, and is closely related to the obromine (dimethylxanthine), the principal alkaloid of cocoa (q.v.). According to

Payen (Ann Chim Phys [3] 16, 108), caffeine is present as a caffetannate, Gorter (Annalen, 1908, 358, 327) states that caffeine occurs in coffee combined with potassium as potassium caffeinechlorogenate  $\mathrm{C_{32}H_{36}O_{12}K_2(C_3H_{10}N_4O_2)_2}$ ,  $\mathrm{2H_{2}O}$  When pure it consists of white silky needles, slightly bitter and odourless, almost insoluble in ether, sparingly soluble in cold water and alcohol, but more soluble in hot water, and readily soluble in chloroform, by means of which it may be extracted from coffee. The crystals begin to sublime below the boiling-point of water

Caffeine is found also in guarana leaves, kola-nut, maté or Paraguay tea and to a small extent in cocoa as well as in coffee and tea, and gives to these their exhilarating qualities. Taken in excess, caffeine is a poison. In coffee it is present to the extent of from 0.6 to 2.2 p.c., the average being 1.1 p.c. Lendrich and Nott bohm (Zeitsch Nahr Genussm. 1909, 18, 299) report nearly 3 p.c. of caffeine in certain African coffees, whilst in Madagascar and other islands off the east coast of Africa a variety of coffee has been found entirely devoid of caffeine Accoffee has recently been placed on the market after being deprived of practically the whole of its caffeine.

Numerous methods have been proposed for the estimation of caffeine That of Lendrich and Nottbohm is detailed in the Analyst, 1909, 214, and gives accurate results. A less tedious method, but sufficiently accurate for ordinary purposes, is that of Fendler and Stuber (Zeitsch. Untersuch. Nahr. Genuss. 1914, 28, 9-20) abstracted in the Analyst, 1914, 394.

Another alkaloid, Caffearine, having narcotic properties, is stated by Paladino (Gazz. chim. ital. xxv. 1895) to be present in coffee in very

small quantity.

Caffetannic acid presents certain of the characteristics of tannin (which, however, is not found in roasted coffee) and to it the bitter taste of coffee is chiefly due. It is very susceptible to change, and its composition has been much disputed. According to Gorter (vide supra), it is a mixture of a new acid discovered by him and called caffalic acid, with chlorogenic acid. A method for its estimation in coffee has been devised by Krug (U.S.A. Dept. of Agric Div. of Chem. Bull. 13, 908) According to Bell, caffetannic acid is present in coffee to the extent of from 3 to 5 p.c., and when distilled with manganese dioxide and sulphuric acid yields quinone.

Cellulose.—In coffee this is of a very hard and horny character, and difficult to define under the microscope, especially after roasting, although the chief characteristics of the cellular tissue are more or less retained. Coffee cellulose is dissolved by an ammoniacal solution of copper oxide, and gives a blue colour with sulphuric acid and iodine. Remnants of the 'silver skin' are always present even after roasting, and its structure, a thin membrane with adherent, thick-walled, spindle-shaped, and hollow cells,

is quite peculiar to coffee.

Fat forms a considerable constituent of coffee, varying from 10 to over 20 p.c. A loss occurs in roasting, due to the separation of volatile fatty acids When pure, coffee fat is white, inodorous, and of the consistency of butter, melting at 37 5°.

Protein, chiefly in the form of insoluble albuminoids, occurs in coffee to the extent of

from 10 to 14 p.c., the soluble albuminoids constituting about 2 p.c. There is but little difference in this respect between raw and roasted coffee.

Sugar.-König and Bell found from 5 to 9 p.c. of sugar in raw coffee, but this practically disappears in roasting, being almost entirely converted into caramel. Herfeldt and Stutzer (Zeitsch. angew. Chem. 1895, 469) state that sugar is not present as such in the raw bean, but only in the form of a glucoside. Bell, however, found that when the saccharine extract of the beans is boiled with a little dilute sulphuric acid, a quantity of glucose is obtained nearly equivalent to the weight of dry extract operated upon, a result inconsistent with the existence of sugar as a glucoside. Bell considers that this sugar is not present as sucrose, since it is not inverted even after prolonged boiling with acetic acid. On the other hand, the with acetic acid chemists of the United States Department of Agriculture have isolated cane sugar in considerable amount as pure, well-defined crystals (v. Bulletin, 13). It is usually accompanied by some invert sugar probably formed during the process of extraction, and a small percentage of dextrin. Starch is rarely found in the coffee bean.

Water—The moisture in raw coffee varies from 8 to 14 pc, the average being about 11 pc. After roasting, it rarely exceeds 3 pc, and frequently falls as low as 0 5 pc.

Mineral matter—The total amount of ash varies from 3.5 to 4.0 p.c. in law, and from 4.0 to 5.0 p.c. in roasted coffee. The composition of the ash is shown in the following table (U.S.A. Dept. of Agric. Div. of Chem. Bull. 13, 904).—

		1	100 00	100 00	100 00	100 00

The principal constituents are potash, magnesia, lime, and phosphoric acid. Ludwig, in his analyses of various parts of the Brazilian coffee tree, shows that the silica increases from the root upwards to the leaves and pericarp of the fruit, after which it declines in the parchment skin, and is nearly absent in the bean (Arch. Pharm [3] 1, 482). Graham, Stenhouse, and Campbell inferred that sodium compounds are entirely absent in coffee (vide table in Bell's Food Adulteration, 46), but although this is not absolutely correct, the amount, as shown in the above table, is very minute.

Adulteration of coffee is very common, and

the number and variety of the adulterants is almost unlimited

Colouring is frequently employed in order to disguise damaged beans and give them the appearance of superior quality, a practice analogous to the 'facing' of tea. The substances most commonly employed are, for the raw beans, chrome yellow, yellow ochre, indigo, Prussian blue, azo- dyes, and soapstone for polishing; and for the roasted beans, burnt umber, oxide of iron, Venetian red, ferruginous earth and clay. The inorganic colouring matters are best sought for in the ash or in the sediment obtained by shaking the beans in cold water; indigo and

Prussian blue by their usual reactions; and other organic colouring matters after extracting them with alcohol.

Glazing is a process resorted to for the alleged purpose of improving the keeping properties of the roasted beans, and the substances used, a mixture of egg albumen with glucose or gum, are said to have the effect of clarifying the infusion. The improved appearance of the beans and increased weight due to the retention of moisture, are probably also important considerations. The latter result is sometimes attained by the addition of sugar before roasting, or by actually steaming the beans and coating them with glycerine, palm oil, or vaseline, to prevent evaporation of moisture Bertarelli (Zeitsch Nahr Genussm. 1900, m 681) describes the adulteration of roasted coffee beans with a solution of borax, which not only gives the beans a glossy appearance, but also adds as much as 12 p c to their weight.

Shellae is occasionally used for glazing, and Nottbohm and Koch draw attention to the fact that shellac is sometimes coloured by arsenic trisulphide Coffee beans which had been glazed with arsenical shellac were found to be strongly contaminated with arsenic (Zeitsch

Nahr. Genussm 1911, 21, 288).

Coffee substitutes comprise a large number of vegetable substances, roasted and ground, and having for their object either the production of a stronger infusion than can be obtained from coffee alone, or the simulation of coffee in order to give weight by the use of thick-walled vegetable tissue of hard or leathery consistency The former, of which chicory is the type, includes acorns, beet refuse, biscuits, bran, cereals (barley, buckwheat, maize, malt, oats, rye, and wheat), caramel (burnt sugar), carrots, dandelion root, figs, lupin seeds, mangolds, parsnips, peas, beans, and other leguminous seeds, turnip, &c, whilst the latter comprise such substances as coffee husks, cassia seeds, date stones, grape stones, locust or carob beans, sawdust, vegetable ivory dust, &c

Imitation coffee -Although adulteration is naturally more prevalent in ground coffee than in the beans, yet the latter have been prepared artificially and on a large scale from the above adulterants (generally without any admixture of coffee), held together by means of gum, molasses, or stiff clay, and skilfully moulded

into the form of coffee beans

The detection of the adulterants above referred to is best effected by means of the microscope By simply digesting with water, a ready means is afforded of differentiating between the pale soft-walled tissues of cereals and roots and the dark-coloured and hard-walled tissue of coffee The former may readily be detected and identified by the presence and characteristics of their starch, coffee (and chicory) being practically free from starch The use of bleaching reagents is of great assistance in the microscopical examination, and reference might usefully be made to the drawings and photographs reproduced in the works of Bell, Leach, Villiers et Collin, and Wiley, and in the Coffee Report of Graham, Stenhouse, and Campbell, referred to below.

The chemical differences between coffee and its adulterants are also strongly marked, as

mixtures usually give high aqueous extract and sugar, and low fat and caffeine. The density is a useful factor in detecting the sophistication of coffee, and, in particular, the artificial moistening of the berries In the Paris Municipal Laboratory, Regnault's volumenometer, as modified by Dupré, is used for this purpose. According to the French chemists, the density of raw coffee varies between 1 041 and 1 368, and that of roasted coffee between 0.500 and 0.635.

By far the most important adulterant of coffee is chicory (qv.), but owing to the public preference for an admixture of chicory with coffee, it is now regarded in the light of an adjunct to rather than an adulterant of coffee, provided its presence in the mixture is disclosed. Chicory has little in common with coffee except a considerable proportion of sugar, which is converted into caramel in the roasting, and thus imparts to the infusion a bitter taste and aroma somewhat resembling that of coffee This and the stronger infusion obtained as well as the comparative cheapness of chicory and similar substances, has, no doubt, led to the present extensive use of chicory and other coffee substitutes

An elaborate research into the nature of coffee and chicory, with a view to the detection of adulteration, was made at the instance of the Commissioners of Inland Revenue in 1852 by some of the leading botanists and chemists of the day, viz. Lindley and Hooker, and Graham, Stenhouse, and Campbell, and the results, chemical and physical, as well as microscopical embodied in their reports are of great practical

value even at the present time

The following table by Graham, Stenhouse, and Campbell, shows the spgr at 60°F. of sulutions made by treating one part of each of the substances named (roasted and finely ground) with 10 parts of water (by weight), raising the mixture to boiling-point, where it is maintained for half a minute, then filtering and cooling :-

It will be seen from the above table that the low sp.gr. of the coffee infusion distinguishes it from the roots and cereals, and when chicory is the only substance admixed with the coffee, its percentage may be calculated with approximate accuracy by a comparison of the density of the infusion of the mixture with the average densities of coffee and chicory given in the

foregoing table.

The same observers lay stress on the relative colouring power of roasted coffee and chicory, the latter being four and a half times as great as the former. This property affords a simple device for detecting the presence of roasted chicory or other substances containing caramel when admixed with coffee. A few grains of the sample are placed on the surface of cold water in a glass, without stirring, when, if roasted chicory or similar substance be present, each particle emits a yellowish-brown coloured cloud, which is rapidly diffused in streaks through the water till the whole acquires a brownish colour, whilst pure coffee gives practically no colour to the water in similar circum-The chicory readily sinks, whilst nearly the whole of the coffee floats.

If examined under the microscope, the sediment of chicory which reaches the bottom of the vessel will be found to exhibit the characteristic loose, large cells, with dotted vessels and branching lactiferous ducts Even to the touch the difference is evident, for, whilst chicory under these conditions will feel soft and smooth, the coffee grains remain hard and

A. Winter Blyth (Foods; their Composition and Analysis, 359) gives the following summary of the influence of chicory on the coffee

mixture :-

(1) It decreases the gum, the latter seldom rising in chicory to more than 15 pc, whilst in coffee it has not been found less than from 21 to 28 pc.

(2) It increases the sugar, roasted coffee having seldom so much as 2 p.c. of sugar; whilst chicory, when roasted, has at least 8 or 9

(3) It decreases the fatty matter, the fat of chicory ranging from 1 to over 2 p.c., that of

coffee being about 14 to over 20 p c. (4) It decreases the tannic and caffeotannic

acids, chicory being destitute of tannin. (5) It decreases the caffeine, chicory pos-

sessing no alkaloid.

(6) It profoundly modifies the constitution of the ash, especially by introducing silica, which is not found to any great extent in coffee

Graham, Stenhouse, and Campbell laid stress upon the presence of silica as a means of detection of the admixture of chicory. analysis, showing the principal differences in the composition of the respective ashes, gives:

	in conee ash	in chicory ash
Silica and sand		10 69 to 35 85
Carbonic acid	14.92	1.78 ,, 3 19
Ferric oxide	0.44 to 0.98	3.13 ,, 5.32
Chlorine .	0.26 ", 1.11	3.28 ,, 4.93

There is a marked difference in the proportion of ash soluble in water, that from coffee Vol II.—T.

amounting to from 75 to 85 p c, and in chicory from 21 to 35 p c.

Negro or Mogdad coffee consists of the seeds of Cassia occidentalis It contains no caffeine nor starch, and its infusion more nearly approaches the character of genuine coffee than any other known coffee substitute

Mussaendar coffee is derived from the seeds of Gaertnera vaginata It contains no

caffeine

French coffee is a description commonly applied to a mixture of coffee with burnt sugar and a large proportion of chicory. As the latter ingredients readily absorb moisture on exposure to the air, such mixtures are usually preserved

Various fraudulent coffee substitutes have been imposed upon the public by specious advertising under fancy names, and as possessing certain desirable qualities not found in coffee. Such are Kunst kaffee, consisting of roasted roots or cereals, and often moulded into the form of coffee beans; Pelotas coffee and Coffee surrogate, made from ground acorns, Date coffee from date stones, or torrified dates mixed with a small proportion of coffee; and many others.
The grosser forms of adulteration above

referred to are much more prevalent in the coffee-drinking countries of the continent of Europe and in the United States of America than in the United Kingdom.

COGNAC v BRANDY.

COHUNE NUT FAT. The nuts of the Cohune Palm (Attalia cohune), indigenous to British Honduras, yield from 65 to 72 p c. of a white solid fat resembling coco-nut oil Sp gr at 100°/15 5° 0 868 to 0 871; acid value 1.2 to 204, saponification value 252 4-256 5; iodine value 11 0 to 13 7; Hehner value 87 7; Reichert-Meissl value 6 8 to 8 3; Polenske value 12.5 and Solidifying point of fatty acids 197°-21 0° (Bull. Imp. Inst. 1913, 11, 226; 1914, 396).

#### COKE MANUFACTURE AND THE RE-COVERY OF BY-PRODUCTS.

Introduction —Previous to the early nineties. practically the whole of British metallurgical coke was made in the old beehive oven, which, as will be seen from what follows, is a semicombustion process, involving the loss of the whole of the gas and by-products, together with With the a portion of the possible coke yield gradual disappearance of the old prejudices against coke made in by-product ovens, the latter and much more economical process began to assert itself, and in 1898, 1.25 million tons of coal were being carbonised in by-product coke ovens, in 1905 the quantity of coal so treated reached 3.31 millions; and in 1916, about 14 60 millions Meanwhile, the number of beehive ovens in operation had decreased from 16,037 in 1910, to 6892 in 1916 According to figures published by the Coal Conservation Committee at the end of 1917, some 8700 byproduct ovens were in operation in Great Britain (of which 8000 were fitted with benzol recovery arrangements) with a total carbonising capacity of 17 5 million tons of coal per annum. In 1917, 166,354 tons of ammonium sulphate were produced in British coke-oven plants. The practice of by-product recovery had become universal in Germany years ago; whilst in the

United States the by-product plants, either building or in operation at the end of 1917, were capable of producing 24 million tons of coke per annum. In view of this rapid adoption of the by-product coking process in all these countries, the following article will be confined to a description of modern coking methods viewed chiefly from a by-product standpoint, with only a passing reference to the wasteful beehive process.

History of the by-product coking process— The earliest reference which we can find of any observation being made on coal as a source of by-products is that contained in the memoirs of Johann Joachim Becher, duting about the end of the 17th century, Becher states that he has found means for treating coal 'so that it no longer smoakes nor stinks,' and in doing so

made a tar equal to the Swedish.

The use of coke in iron smelting became general within 50 years of Becher's discovery, and a French metallurgist, De Gensanne, describes a process working at Sulzbach near Saarbrucken prior to 1768, where coal was coked for iron smelting, tar being recovered as a byproduct, Stahl is said to have been the inventor of this process, and he produced therefrom an 'oil,' bitumen, sal-ammoniac, and lamp-black

In 1781 Archibald, Earl of Dundonald, was granted a patent for 'allowing coals to burn or ignite without flaming, so by their own heat to throw off the tar or oils that they contain Dundonald stated that the only method whereby tars could be obtained prior to his discovery, was by a distillation in closed retorts, where the admission of external air was prevented, and where other coals were required for heating besides the coal contained in the closed vessel It is interesting to note that Dundonald was perfectly aware of distillation in closed retorts, which is the basis of modern by-product coking methods, and it is also evident that his knowledge of closed retorts was 16 years previous to the introduction of coal gas for street and household illumination in 1797

In 1838 Frederick Neville obtained protection for an invention which consisted in heating ordinary gas retorts by the waste heat from beehive coke ovens, the distilled gases from the retorts being passed though condensing and scrubbing appliances William Newton, in 1852, introduced the use of an aspirator or pump for withdrawing the gases from coke ovens through and  ${f rubbers}$ Newton likewise mentions the use of acids for removing the ammonia from the gases. In 1860 W. H Kingston patented a coke oven provided with external furnace, from which the heat evolved by the combustion of an auxiliary supply of coal was conducted round the oven through a system of flues; the evolved gases were passed through a series of pipes and condensing vessels for the recovery of the by-products Kingston's patent is especially noteworthy, since he recognises that the true method for the recovery of by-products from coal lies in heating the coal in closed chambers, and not in chambers to which air is admitted

With regard to Continental practice, in 1850 M M Pauwels and Dubouchet, and in 1862, Pernelot, introduced systems of carbonising

coking coals in long rectangular chambers, heated from below by the regulated combustion of part of the gas in flues specially constructed under the floor, for the purposes of manufacturing metallurgical coke and removing tars, oils, and ammonia The Pernelot system was tried in the north of England in 1870, but the coke produced was too soft for metallurgical purposes

In 1856 Knab erected a coal-distillation plant at Commentry, on the closed-retort system with bottom flues, but made no attempt to recover by-products Later Knab was joined to recover by-products (1866-1873) introduced by Carvès,  $\mathbf{w}$ ho improved methods of heating by side flues in addition to the bottom flues, thus obtaining a more even distribution of temperature and a Carvès likewise quicker rate of carbonisation utilised the gases (from which the by-products had been extracted) in the side-wall flues, in addition to the auxiliary coal as employed by The Knab-Carves ovens at Commentry gave the following results -

Large coke .		70 00
Breeze		1.50
Dust		2 50
Graphite		0.50
Tar		4.00
Ammoniacal liquor		9 00
Gas .		10.58
Loss		1 92
		$100 \ 00$

Further plants on the Carvès system were erected at Bessèges and Terre-Moire, near St. Etienne, between the years 1866 and 1873, and were still further improved, the Carvès ovens working at Besseges in 1880 were built with carbonising chambers only 24 inches wide, to facilitate rapid heat penetration and quick carbonisation In 1881 Mr. H. Simon of Manchester introduced a recuperator, whereby the air necessary for the combustion of the gas in the side-wall flues of the Carves oven was preheated by the waste gases escaping from the flues, and thus the rate of carbonisation was still further increased, the combined work of the two investigators resulting in the wellknown Simon-Carvès oven, which may be held to be the precursor of the modern by-product coking retort

Following on the success of the Simon-Carvès process, other coke-oven patents were filed, viz Semet-Solvay, 1880, Hussener, 1881; Lurmann, 1882; Otto and Brunck, 1883, but although development was rapid on the Continent, little was done in this country before the nineties, owing to the prejudice of iron smelters against by-product coke; that this prejudice has now disappeared will be seen from the rapid adoption of the process, indicated by the figures at the beginning of this article. The by-product coking plants which have generally found acceptance in this country are the Otto-Hilgenstock, Simon-Carvès, Koppers, Semet-Solvay, Simplex, Coppée, and Hussener.

Non-by-product and by-product ovens compared.—Prior to the establishment of the by-product coking process, the type of oven universally employed was that known as the beehive.

This oven (Fig. 1) consists of a fireclay chamber, bechive shape in elevation and circular in plan, provided with a loose brick charging door at ground level, and with an exit flue in its crown for carrying the waste gases to the chimney. The 'coal is charged into the oven by spades, through the charging door, to a height of 2 feet 6 inches to 3 feet, is then ignited, and the charging door bricked up and plastered, a small hole 6 inches square being left for the admission of air. The upper layer of the coal burns and or an. The upper layer of the coar burns and sets up distillation of the under layers, the evolved gases passing upwards and burning in the dome of the oven, with the air drawn in at the door. The dome is thus soon heated up to a high temperature, and by radiation powerfully assists in carbonising the charge of coal below. This operation of distillation and immediate combustion proceeds until the whole of the volatile constituents of the coal have been evolved, which for a 10-ton charge occupies 70 hours. The coke is then quenched with water and withdrawn by rakes

It will be seen that by this process, the whole of the volatile products, that is to say, benzols and ammonia together with the permanent gases, are burned immediately they are evolved within the coking chambers itself; further it is not possible to so regulate the combustion of these gases without burning a portion of the coke in addition; in actual practice, from 15 to 20 pc of the coke is burned to waste the reason, too, that the coke is quenched inside the oven, the temperature of the latter is lowered, so that before the next charge can be coked, considerable expenditure of heat is necessary to raise the oven to coking temperature. The removal of the coke by hand-rakes

is also tedious and expensive With the object of overcoming the main drawbacks of the bechive oven, Coppée introduced a non-by-product retort of rectangular form, from which the coke could be discharged en bloc by a ramming machine and quenched outside the oven, thus expediting the operation In Ćoppée's and greatly increasing the yield oven (Fig. 2) the gases evolved from the coal are drawn into flues in the side walls where burned, and in this way they are

bustion within the coking chamber and loss of coke, as occurs in the beehive oven, is avoided.

The by-product retort (Fig. 3) is built on the same lines as the Coppée, that is to say, it is a rectangular chamber heated by flues in the side walls, and the coke is discharged by a ramming machine; the essential point of difference lies in the fact that in the Coppée the whole of the gases containing the by-products are drawn immediately they are evolved into the side-wall heating flues, where they are burned; in the by-product retort, the gases and products are drawn from the oven through cooling and washing plant for the recovery of the tars, ammonia, and benzol, and the permanent gas only is burned in the flues after the said products have been extracted. In the Coppée, the whole of the permanent gas is burned in the heating flues; in the by-product oven, only one-half to two-thirds of the gas is utilised in the flues, the remainder being available for heating or power purposes.

The following diagrams illustrate the essential differences in the three types of oven

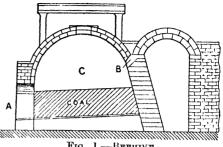

FIG 1 -BEEHIVE.

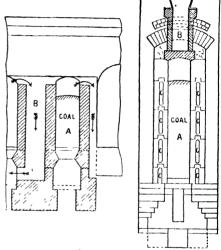

Fig. 2.—Coppee Fig. 3.—BY-PRODUCT RETORT.

It will be seen, therefore, that in addition to effecting the theoretical coke yield, and a large output, the by-product retort yields valuable by-products and a considerable yield of power or heating gas The average yields (calculated upon 100 parts of dry coal) of coke and by-products obtainable from British coking coals of different origin by the most up-to-date methods. are approximately as follows -

Origin	Coke	Anhyd tar	Crude ben <b>z</b> ol	Ammo- nium sulphate	
Durham	75 0	3 85	0 93	1 16	
South Yorkshire	70 0	3 62	1 37	1 35	
Lancashire	70 0	3 50	1 20	1 25	
South Wales .	80 0	2.62	0 60	0 95	
Scotland	68 0	3 25	0 70	1 00	

The by-product process described in detail -The by-product retort usually measures from 30 to 33 feet in length, from 5 feet 9 inches to 7 feet 6 inches in height, from 17 to 22 inches in width, and is built in batteries of from 25 to 60 ovens, capable of carbonising from 100 to 350

Table showing the Return from carbonising a Lancashire Coal containing 30 p.c. Volatile Matter, i.e a Theoretical Coke Yield of 70 p.c. in the Three Types of Oven.

tons of coal per day. Each oven is provided with cast-iion or rolled-steel doors at each end, lifted by a small crane whenever an oven is discharged, and with three holes in the roof through which the coal is charged into the oven from the charging hoppers, a fourth hole is provided, through which the gases are led to an ascension pipe from which they pass to the by-product plant. The oven limings and combustion flues are constructed of silicious firebricks containing from 80 to 84 p.c. of silica, from 13 to 18 pc of alumina, and 2 pc of other constituents (iron oxide, lime, magnesia, and the alkalis) In the United States, however. silica bricks (SiO<sub>2</sub>=94 p c) are extensively employed They are superior in heat conductivity to a more aluminous brick, but are less satisfactory when 'washed' coals (containing say 10 to 15 p c water) are being coked. The design of the heating flues constitutes the main difference between the various types of oven; the Simon-Carvès, Semet-Solvay, Hussener, and Simplex containing horizontal flues, the Otto-Hilgenstock, Otto-Hoffmann and Koppers prefer vertical flues (Figs 4 and 5) In all cases the air required for the combustion of the gas in the heating flues is preheated either by passing it through recuperators in which it travels through a system of flues situated alongside the waste gas flues of the oven, or through regenerators similar to those employed in open-hearth steel furnaces, where the hot waste gases and air are alternately taken over the same surface (Fig 6). Where a large supply of surplus gas is desired from a coking plant, the regenerative method of preheating the air is to be preferred, since it is more effective and less gas is required for heating the flues; the amount of surplus gas available from a Lancashire coal containing 30 p.c. of volatile matter, may be taken at 2000 cubic feet per ton, where recuperative heating is employed,

and 5000 cubic feet per ton where regeneratives are used

The coal is generally charged into the oven through the crown from small hoppers, carrying the coal on rails from the storage bunker, the coal flowing into the oven being levelled by hand-rake or levelling machine In cases where the coal employed is not of a strong coking character, the fuel is stamped into a solid cartridge in a compressing machine and charged into the oven en bloc through the end doorway, The coke is discharged from the oven by a ram, generally electrically driven, often the levelling machine or compressor is built on the same carriage as the ram, and driven by the same The coke is received from the ovens on a sloping bench, where it is quenched with water, and from which it slides into railway trucks, furnace barrows, or a conveyor heating flues of each oven discharge into a common flue, which leads the waste gases in the case of recuperator types to steam boilers; with regenerator-ovens, the gases are led direct to the chimney stack The gases distilled from the coal collect above the level of the fuel and pass forward to the ascension pipe or stand pipe, which delivers the gas into the tar or hydraulic main, which receives the gases from the entire battery. A valve or damper is provided on each ascension pipe for shutting off each oven whilst the latter is being discharged and recharged In the tar or hydraulic main the heavier tars or pitches are deposited, and in the 'dry' types of main, it is necessary to pump the thinner tars made at a later stage of the cooling, through the main to clear the pitch and prevent stoppages.

In the older systems of by-product recovery, which are now being rapidly superseded by more 'direct' methods (q v), the gases are drawn from the main by an exhauster (either

steam or electrically driven), a Root's blower, or some form of aspirator, through coolers. These coolers are either plain pipes or cylinders offering a large amount of atmospheric cooling surface, or are water-cooled chambers, in these condensers, the bulk of the remaining tar, together with the greater proportion of the ammonia liquor, is precipitated. From the condensers, the gases pass into the exhauster or aspirator, which then delivers them at a pressure into a tar-fog extractor This vessel is employed to remove the last traces of tar

state of division, and which no amount of The tar extractor, of cooling would remove which the Pelouze Andouin and Livesay are types, operates by dividing the gas into numerous thin streams by means of very small gas passages, the agglomeration and removal of the tar particles being effected by the wire drawing and friction thus afforded.

From the tar catcher the gases pass into the ammonia scrubber, where the last of the ammonia not recovered by the condensers is removed by contact with weak ammonia liquor and water. which exist in the gas in an extremely fine | The types of ammonia scrubber generally em-

ployed are similar to those employed at gas works, and are either of the tower or rotary In the tower scrubber, the gases pass upwards through a mass of coke or other open material, meeting a downward current of water or ammonia liquor pumped in at the top. In the rotary scrubber, the gas is caused to impinge on revolving brushes or circular wooden screens, which dip into the water or liquor in the lower half of the vessel, and pass upwards with wet surfaces into the upper half of the scrubber, where the gas is circulating, and solution of ammonia is attained. The gas then passes forward to the benzol scrubber, which is constructed on similar lines to that employed for ammonia removal, creosote or anthracene

heavy oil being employed for the solution and recovery of the benzol vapour.

The gas having been freed from its tar, ammonia liquor, and benzol, is then passed forward to the ovens, where it is fed into the heating flues, the surplus being passed forward to boilers, gas engines, or gas holder

The tars and ammonia liquors made in the hydraulic main, condensers, tar catchers, and ammonia scrubber are collected and run into separators or tanks, where the denser tar settles to the bottom, is withdrawn and despatched to the tar stores. The liquors which remain above the tar are run off to the sulphate of ammonia plant, where the liquor is pumped into overhead store tanks, whence it is allowed

to flow by gravity through a preheater (heated by the waste gases from the sulphate plant), and thence into a distilling column, where it flows downwards, meeting in its travel an upward current of steam, which liberates the free or combined ammonia. In the lower half of the still, milk of lime is mixed with the liquor for the liberation of the ammonia from the fixed salts; the whole of the ammonia, together with steam, sulphuretted hydrogen, carbonic acid, and hydrocyanic acid, pass upwards through the still and into a lead-lined vessel called the saturator, containing sulphuric acid. The ammonia combines with the acid to form ammonium sulphate, which, when the liquor in the bath becomes saturated, crystallises out and is removed either by copper scoops, a valve, or by a steam injector. The sulphuretted hydro-gen and other gases pass from the saturator to the preheater, where they serve to heat the liquor passing to the still; thence the gases travel to a condenser where they are cooled, and afterwards to purifiers where the sulphur-etted hydrogen is removed by oxide of iron The waste liquors, which should not contain more than 0 01 p.c ammonia, are run into the sewers or watercourses, and are a frequent source of trouble to the river boards. By the Otto-Hilgenstock method of by-product recovery, to be described later, the production of these waste liquors is entirely obviated.

The recovery of crude benzol from its solution in creosoto or anthracene oil is effected in a distilling column somewhat similar to that employed for the recovery of ammonia from liquor, the heating of the solution of benzol in the absorbent being effected by wet steam assisted by dry steam. The vapours, steam, and benzol pass from the top of the still to a water-cooled coil, where they are together condensed, the condensates being separated by reason of their different densities. The grade of crude benzol thus obtained varies with the class of absorbent oil employed; with creosote, 62 p.c. of the product distrils at 120°, with anthracene oil the benzol is richer, 80 p.c. distilling at 120°. For the rectification of crude benzol, the product is washed successively with strongest oil of vitriol, water, and caustic soda, and redistilled.

Direct Recovery Systems -Two successful attempts have been made to simplify the old system of treatment of coke-oven gases for the recovery of ammonia, viz the inventions of the Koppers and Otto-Hilgenstock Coke Oven Companies. Koppers treats his gases by the old system up to the point of the tar-fog extraction He then reheats his tar-free gas by passing it in pipes surrounded by the hot gases coming from the ovens in an apparatus called a heat exchanger, and then passes the heated gas direct into a sulphate saturator, into which is likewise passed the ammonia from the liquor made in the condensers, which is distilled in an ordinary ammonia still. In short, Koppers abolishes the usual ammonia scrubber and substitutes the sulphate saturator, thus making his sulphate direct on the gas main (Fig 9). By thus using the sulphuric acid in the saturator for scrubbing out the ammonia, Koppers dispenses with the water utilised in the old scrubber, thereby reducing the total amount of liquor produced, and required in the ammonia distillation.

A more extensive simplification is effected the invention of the Otto-Hilgenstock Co of Dahlhausen, who dispense entirely with the old condensing plant and remove the tar from

effecting an economy in the amount of steam | the gases by means of a tar spray at a temperature above the dew-point of the liquors tar-free gases then pass direct into a saturator, where the whole of the ammonia is caught by sulphuric acid. The gases issuing from the saturator still contain their liquors in steam

form, and the whole passes forward to the ovenflues, and the offensive and troublesome waste liquors are thus got rid of The Otto system, by abolishing the condensing plant, liquor tanks, ammonia stills, lime mixers, and pumps, waste hquor tanks, &c, effects a great economy in ground space. It likewise saves nearly the whole of the steam required to distil the ammonia liquor made by the old condensing

process, and, by passing the whole of the ammonia through sulphuric acid, losses of ammonia, which are hable to occur in the old process of ammonia liquor distillation, are rendered impossible. The ammonium sulphate made by the Otto direct-recovery, tests from 25 to  $25\ 5$  p c of ammona, and contains only the merest traces of tar, viz  $0\ 05\text{--}0\ 1$  p c (Figs 10, 11, and 12).

### MODERN METHODS FOR THE RECOVERY OF NAPHTHALENE AND BENZOLS.

Recovery of Naphthalene.—The gas from the saturator, which is now freed from both ammonia and tar, but still containing the benzol, moisture and naphthalene, passes through a lead-lined eatch pot (not shown in the diagram, but whose

situation prevents all fear of any acid spray being carried over from the saturator) and on to the naphthalene extractor and spray cooling tower, H (Fig. 13.) This tower is quite devoid of any filling or apparatus, but at the top there are several jets through which cold water is sprayed at high pressure. The action of this mass of

finely-divided cold water beating suddenly on to the hot gas produces a rapid chill, which, together with the concussion brought about by the water, precipitates and washes out practically all the naphthalene, which flows away along with the water into a catch tank beneath this apparatus. The naphthalene is filtered off whilst the water can be either allowed to flow away, or re-cooled and used over again continuously, as circumstances permit This tower also serves the purposes of cooling the gases. It is necessary to extract the naphthalene, otherwise it would pass on to the benzol scrubbers, where it would be dissolved by the benzol wash oil, which would very soon become saturated with naphthalene and rendered useless for the purpose of collecting benzol naphthalene thus extracted is of a pale yellow colour, and is readily sold in this country for 50s a ton, which more than pays the cost of

running this part of the plant.

Recovery of Benzols.—The gas now being cooled but still containing the benzol, passes through the exhauster, K, and a second water cooler, L, and thence to the benzol scrubbers, MM, which vary in number according to the size of the plant (Fig. 13). These scrubbers are from about 50 to 70 feet high, the lower portion forming a reservoir for the circulating benzol wash oil, and the remaining portion being filled with wooden grids. Benzol wash oil is constantly circulated downwards over these grids, the gas having to pass upwards through them By this means the gas is brought into vory intimate contact with the oil, with the resulting absorption of the benzol. After leaving these scrubbers the gas passes either wholly back to the ovens, or in the case of regenerative ovens about one-half of it returns to the ovens, and the other half is used either for firing boilers, town lighting, operating gas engines, or any other purpose

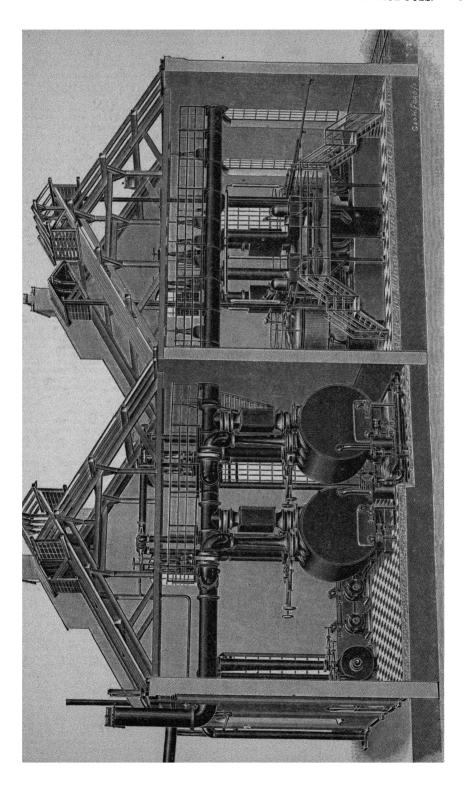

other purpose

A fuller account of the process is given in a paper by Mr. E Bury before the Institution of Mining Engineers in the year 1914, from which the following temperatures of a plant at New Brancepeth Colliery (Co Durham) are

taken:-

Hydraulic main		$rac{\mathrm{Cent}}{225^\circ}$	
Before tar extracts		86°	
After ,, ,,			58°
In saturator .			67°
After ,, .			58°
After exhauster			66°

Distillation and Rectification of Benzols—
The 'wash oil' containing the benzols in solution is sent on to the continuous crude benzol still, N (Fig. 14), where, after being pre-heated by the hot vapours coming away from the still, it passes downwards over a series of trays. Dry steam at about 100 lbs pressure, reduced, however, at the still to 10 lbs. pressure, is delivered into the bottom of the apparatus, and passing upwards bubbles through the wash oil liberating the benzol hydrocarbons which it carries over into the condenser, P. Here the steam and benzols are condensed, and the condensed water and oil separated. The crude benzol then either passes into a storage tank, or (if its rectification is to be carried out) into the 'primary rectifying still,' s. The debenzolised

'wash oil' leaving the crude benzol still is passed through the refrigerator, R, whence, after being cooled down to the atmospheric temperature, it is sent into the 'oil storage tank,' T, and from there it is used over again in the benzol scrubbers

The crude benzol is first of all fractionally distilled in the primary rectifying still, s, 3000-5000 gallons capacity and intermittent in its working, in which it is heated under high pressure by means of steam coils, and, with the aid of a long dephlegmating column, it is separated into—

(1) Crude 90 p c Benzol

(2) ", 90 ", Toluol

(3) ", 90 ", Xylol

(4) ,, 90 ,, Solvent naphtha

Each of these fractions is separately condensed and pumped into a large vessel, v, termed the

agitator, where it is successively treated with (a) pure strong sulphuric acid, and (b) a solution of caustic soda, in order to remove all resinous, basic, or acidic substances. Each of the 'washed' fractions is finally refractionated under reduced pressure in the 'secondary rectifying still,' w, and the redistilled resulting fractions, after condensation, are sent forward into their respective storage tanks, xyz, ready for transport

Other firms (e q the Simon-Carvés and the Simplex Companies) have also adopted efficient 'direct recovery' processes, on much the same lines as the Otto process just described, the chief difference between them being in the precise mechanical arrangement for the removal of tar and tar fog from the hot gas before it enters the saturator where the ammonia is absorbed.<sup>1</sup>

Alcohol from Coke Oven Gas —Attention

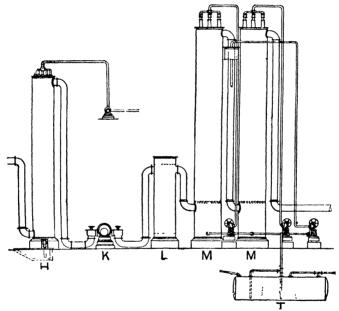

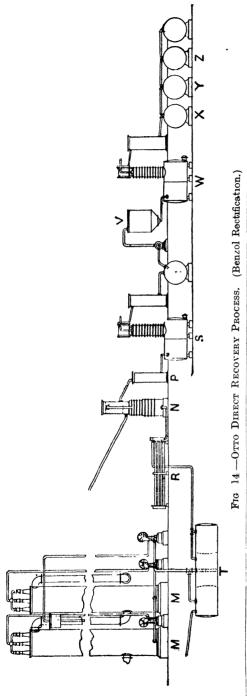

Fig 13.—Otto Direct Recovery Process (Benzol Recovers)

should here be drawn to the successful process worked out by E Bury and O. Ollander at the Skinningrove Ironworks for the absorption of the ethylene in coke oven gas by cone H<sub>2</sub>SO<sub>4</sub> (forming ethyl hydrogen sulphate), and its subsequent recovery therefrom as ethyl alcohol The process, which is fully described in the Coal and Iton Trades Review for December, 1919 (q v), consists essentially in (a) absorbing the C2H4 from the dried, debenzolised, and H<sub>2</sub>S-free gas by means of 95 pc H<sub>2</sub>SO<sub>4</sub> in a series of towers, on the counter-current principle, at a temperature between 60° and 80°C.; and subsequently (b) treating the strong acid containing the ethyl hydrogen sulphate with a current of steam in a special form of distilling column, so as to dilute it to between 70 and 75 p.c. strength, thereby also hydrolysing the ethyl hydrogen sulphate and liberating the resultant ethyl alcohol, which then distils over,

and is condensed. The whole process is worked in a continuous cycle, the diluted acid being (c) reconcentrated to 95 p c. strength in a Guilland 'concentration tower,' and then being reused for extracting ethylene from the gas. A notable feature of the process is that the small amount of  $\mathrm{SO}_2$  formed by the reducing action of the gas upon the hot conc.  $\mathrm{H_2SO}_4$  in the absorption towers is subsequently utilised to remove  $\mathrm{H_3S}$  from the gas by the well-known reaction  $2\mathrm{H_2S} + \mathrm{SO}_2 = 2\mathrm{H_2O} + 3\mathrm{S}$ , so that all the S contained as  $\mathrm{H_2S}$  in the gas is removed and recovered from it without the employment of elaborate 'iron-oxide' or other purifiers. From the gas (containing between 1.75 and 2.25 p c. ethylene) evolved in carbonising a typical Durham coking coal in regenerative ovens, with the 'direct'

<sup>1</sup> See a paper on Recent Developments in Ryproduct Coking, by Mr G. Blake Walker. (Proc. Inst. Civil Engineers, 1917.)

COLCHICUM.

system of recovering tars, naphthalene, ammonia, and benzol, it is claimed to be possible to obtain about 15 gallons of 95 p.c. ethyl alcohol per ton of coal at a present-day cost not exceeding one shilling per gallon.

Utilisation of Coke-Oven Gas. The composi-

tion of the surplus gas obtained in working the process depends somewhat on whether it is 'debenzolised' or not, as well as on the character of the coal carbonised, but for gas from a typical Durham coking coal it would be approximately as follows -

Gross calonific value B Th U per cub ft at N<sub>2</sub> 760 mm.

333

(1) Without benzol CO<sub>2</sub> CO  $C_nH_m$   $CH_4$   $H_2$   $N_2$  recovery 2 5 6 5 3 2 28 0 48 0 11 8 (2) 'Debenzo-

 $2\ 5\ 6\ 5\ 2\ 0\ 25\ 0\ 55\ 0\ 9\ 5\ 485$ lised?

With a regenerative oven giving 5000 cubic feet of such surplus 'debenzolised' gas per ton of coal carbonised, the corresponding heat units available for outside purposes would be 2,450,000 (gross) and 2,150,000 (net) B Th Us. respectively This gas may be utilised (a) for generating steam in a Bonecourt surface-combustion boiler with an efficiency of 92 pc: or (b) for generating power in internal combustion engines with an efficiency of from 20 to 25 p c Where coke-ovens are erected in conjunction with blast-furnaces and steel-works, the surplus gas is usually mixed with cleaned blast-furnace gas, and the mixture used both for generating power in gas-engines and also for heating purposes in open-hearth steel-furnaces, soaking pits, &c. In both Germany and America, cokeoven gas (after purification in the usual manner from H<sub>2</sub>S and eyanogen compounds) is extensively used as a public supply for domestic purposes As long ago as 1910, Parliament granted powers for the supply of gas from Loid Ellesmero's Brackley Coke-Works to the urban district of Little Hulton (Lanes), under a guarantee of a minimum illuminating power of 14 candles when tested in a No 2 Metropolitan Argand burner, and a gross calorific value of 550 B Th U per cubic foot at 60°F and 30 mm pressure Its average composition was CO2=2 5, CO = 7.0,  $C_nH_m = 3.8$ ,  $CH_4 = 31.0$ ,  $H_2 = 49.0$  and N<sub>2</sub>=67 pc More recently, the town of Middlesbrough now draws its entire gas supply from a battery of Otto regenerative ovens at the Newport Ironworks Also Leeds takes part of its supply from the Simon-Carvès ovens of the Middleton Estate and Colhery Co, Ltd · whilst at the Birmingham (Saltley) Gasworks a battery of 66 Kopper's regenerative ovens, fired by Mond gas, has been installed for the production of furnace coke and town's gas

COLALIN. Syn for cholalic acid

C24H40O5,H2O

COLATANNIN v TANNINS. COLCHICEINE v Colchicum.

COLCHICUM. Meadow saffron. (Colchique, Fr.; Herbstzeitlose, Ger) Colchicum autumnale (Linn); the corms and the seeds are official in the BP. and U.SP., the alkaloid colchicinn only in the U.S.P. The plant is found in meadows and pastures throughout Europe, where its crocus-like flowers, usually of a lilac hue, occur in September and October.

334 COLCHICUM

The only constituent of importance is the alkaloid colchicine  $C_{22}H_{25}O_6N$ , which was regarded as identical with veratrine by Pelletier and Caventou as early as 1820, and was recognised as a separate individual by Geiger and Hesse (Annalen, 1833, 7, 274) Its constitution has in part been clucidated, chiefly by Zeisel (Monatsh 1883, 4, 162, 1886, 7, 557; 1888, 9, 1; Zeisel and Johanny, ibid. 1888, 9, 865; Zeisel and Stockert, ibid. 1913, 34, 1327, 1339), and more recently by Windaus (Chem. Soc Abstr. 1911, 1. 904; 1915, 1. 708) According to these investigations the formula may be resolved into:—

$$\begin{array}{c|c} \textbf{MeO} \\ \textbf{MeO} \\ \hline \\ \textbf{MeO} \\ \end{array} \begin{array}{c} \textbf{C}_{\textbf{10}}\textbf{H}_{\textbf{9}}\textbf{O}(\textbf{OMe)}\textbf{NH} \ \textbf{CO} \ \textbf{CH} \,, \end{array}$$

By boiling with 02 pc sulphuric acid one methoxy group is hydrolysed and there results colchiceine  $C_{21}H_{23}O_0N, 1H_2O$ , crystals, m p 139°, or anhydrous, m p 172°, which has been described, probably erroneously, as a constituent of the plant. Zeisel regards colchiceine as a carboxylic acid; Windaus, on account of the green colouration by ferric chloride, considers By methylation it is transformed it an enol back to colchieme, and to N-methylcolchieme. Concentrated hydrochloric acid hydrolyses colchicine further, removing the N-acetyl group and finally the remaining three methyl groups, yielding colchicinic acid C<sub>16</sub>H<sub>11</sub>NO(OH)<sub>3</sub>OH Windaus obtained, by permanganate oxidation of colchicine, 3 4 5-trimethoxy-o-phthalic and succinic acids, and by potash fusion of colchicinic acid terephthalic and trimellitic (1·2·4-benzenetricarboxylic) acids, which indicates that the complex C<sub>10</sub>H<sub>8</sub> of the above formula contains a (second) benzene ring Iodine and sodium hydroxide remove one carbon atom, oxidising to  $C_{20}H_{22}O_5NI$ , which may be reduced to a substance  $C_{20}H_{23}O_5N$  Colchicine apparently contains no heterocyclic nitrogen According to D R P 279999 of Hoffmann-La Roche and Co tetrahydrocolchicine is formed by reduction with hydrogen and palladium; this base is amorphous and less toxic than the parent alkaloid.

Properties—Pure dry colcheme usually forms a yellowish varnish, softening at 142°, and wholly melting at 147°; but Clewer, Green, and Tutin (Chem Soc Trans 1915, 107, 839) obtained from ethyl acctate soft, pale yellow needles, m.p 155°-157°; [a]<sub>D</sub>-121° (0 88 gram per 100 c.c) in chloroform, -429° in water. Zeisel first crystallised it from chloroform, with two molecules of chloroform of crystallisation; according to Merck (Apoth. Zeit. 1916, 31, 399), there are two such compounds, B,CHCl<sub>1</sub> and 2B,CHCl<sub>3</sub>. The crystalline colchicine of commerce is the latter compound, in which the 14-16 p.c. of chloroform is retained tenaciously, and is only given off slowly at 100°. According to Merck, pure colchicine, dissolved in 3 parts of water, slowly crystallises as the hydrate B<sub>2</sub>,3H<sub>2</sub>O. Colchicine has a very bitter taste. It dissolves slowly but abundantly in water, readily in alcohol, chloroform, and hot benzene, hardly at all in ether. Being an acid amide, it is a very feeble base,

and one of the few alkaloids which can be extracted from acid solution by chloroform. Its salts are generally hydrolysed by water; the only crystalline one appears to be the aurichloride B, HAuCl<sub>4</sub>, mp. 209°. Dilute mineral acids and alkalis colour colchiene solutions intense yellow Nitric acid (d. 14) colours the solid alkaloid a deep violet, changing to yellow, and finally to green (characteristic) Tannic acid, phosphomolybdic acid, potassium triiodide, and bismuth potassium iodide are the most sensitive precipitants; potassium mercuric iodide only precipitates in acid solution.

Extraction, Toxicological Recognition, Assay. —These are all based on the removal from acid solution by chloroform To prepare colchicine, uncrushed seeds are exhausted with 85-90 p c. The extract is evaporated and diluted with much water, filtered from fat, and extracted with chloroform, The chloroform solution is evaporated to the consistency of olive oil and diluted warm with small quantities of alcohol, until the whitish masses which separate at first again dissolve. After cooling to 0° for some time yellow needles of the chloroform compound separate, which may be suspended in very little hot water and decomposed by steam. The aqueous solution is then evaporated in vacuo On a smaller scale, eg in the toxicological recognition, the acid solution is first agitated with petrol and then with chloroform residue, after evaporation of the latter solvent, is dissolved in water, and precipitated with tannic acid. The precipitate is decomposed with lead oxide and extracted with alcohol or chloroform On evaporation the solid product so purified can be tested by the reactions given above; 1 mg will give the nitric acid test (see also Allen's Commercial Organic Analysis,

1913, vol vn pp 4-12)
The assay of colchicum seeds and the estimation of colchicine is based on weighing the residue from a chloroform extract of an acid solution, previously washed with petrol (Farr and Wright, Pharm. J. 1891, [iii.] 21, 957; for the assay of corms, v. Lyons, ibid. 1909. [iv.] 28, 270, v also the mere complicated process of the U.S.P.)

The alkaloidal content of the seeds and corms varies greatly, mostly from 0 2 to 0.8 p c. in the seeds, from 0.1 to 0.5 pc in the corms. The Brussels Conference agreed that the seeds The alkaloid occurs to a only should be used slight extent also in the flowers. It is present in other species of the same genus, and also in the large tubers of Gloriosa superba, L. (NO. Lihaceæ), common in India and Ceylon (Clewer, Green, and Tutin, lc, found 03 p.c. of dry weight) Perhaps this plant would afford a suitable commercial source of colchicine. Colchicum is a specific in acute gout, and an ingredient of many advertised gout remedies. It is gastro-intestinal irritant, and may cause vomiting and purging. Its degradation and substitution products are much less active or without action (Fuhner, Arch. exp Path. Pharm 1913, 72, 228). G. B. Pharm 1913, 72, 228).

**COLCOTHAR.** The reddish-brown residue of ferric oxide formerly obtained in the manufacture of fuming oil of vitriol from iron sulphate.

COLEMANITE. A hydrated calcium borate Ca<sub>2</sub>B<sub>6</sub>O<sub>11</sub>,5H<sub>2</sub>O, containing 50 9 p.c. boron

trioxide It is found in California at Death Valley in Inyo Co., and the Calico district in San Bernardino Co; and although not discovered until 1882 and 1883, is now of some importance as a material for the preparation of borax and boracic acid Cavities in the massive, white material are lined with beautiful, water-clear crystals with a profusion of brilliant facets; these are monoclinic, with a perfect, pearly cleavage parallel to the plane of symmetry They are considerably harder (H 4-4½) than borax, sp gr 242. The mineral forms, together with other borates and borosilicates, a bed 7 to 10 feet in thickness in sandstones and clays

The compact minerals, priceite from Oregon and pandermite from Asia Minor, have very nearly the same composition (Ca<sub>5</sub>B<sub>12</sub>O<sub>23</sub>,9H<sub>2</sub>O), and they have been regarded as impure, massive varieties of colemante. E. S. Larsen (1917) has, however, by an examination of the optical characters established the identity of priceite and pandermite, and proved them to be triclinic and distinct from colemanite. These also are mined as borates v Boron. L. J. S.

COLLIDINE v. Bone oil

**COLLIN.** A preparation made by heating a solution of hide powder or gelatin with caustic soda and neutralising with acetic acid. Used in the analysis of tannin and tanning materials (Parker and Payne, J. Soc Chem. Ind. 1904, 648; Wood and Trotman, *ibid.* 1904, 1071)

**COLLODION** v PHOTOGRAPHY **COLLODION COTTON** v. EXPLOSIVES.

COLLOIDS. In 1861 Graham pointed out that substances which crystallise readily from water are characterised by a high power of diffusion and by the ability to pass through animal or vegetable membranes, substances, on the other hand, which cannot easily be obtained in the crystallised condition are characterised by a low power of diffusion and by mability to pass through animal or vegetable membranes. Graham termed substances of the first class, such as sucrose or sodium chloride, crystalloids; and those of the second class, such as starch, gum, or albumin, colloids The separation of a colloid from a crystalloid is effected by dialysis, a process based on the inability of a colloid to pass through parchment or other membrane

At the present time, the term 'colloid' is used in a sense different from that in which Graham employed it, and is to be interpreted as referring, not so much to a particular class of substances, as to a condition which very many, if not all, chemical elements or compounds may be made to assume From the modern standpoint 'colloidal solutions' are to be regarded as forming a special group of the physical systems built up from two substances, one of which is present in relatively small quantity. Such systems may be described as 'dispersed systems,' the substance present in excess being termed the 'dispersion medium,' and the other the 'dispersed phase.' The main groups of dispersed systems are: (1) mechanical suspensions; (2) colloidal solutions; (3) molecular solutions, the feature which characterises each group being the degree of dispersion or division of the dispersed phase From this point of view a colloid solution is a

dispersed system in which the degree of dispersion is intermediate between that of a mechanical suspension and that of a molecular solution.

Now the smallest suspended particle which can be observed directly under the microscope is of the order 0  $1\mu$ , and this size of particle may be taken as roughly marking the boundary between mechanical suspensions and colloidal On the other hand, the size of an average molecule is 0 0001 µ-0 001 µ, and although there is no haid-and-fast line of demarcation to be drawn between the three groups of dispersed systems, the dispersed phase of a colloidal solution may conveniently be regarded as consisting of particles of the dimension  $0.1\mu$ -0  $001\mu$ This conception of the continuity of dispersed systems, from mechanical suspensions at one extreme to molecular solutions at the other, finds its justification in the graded character of the physical properties of the three groups, as evidenced, for example, by observations on diffusion and filtration, and by osmotic, optical, and electrical experiments (see below). It should further be observed that the colloid condition is independent, not only of the chemical character of dispersion medium and dispersed phase, but also of their states of aggregation whilst in many colloidal solutions, such as those of platinum, arsenious sulphide or ferric hydroxide, the dispersion medium is a liquid, and the dispersed phase is a solid, there are other cases, as, for example, an aqueous solution of gelatin, in which the dispersed phase also is a liquid. The terms 'suspension colloid' and 'emulsion colloid' are commonly used to differentiate the Again, there appear to be many cases in which both the dispersion medium and the dispersed phase are solids, instances of this kind being furnished by ruby glass, some coloured minerals, and probably also alloys in certain conditions

Osmotic properties of colloidal solutions — The osmotic pressure of a colloidal solution is extremely low According to Duclaux, for instance, the osmotic pressure of an 886 pc ferric hydroxide solution is only 22.6 cm. of water, which is about equal to the pressure given by a solution of sucrose containing onethirtieth of a gram in 100 grams of water. It has, indeed, been suggested that the osmotic pressures which have been observed for colloidal solutions are due, not to the colloids themselves, but to small quantities of electrolytes associated with the colloids While it is certainly true that the removal of the last traces of electrolytes from a colloidal solution is no easy matter, and that electrolytes are extremely active material from the osmotic point of view, still the most recent investigations indicate that colloidal solutions do possess a definite, if small, osmotic pressure In this connection the epoch-making work of Perrin is of great significance, for his determination of the Avogadro number, based on a study of the distribution of suspended gamboge particles in a vertical column, really involves the extension of the gas laws to mechanical suspensions. This extension is justified by the experimental results (see Perrin's book, Atoms) and it is therefore to be expected that the osmotic pressure of a colloidal solution will be related in the usual way to concentration and temperature.

It appears, however, that the osmotic pressure of a colloidal solution may not be in every case completely defined, as is that of a crystalloidal solution, by concentration and temperature. Thus Moore and Roaf have found (Biochem J 1906, 2, 34) that the osmotic pressure of a given gelatin solution at a given temperature depends, to some extent, on its previous history, while Lillie has found (Amer. J. Physiol 1907, 20, 127, see also Bayliss, Proc Roy Soc B, 1907, 81, 269) that the osmotic activity exhibited by the colloid itself is modified by the presence of electrolytes in a remarkable degree. The osmotic pressure of a colloidal solution, it is clear, will be determined not only by the total solute concentration and by the temperature, but also by the actual degree of dispersion

The depression of the freezing-point and the elevation of the boiling-point of water by a dissolved substance are quantitatively related to the osmotic pressure of the solution, and, like the latter, may be made the basis for a determination of the molecular weight of the solute freezing-point and boiling-point of a colloidal solution are, however, very slightly different from those of water itself, and the experimental error of the determination of the molecular weight of the colloid by this method is relatively In view, further, of the fact that the osmotic activity of a colloid depends on other factors than those of concentration and temperature, it is obvious that the values for the molecular weight of a colloid deduced from its effect on the freezing-point or boiling-point of water have a very limited significance values have reference only to the particular condition of the colloid at the time of the determination

In connection with the interesting question of the osmotic activity of colloids, attention should be directed to the investigations of McBain and others on soap solutions (Chem Soc Trans 1919, 115, 1279)

Colloids in an electric field -In 1892 Linder and Picton observed (Chem Soc Trans 1892. 61, 148) that when two wires, connected with the terminals of a battery, are placed in a colloidal solution of arsenious sulphide, this substance is attracted by the positive pole and is gradually transported thither Ferric hydroxide in colloidal solution is, on the other hand, attracted by the negative pole It appears, therefore, that the particles of colloidal arsenious sulphide carry a negative charge, whilst those of colloidal ferric hydroxide carry a positive charge Other colloids are similarly found to carry a definite charge, thus chromium and aluminium hydroxides, methylene blue, Bismarck brown and hæmoglobin, are electropositive; tannin, caramel, starch, platinum, gold, and indigo are electronegative Very significant in this conelectronegative nection is Hardy's observation (J Physiol 1899, 24, 288), that protein is electronegative in an alkaline medium, but electropositive in an acid medium. A reversal of the electric charge on a colloid has been observed in other cases also (see Burton, Phil. Mag. 1906, 12, 472). The (see Burton, Phil. Mag. 1906, 12, 472). behaviour of substances in colloidal solution, when exposed to the action of an electric force is very similar to the behaviour of suspensions in the same circumstances, for when wires connected with the terminals of a battery are immersed in suspensions of quartz powder, gum mastic, or shellac, the suspended particles move towards the positive pole.

Colloids and the ultramicroscope.—The view that there must be a close relationship between colloidal solutions, on the one hand, and mechanical suspensions on the other, is strongly supported by various other lines of evidence. Thus the majority of colloidal solutions exhibit the Tyndall phenomenon, i.e. the opalescence observed when a powerful beam of light is passed through a fluid medium containing definite suspended particles. Further, the ultramicroscope, devised by Zsigmondy and Siedentopf, makes it possible to detect the individual particles in colloidal solutions, even when the most powerful microscope fails to reveal any trace of heterogeneity.

There are, however, cases on record in which colloidal solutions, even when examined with the ultramicroscope, have been found free from distinct particles. On the other hand, evidence has been adduced (Lobry de Bruyn, Rec. trav. chim 1904, 23, 155, 218) showing that solutions of a heavy crystalloid, such as sucrose, are non-homogeneous. Hence it is evidently impossible to draw a hard-and-fast line of division between colloidal and crystalloidal solutions, so far at least as the size of the particles of the dispersed phase is concerned.

The particles which are detected in a colloidal solution with the help of the ultramicroscope are seen to be in a state of constant motion—a phenomenon essentially the same as the Brownian movement exhibited by gamboge or fat particles suspended in water. The finer the particles the more rapid is their movement, and a study of the relationship between the size of the particle and its rate of movement has led to a calculation of the rate at which a particle of molecular size would move. The value so calculated is in good agreement with the value deduced from the kinetic theory, and this agreement is regarded as amounting to a definite proof of the kinetic nature of heat.

Substances in colloidal solution pass through the finest filter paper, but if the close relationship between mechanical suspensions colloidal solutions is borne in mind, it will be seen that the question whether filtration can be effected in the latter case as in the former reduces itself to the question whether filters with sufficiently small pores can be procured. The most successful attempts that have been made to solve this problem depend on the impregnation of a suitable supporting medium with a colloid such as gelatin or collodion. Filter paper, for instance, may be soaked in gelatin solution and then hardened with formaldehyde, or impregnated with a solution of collodion in glacial acetic acid and then dipped in water As the concentration of the impregnating gelatin solution is increased, the permeability of the filter to colloids diminishes, so that a series of graded filters can be prepared which may be employed to sort out a number of colloidal solutions, according to the size of particles they contain (see Bechhold, Zeitsch. physikal. Chem. 1907, 60, 257). It is noteworthy that these 'ultra-filters,' as they are called, may be

employed to separate oil-water emulsions (see Hatschek, J. Soc. Chem. Ind. 1910, 29, 125).

Another method of separating a colloid from its solution is to precipitate the colloid and then filter off in the ordinary way. It is found that in relation to precipitating or coagulating agents, solutions of suspension colloids behave differently from solutions of emulsion colloids. The former give non-viscous solutions which are coagulated by small quantities of electrolytes, these colloids are known also as 'non-reversible,' for when once they have been separated they do not again pass into solution by mere contact with water; their solutions can be obtained only by indirect methods. Emulsion colloids, on the other hand, give viscous solutions which are not readily coagulated by electrolytes, they are also termed 'reversible' colloids, because, even if separated from solution by any means, they will again pass into solution on mere contact with water.

The coagulation of suspension colloids, such as arsenious sulphide or ferric hydroxide, is brought about by extremely small quantities of electrolytes. When experiments are made to determine the minimum concentration of various electrolytes required to precipitate colloidal arsenious sulphide, it is found that this minimum concentration is of the same order for all salts containing cations of equal valency higher the valency of the cation, the smaller is the concentration of the electrolyte required to bring about coagulation In relation to colloidal ferric hydroxide, on the other hand, the coagulating power of a salt is mainly determined by the valency of the negative ion; the valency of the cation is relatively unimportant The contrast in this respect between colloidal arsemous sulphide and colloidal ferric hydroxide is very interesting in view of the fact that the colloid particles of arsenious sulphide are negatively charged, while those of ferric hydroxide are positively charged. The full significance of this was first emphasised by Hardy (Zeitsch physikal. Chem. 1900, 33, 385), who formulated the rule that the ion of an electrolyte which determines the coagulation of a colloidal solution is the one which has a charge opposite in sign to that on the colloid particles. The validity of this rule has been extensively confirmed.

The 'coagulum' or 'hydrogel' obtained when a solution of a suspension colloid is precipitated by a salt contains some of the acidic or basic part of the salt. Thus the coagulum obtained when colloidal arsemous sulphide is precipitated with barium chloride, is found to contain barium, and in proportion as the coagulum retains barium, the filtrate becomes acid. The barium cannot be removed by continued washing with water, but may be replaced by an equivalent quantity of another metal by digesting the coagulum with a colution of the chloride of this metal

If, as suggested by the facts just mentioned, the coagulation of a suspension colloid by a salt is essentially a neutralisation of electric charges, it may be expected that colloids of opposite electrical sign will precipitate each other. In harmony with this, it is found that while no coagulation occurs when colloidal solutions ('hydrosols') of the same electrical sign are mixed, precipitation immediately follows the

addition of the solution of a positive colloid to the solution of a negative colloid, unless one of the colloids is in very large excess. For a certain proportion of the colloids, the precipitation of both is complete, but as the quantities deviate from this optimal ratio, precipitation is increasingly incomplete. The precipitation of egg albumin by solutions of various complex acids—e g molybdic, tungstic, and tannic acids—furnishes an example of the mutual coagulation of two colloids. Metaphosphoric acid, too, forms a pseudo-solution or hydrosol which precipitates albumin, while the crystalloidal orthophosphoric acid has no such effect.

The separation of emulsion colloids, such as serum protein, from their solutions, may also be effected by the addition of electrolytes, but the process is essentially distinct from the corresponding precipitation of suspension colloids; it is not electrical in character When a number of alkalı salts are arranged according to their efficiency in precipitating emulsion colloids, the order is practically the same as when they are airanged according to their efficiency in salting out an organic compound from water or according to their power of lowering the solubility of gases in water. The precipitation of emulsion or reversible colloids by neutral alkalı salts appears, therefore, to be closely allied to the process of 'salting out,' and this result of itself shows that solutions of reversible colloids approximate more closely to true solutions than do solutions of suspension colloids

Not only are emulsion colloids themselves very slightly sensitive to electrolytes, but in presence of an emulsion colloid the precipitation of a suspension colloid by salts is more or less inhibited. This is not due to an increase in the viscosity of the medium and consequent increase of resistance to sedimentation, for the protective effect is exhibited by quantities of the reversible colloid insufficient to cause any appreciable change in viscosity. It is probable that the emulsion colloid forms a thin envelope round each particle of the suspension colloid and so prevents the aggregation and subsequent

flocculation of the particles.

Adsorption - Reference has already been made to a difference of electrical potential as determining in some cases the relation between a colloid and its environment There is, however, another factor which must be taken into account in the consideration of this question. and that is the relatively enormous surface of contact between the colloid and the surrounding medium. The evidence sketched in the foregoing paragraphs shows that a colloidal solution is really a two-phase system, consisting of a dispersion medium in which are distinct suspended particles of extremely small size Now, it is obvious that as a given quantity of matter is divided up more and more finely, its surface area increases regularly. The surface area, for instance, of a single sphere with a diameter of 1 mm is 0 0314 sq cm.; if the matter composing this sphere were broken up into a number of smaller spheres, each 0 0001 mm in diameter, the total surface area of the spheres would be 314 sq. cm. It is evident, therefore, that in a colloidal solution with its fine suspended particles, there must be relatively a very large surface of contact between the colloid and its medium.

Vol.  $\Pi - T$ .

On the basis of the two-phase character of colloidal solutions and the large surface development of the colloid phase, the relation of colloids to each other and to various solid and dissolved substances may be regarded as being essentially of the nature of 'adsorption.' This term is used in reference to the observation that when a substance is introduced into a two-phase system, and provision is made for its distribution throughout the system, it is frequently found concentrated at the surface of one of the phases. The nature of this phenomenon will perhaps be best appreciated by contrasting it with cases in which the substance is distributed uniformly in each phase of the two-phase system. When iodine is shaken up with two immiscible liquids, such as water and carbon tetrachloride, a state of equilibrium is soon reached at which the concentration of the iodine is uniform throughout the aqueous phase, uniform also (but different) throughout the carbon tetrachloride phase If  $c_i$  is the concentration of iodine in the aqueous layer. and  $c_2$  its concentration in the carbon tetra-chloride layer, then  $c_2/c_1$ , the 'partition coefficient, is found to be a constant, independent of the absolute values of  $c_1$  and  $c_2$ . This is a rule applicable to the distribution of any substance between two immiscible liquids, provided the molecular condition of the substance is the same in each liquid If, on the other hand, the molecular weight of the substance in the first liquid is n times its molecular weight in the second liquid, then  $c_2^{n}/c_1$  is a constant, independent of the absolute values of  $c_1$  and  $c_2$ versely, the distribution of a substance between two liquids at various concentrations has been found to be such that  $c_1^{n}/c_1$  is a constant, the conclusion may be drawn that the molecular weight of the substance in the first liquid is ntimes its molecular weight in the second liquid

The distribution of a substance in a twophase system which consists, not of two immiscible liquids, but of a solid and a liquid, is generally quite different in character. for instance, acetic acid solutions of various concentrations are shaken up with earbon, a state of equilibrium is rapidly attained, and it is found that some of the acetic acid has been taken up by the carbon If  $c_s$  and  $c_l$  represent the equilibrium concentrations of the acetic acid in the solid and the liquid phase respectively, then the experiments show that  $c_s^{\ 2\ 35}/c_l$  is a constant According to the foregoing paragraph, this would mean, on the assumption of a uniform distribution of the acetic acid throughout the carbon, that the molecular weight of acetic acid in the carbon must be less than half what it is This conclusion must obviously be rejected, and the assumption of a uniform distribution of the acetic acid throughout the carbon is incorrect. The acetic acid must be concentrated at the surface of the carbon, a view supported by the rapidity with which equilibrium is established The acetic acid is said to be 'adsorbed' by the carbon, and the phenomenon is termed 'adsorption.'

The distribution of a substance in a twophase system where one of the phases is a solid with largely developed surface, is generally found

to consist in an adsorption equilibrium. This is indicated, qualitatively, by the concentration of the substance in the solid phase increasing more slowly than its concentration in the liquid phase, and quantitatively by the validity of the formula  $c_8^n/c_l = \text{constant}$ . In this way it has been shown, to quote one or two examples, that the taking up of gases by charcoal, the removal of arsenious acid from solution by freshly precipitated ferric hydroxide, and the dyeing of silk with pieric acid and numerous other colouring matters, are all cases of adsorption. The complexes formed, although not due to chemical combination in the strict sense, and although lacking the characteristics associated with a definite chemical substance, are frequently referred to as 'adsorption compounds' As van Bemmelen especially has shown, colloids in the form of hydrogels have a very marked power of adsorbing other colloids, crystalloids and water, and evidence is accumulating in favour of the view that the behaviour of colloids in solution towards other substances is also to be interpreted in terms of adsorption.

The question may be asked: Is there any physical reason for the concentration of a substance at the surface of one of the phases in a two-phase system, such as a colloidal solution undoubtedly is? The answer is that if surface tension considerations only are taken into account, then it follows on thermodynamical grounds that the most stable relation between the two phases of a colloidal solution is the one characterised by a minimum surface tension Hence if the substance present in the solution lowers the surface tension of the solvent, that substance will accumulate in the surface layer of the solution That such spontaneous accumulations may occur in the surface layers of solutions has been shown by Ramsden (Proc Roy Soc A, 1903, 72, 156), who observed the formation of solid or highly viscous coatings on the free surfaces of protein and many other colloidal solutions

Bearing of colloid chemistry on technical problems.—The  $\imath \delta lc$  played by colloids in the operations of applied chemistry is of great importance In the manufacture of starch, cellulose, glue, leather, caoutchouc, artificial silk, paper, and photographic plates, colloids are involved, and a knowledge of the general behaviour of colloids throws much light on these and other industrial operations Many dyes give colloidal solutions, and dyeing, in a large number of cases at any rate, depends on the adsorption of the colouring matter by the fibre The relation between hide and tannin appears to be of the same description, and the investigation of the tanning process from this point of view shows the definite bearing which colloid and adsorption phenomena have on this opera-The problem of sewage disposal also is closely related to colloid chemistry, and it has been found practicable to retain the colloids of the sewage in the form of adsorption compounds. The tints of coloured glasses are frequently due to the presence of metals in the colloidal state. This is notably the case with gold ruby glass, which owes its colour to the presence of ultramicroscopic particles of the metal. Colloid chemistry has an important bearing, too, on

agricultural chemistry. Many of the properties of soils—for example, permeability, absorptive power, and moisture content-depend more on the size of the constituent particles than on their chemical composition The retention by the soil particles of materials of nutritive value for plants is closely related to the phenomenon of adsorption already discussed, and it has, in fact, been shown that the removal of dissolved substances by soil from solutions of different concentrations takes place in harmony with the adsorption formula. Colloids are of importance further in connection with the pottery trade Highly plastic clays behave like colloids, and the treatment of clay with a colloid, such as tannin, notably increases the plasticity of the material. On the view that the plasticity of a clay is determined mainly by its colloid content, and that the latter is chiefly responsible for the power of the clay to adsorb colouring matters, attempts have been made to utilise the adsorptive power of clays, say, for malachite green, as a measure of relative plasticity

Colloid clay has been found to be capable of use as a catalyst in process of oxidation and

hydrogenation

Of great interest are recent attempts to interpret the properties of many alloys in terms of colloid chemistry. The view is taken that the technical and physico-chemical properties of an alloy are largely dependent on the state of division of the constituent particles, and that in many cases the size of these particles is such as to bring them within the colloid range. The relation between tempering carbon and hardening carbon, is on these lines described as a 'dispersion allotropy' (For development of this point of view, see Benedicks, Journ Iron and Steel Inst. 1905, 352., Koll. Zeitschrift, 1910, 7, 290.)

Reference has been made above to the protective action of emulsion colloids, and this phenomenon is of frequent occurrence presence of such colloids, generally and vaguely referred to as 'organic matter,' may altogether prevent the flocculation and precipitation of insoluble compounds In presence of gelatin, for example, silver nitrate gives with sodium chloride only an opalescence which is not altered by filtration This is a fact of the greatest importance in connection with photographic emulsions (losely related to this phenomenon is the use of glues and gums as retarders in the setting of plaster of Paris, and the inclusion of such materials in mixtures which have for their object the prevention of scale in boilers Detailed references to the bearing of colloid chemistry on technical problems will be found m a monograph, Die Bedeutung der Kolloide für die Technik (Dresden, 1909), by K Arndt; in a paper on Colloid Chemistry and some of its Technical Aspects, by J. Alexander (J. Soc Chem Ind 1909, 28, 280), in W. W. Taylor's book on The Chemistry of Colloids, 1915; and in Wo. Ostwald's volume, Theoretical and Applied Chemistry, 1917. J. C. P.

collophanite. A colloidal hydrated phosphate and carbonate of calcium forming an important constituent of phosphorites and rockphosphates. It is amorphous and optically isotropic, and forms concretionary masses resembling opal or gum in appearance, with a

vitreous to resinous lustre and a conchoidal fracture. The material may be opaque or translucent to nearly transparent, and the colour ranges through colourless, white, yellow, brown, and reddish. An earthy variety is known as monte. Sp gr 2 69-2 77 (of monte 2 1), haidness 4½, refractive index 1 569-1612 A Lacioix (1910) gives the formula as:—

$$\begin{array}{l} (a[({\rm Ga_3(PO_4)_2}] + y({\rm GaCO_3} + z{\rm H_2O}) \\ x[({\rm GaF})_2({\rm Ga_8(PO_4)_6}] + y({\rm GaCO_3} + z{\rm H_2O}) \end{array}$$

which includes also the variety called fluocollophanite W T Schaller (1911) gives the formula as  $9 \text{CaO} 3P_2 O_5 \text{CaO} 2O_2 H_2 O_7 + nH_2 O$  The immeral is found in three classes of deposits; in guano deposits, having been first recognised in the guano of Sombreio, West Indies, in pockets of phosphorites, and in the phosphatic nodules and coprolites of sedimentary rocks tanging in age from the Eocene to the Siluian. Material of the last of these modes of occurrence frequently contains fluorine in addition to carbonate and phosphate, and is distinguished as fluorollophanite L J S

COLLOTYPE v. PHOTOGRAPHY.

COLOCYNTH. Bitter apple Colocynthidis Pulpa, BP, Colocynthis, USP. (Coloquinte, Fr; Koloquinte, Ger)

Fr; Koloquinte, Ger)
The dried pulp of the fruit, freed from seeds, of Citrullus Colocynthis (Schrader), a chimbing plant of the gourd family, inhabiting the warm dry districts of the Old World—India, Persia, Arabia, Syria, and the African and European shores of the Mediterianean. It is cultivated in Spania and Cyprus. (Cf. Bentl. a. Tum. 114.)

m Spain and Cyprus (Cf Bentl a Tim 114)
The BP, and USP demand that not more than 2 pc, of fixed oil be extracted by petrolcum spirit (r. Dowzard, Phaim J. 1903, 71, 400)
The B.P. demands at least 9 pc. of ash, the USP not more than 15 pc.

Chattaway and Mooi (Analyst, 1903, 28, 205) consider 8 pc a more reasonable minimum, Umney (Pharm J. 1903, 71, 879) found the ash to vary from 72-135 pc, and thinks a microscopical examination and the estimation of fixed oil better ways of detecting impurities. The seeds contain the oil, and only 2-3 pc. of ash, as they constitute 75 pc of the peeled fruit they raise, when mixed with pulp, the amount of fixed oil, and lower the ash content. The two chief varieties imported are Turkey and Spanish colocynth, of which the former is the whiter, the richer in pulp, and the more esteemed

Colocynth was well known to Greek, Roman, and Arabian medicine, and in the form of solid extract enters into many of the purgative pills of modern pharmacy.

Power and Moore, who gave an account of the earlier literature (Chem Soc Trans 1910, 97, 99), have cast doubt on the existence of the colorynthin and colorynthin of previous investigators. The former substance was described as an extremely bitter glucoside and drastic purgative, soluble in water and alcohol, but not in ether, the latter substance as insoluble in water, but soluble in ether Power and Moore examined the pulp of the fruit separately from the seeds, and the following substances were isolated · citrullol, a dihydric alcohol C<sub>22</sub>H<sub>\*</sub>, O<sub>2</sub>(OH)<sub>2</sub>, m.p. 285°-290°, yielding a

diacetyl derivative, melting at 167°; an amorphous alkaloidal substance possessing an extremely bitter taste and representing one of the purgative principles of the fruit; a-elaterin (see ELATERIUM); a small amount of hentriacontane C<sub>31</sub>H<sub>64</sub>, m.p 68°; a phytosterol C<sub>27</sub>H<sub>46</sub>O, and a mixture of fatty acids. The seeds, which represent 755 p.c. of the peeled fruit, were found to contain traces of an alkaloidal principle, a small amount of an enzyme hydrolysing \(\beta\)-glucosides, and fatty oil proportion of glucosidal substance in the fruit is found to be very small. The purgative action depends on at least two compounds, one of which is alkaloidal. After removal of the alkaloidal compound, the fruit still possesses marked purgative properties, but the substance to which these are due has not yet been obtained in a definite form

It has been sometimes required to search for colocynth in beer (v Dragendorff, Chem Zentr 1881, 285, 299). G. B.

CHROMOMETERS. COLORIMETERS. **CHROMATOMETERS** Under this heading are included those instruments (colorimeters) which are used for determining the relative intensity of colour in solutions, and those (chromatometers, tintometers) which are used to obtain a numerical record of the hue and intensity of a colour.

Colorimetric measurements depend on obtaining equal intensity of colour in two columns of liquid, one of which contains a known amount of the substance to be estimated This can be done either (a) by varying the concentration of one liquid, keeping the lengths of columns equal, or (l) by altering the length of one column,

keeping the concentration the same

The first method is used in Nessler's test, in Eggertz' method of estimating 'carbon in steel, and in the simple colorimeter of the US Geological Survey (Bulletin 422) It is ap-Tĥe plicable to all colorimetric measurements second principle is adopted in most cases because it allows the repeated use of the standard solution and facilitates rapid work In certain cases, however, eq. in comparing manganese solutions, this method fails, as varying the length of column changes the hue as well as the intensity of the colour.

The standard used may be of the same composition as the liquid under examination, or may be made of any suitable materials, but its colour must be identical in quality with that of the liquid tested, and its value per unit volume in terms of the substance estimated must be accurately known Thus the permanent standards used in the estimation of combined carbon in steel are generally made of mixed solutions of metallic salts, and in the estimation of ammonia in water a solution coloured with caramel and a little aniline red has been used (Leeds, Chem. News, 37, 229)

Equality of tint having been obtained, the lengths of the columns are noted, and the comparison is repeated, using, preferably, a different length of column of the standard.

The relative strength of the solutions varies inversely as the lengths of the columns, so that if 1 cc. of the standard solution correspond with x parts by weight of the substance estimated, the weight of that substance in 1 c c of the test solution will be

length of column of standard solution  $\times x$ length of column of test solution

If the strength of the standard differs by more than 10 pc. from that of the test liquid, it is advisable to dilute one or other before comparison

For the examination of precipitates, a solution of considerable suspensory power is prepared by dissolving 100 grams of gelatine, 100 grams glacial acetic acid, and 1 gram of salicylic acid (to prevent decomposition of the gelatine by

keeping) in 1 litre of distilled water.

The solution is clarified with white of egg and filtered hot For estimation of sulphuric acid, this solution is charged with barium chloride, and is added to a weak standard solution of sulphuric acid or a sulphate and to the solution to be tested, the two turbid liquids being then compared as above By the use of other reagents, lime, vinc, and a large number of other substances may be estimated.

A useful colorimeter for general purposes, devised by Mills, is shown in Fig. 1. It con-

sists of a glass jar closed above by a cap of which the length is sufficient to cover the top of the liquid The cap is perforated in middle and carries a short tube in which slides a glass rod bent as shown, and supporting, exactly at right angles to the axis of the jar, a flat circular opaque white In the bottom of the jar are laid, one above another, a red and a green glass disc which form a black background to the white disc When examining solutions of certain colours, a background of a colour other than black may be advantageous, and the white disc itself may be covered by a coloured plate The white disc is lowered to the bottom of the par by moving its rod, and the jar is filled to exactly 100 divisions with a standard liquid.

The white disc is raised until, on looking vertically down through the liquid at the disc, the depth of tint appears suitable. A second apparatus is then filled to 100

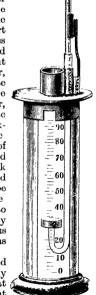

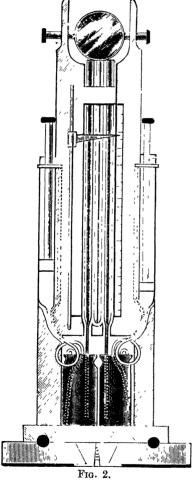

Fig 1.

divisions with the liquid to be tested and its disc is adjusted until the colours of the columns of liquid in the two jars appear of equal intensity.

By placing on the white disc a small, black, hemispherical button, this instrument may be used for determining the strength of turbid solutions, such as milk, or for ascertaining the amount of a precipitate suspended in a liquid. Milk is diluted before examination with 99 parts of water, and is compared with a similarly diluted milk of known quality, the disc with the button being adjusted in each tube as above until just invisible.

The slight alteration in the level of the liquid caused by the varying length of the sliding tube contained in the liquid when adjusting the height of the white disc is found by experiment, and a correction must be introduced into the calculation for variations of more than two or three divisions.

A very useful colorimeter, especially designed for the estimation of carbon in steel, but of course available for other purposes, has been introduced by Stead (Proc Iron and Steel Inst 1883, No 1, 213) A similar, but more convenient apparatus, devised by Ridsdale (J. Soc. Chem. Ind. 1886, 586) is shown in Fig. 2. Three glass tubes, each fitted below with a small,

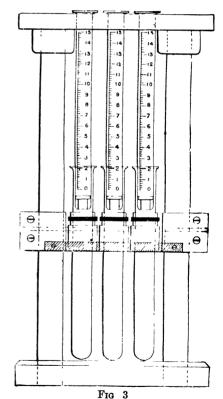

opaque, white cylinder, are placed beneath a movable mirror, in a stand which may be turned to any position upon its weighted base. The central tube is removable and is closed below; the outer tubes are drawn out and pass through indiarubber corks into ruby glass bottles, containing standard solutions of different strengths. Each bottle has a tube with a stopeock through

which the liquid may be introduced or removed, and each is connected by a flexible tube with a syringe.

The liquid under examination is introduced into the central tube, and by working the syringes the standard solutions are raised in their tubes until the intensity of colour in each tube, as seen by looking into the mirror which is adjusted to reflect the light passing upwards through the tubes, is identical. Two distinct comparisons are thus simultaneously made, and, by noting the height of each column by means of the sliding pointer, the strength of the tested liquid may be ascertained from the formula already given. A very important advantage of this apparatus is that every part except the central tube is cleansed and recharged without disconnection.

Ridsdale (J Soc Chem Ind 1888, 70) has devised an apparatus for the examination of liquids of deeper tint than can be used in the foregoing apparatus. The central upper tube (Fig 3) is sealed below, the upper side tubes are perforated at the bottom. Each tube contains a loose white opaque plug, and each is held at

any height by a movable jaw pressed against it by an indiarubber band

The centre tube is charged with, say, 10 divisions of the standard solution, and the test liquid is run into one of the side tubes, whence it passes at once into the lower tube. When this is nearly filled, it is gradually raised to bring a portion of its contents into the upper

tube, until, on looking down vertically, the colours in the upper side tube and in the standard tube are of equal intensity. The calculation is made as already described. The lower tube beneath the standard tube must be raised with that of the side tube in order to equalise the effect of the double thickness of glass. When the solutions to be tested differ widely in tint, the standard tube may be perforated so that the length of its column may be readily adjusted.

Stokes' apparatus (Chem Soc Proc 1887, 135) has two tubes placed vertically in a stand with a reflector below. One tube is connected with a reservoir of the standard solution, by raising or lowering which the level of liquid in

the tube can be altered

A similar arrangement is used in Le Docte's colorimeter (Eng. Pat. 20667, 1898)

The Kennicott-Sargent colorimeter (Chem Engineer, 1907, 213) differs from the above only in altering the level of the standard liquid by moving a glass plunger in a fixed cylindrical reservoir

Another arrangement, in which the standard liquid is forced into a graduated tube from a reservoir, is described by Gunsberg (Dingl poly J. 228, 457).

The Nesslerising tubes adopted by Hehner (Chem News, 33, 185) and recommended by Milne (J. Soc. Chem Ind 1887, 33) are two cylinders of equal and perfectly uniform diameter, holding about 100 c c Each is graduated from below, and at about the 30 c c division has

a glass stopcock.

The two cylinders are placed side by side on white paper, and to one of them is added 100 c c of the liquid to be tested, followed by 2 c c of To the other tube a suitable Nessler's solution and known amount of standard solution of ammonium chloride is added, and the volume is made up to 100 cc. with distilled water, after which 2 c c of Nessler's solution is added two liquids are looked at vertically, and the darker is allowed to slowly run off into a clean beaker, until their colours are equal The comparison may be repeated after filling up from the beaker The mode of calculation is the same as in former cases

A modified form of Eggertz tube has been described by Hogg (J. Soc Chem Ind 1895, 1022)

In a colorimeter devised by Leeds (Chem News, 37, 229) comparison tubes are arranged in a rack, light being reflected through them by an inclined upper mirror, and again reflected to the eye of the observer from a mirror similarly placed beneath them. The standard liquid is contained in a bottle prism which is moved beneath one of the comparison tubes containing distilled water only until the colour observed is identical with that in the tube containing the test liquid. The strength of the test liquid is calculated from the thickness of liquid in that section of the prism which is interposed.

Gallenkamp's colorimeter (Chem Zeit Rep 1891, 324) consists of two vertical troughs enclosed in a metal frame. That which contains the standard solution is wedge-shaped, while that for the test liquid is rectangular. An observation apparatus, moving vertically over a scale of 100 parts, has two slits at the same level, one

opposite each trough, the light from which is reflected and brought into one eyepiece. The observation consists in finding the thickness of the stratum of standard solution in the prism, which shows the same depth of colour as the test liquid.

White's apparatus differs from the above in having two wedge-shaped tanks, both movable with reference to two fixed slits through which

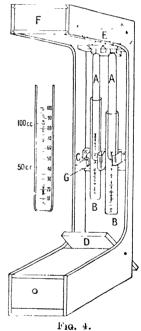

the depth of colour is observed

A colorimeter, described by Autenrieth and Koenigsberger (Chem Zentr 1910, 1 2032) and recommended especially for the determination of hæmatine in blood, depends on comparison of the test liquid with a stable solution of similar hue contained in a wedge-shaped reservoir which is movable vertically beside the trough containing the test liquid. The movement of the wedge is measured on a millimetre scale, and the reading translated directly into percentages by reference to a plotted curve The two colours are observed through a Helmholtz 'Doppelplatte,' which obviates a dividing space in the field of view By substituting a suitable wedge, the instrument can also be used for the estimation of titanium, iron, chromium, iodine, ammonia, nitric acid, &c

Schreiner's colorimeter (J. Amer. Chem. Soc. 1905, 1192) consists essentially of two parts.

wide flat-ended tube, B, about 26 cm × 3 cm, graduated in millimetres, and the flat-ended immersion tube A, about 26 cm × 2 cm, which slides inside the wider tube

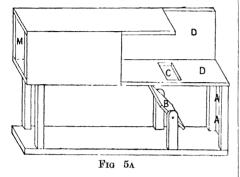

Two such pans of tubes are mounted on stand (Fig. 4), the inner tubes being fixed to the top the camera οf while the outer tubes are held in brass clips which them in position, but permit their being moved up and down. The length of the column of liquid enclosed between the ends of the outer and inner tubes can thus be adjusted at will Light,

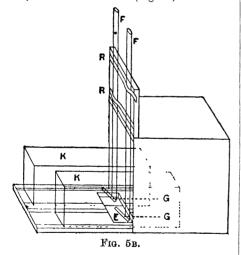

reflected from a white surface D, passes through the two columns of liquid, and is then reflected at a mirror E to the observer's eyes at F. The axes of the tubes are inclined to one another so as to bring the images close together Standard glass slides may be inserted at G in place of one of the wide tubes, the immersion tube being left in position.

Patterson has described (J Soc Chem Ind 1890, 36) a more complex apparatus employing the same principle. In this case the adjustment of the concentric tubes is made by rack and pinion, and total reflection prisms are employed to bring the two images into one eyepiece. By substituting a direct-vision spectroscope for the eyepiece, the apparatus becomes a spectrum absorptimeter.

The simple and effective colorimeter devised by Steiger (J. Amer Chem Soc. 1908, 215) consists of two wooden boxes painted dead-black inside, one of which (Fig. 5A) is mounted on a

stand and has a rectangular opening c in the base, while the second box (Fig. 5B) fits into the

first, and has a rectangular opening, E, which coincides with c

In the base of this box are two grooves in which slide two rectangular glass cells  $\kappa$ ,  $\kappa$ , about 15 cm long  $\times$  25 cm wide  $\times$  5 cm deep.

Fixed vertically over the opening E are two glass rods F, F, held in place by the springs R, each carrying at the lower end a small plane mirror, G, fixed at an angle of 45°. Light coming through the ground-glass A is reflected by a mirror, B, through the aperture E into the tank, where it is again reflected at the mirror G and passes through a column of liquid, the length of which can be altered by moving the tank backwards and forwards. When equality of colour is obtained, the lengths of the columns are read

off on millimetre scales engraved on the base of each tank. The reading is taken where the lower edge of the mirror touches the bottom of the tank

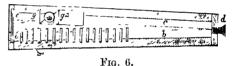

Otto's ozonometer has two parallel tubes for gases or liquids, and employs wedges of coloured glass moving over a graduated scale as a means of measuring the depth of tint (Eng. Pat. 17524, 1892).

H Kruss suggests (Zeitsch anorg Chem 5, 325) the application to colorimeters of the Lummer-Brodhun double prism, which gives a field of view in which there is no visible line of separation between the two colours under observation. This condition gives maximum accuracy in matching the colours (see also Chem Soc Abstr 1894, ii 158)

Andrieux (Compt rend 103, 281) describes an apparatus in which the *quality* and *intensity* of a colour are determined by comparison with a ray of polarised light

An apparatus has been described by Meisling (Zeitsch anal Chem 1904, 137), in which the hue is matched by the colour of a quartz plate in polarised light, and the intensity is measured by varying the length of the column of liquid

An ingenious instrument, introduced by Mr. J. W Lovibond, for the examination of liquids, powders, fabrics, &c, and known as the tintometer, is shown, partly in section, in Fig. 6. It

consists of a box, closed at one end by a ground glass plate, e, and separated into two divisions b, c. The box is carried by a stand, adjustable to any angle A square glass cell, of known width, along the line q'  $q^2$ , containing the solution to be examined, is placed in one division, and glass plates h of similar colour (or, if necessary, of different colours, producing the proper tint in combination), and of known intensity, are placed in grooves in the other division, until, on looking through both tubes simultaneously through a single eyepiece, d, shaded to prevent access of side light to the eye, the appearance through the glass plates is identical with that through the solution.

The standard plates are specially prepared of various colours, and each is distinguished by a number indicating its colour, and another number showing the intensity of colour, i.e. the number of plates of that colour of unit intensity required to produce an intensity equal to that of the plate. The unit chosen by the inventor for each colour is an arbitrary one, but its actual value can be ascertained at any time by comparison with a standard solution of similar colour.

In some cases the glass plate e is wanting, and an adjustable plane glass mirror is used to reflect the light to the apparatus (Eng Pat 12867, 1886)

When the colour of a fabric is to be estimated, the fabric is stretched on a block placed in the division c, and a white fabric of similar texture, previously compared with a plate of pure plaster

The stanof Paris, is placed in the division b dard plates are then inserted as above until the appearances through the eveniece are identical. Powders, sugars, &c, pressed in a small tray placed in the division c, may be similarly examined, a tray containing pure plaster of Paris being placed in the division b (J Soc Chem. Ind 1888, 234)

For very delicate observations, the intensity of the light used may be found and noted, before commencing, by closing the division c and placing in the divisions b as many standard plates of neutral tint as serve to obstruct all the

light

The substitution of a movable wedge of coloured glass for the standard plates makes the apparatus available for ordinary colorimetric determinations († Soc Chem Ind 1888, 234). An improved form of Lovibond's apparatus is binocular, and has a movable diaphragm makes it applicable to tests of colour vision (ibid 1891, 489) (see also Lovibond, ibid. 1909,

Procter has described (ibid. 1895, 123) a modified form of tintometer in which, by a system of mirrors, the colours to be compared are brought close together in the field of view,

thus giving greater accuracy Sczepanik (Eng. Pat. 22995, 1907) has patented an ingenious apparatus with which a numerical record of any colour can be obtained Three strata of liquid of the three primary colours are superimposed. The thickness of each stratum can be measured and altered independently of the others, and thus any hue or intensity of colour can be matched

Gardner and Dufton have introduced the 'Dalite' lamp, which gives a light of the quality of daylight, and may be used for tintometric work (J Soc Chem Ind 1904, 598) This lamp is also of use in performing titrations by

artificial light.

A useful device, introduced by Dupré (Analyst, 5, 123), may be mentioned under this heading In the volumetric estimation of silver with potassium chromate as an indicator, especially when the solution is weak, it is somewhat difficult, on account of the original yellow colour of the solution, to observe the first tinge of red produced by the formation of the silver Dupré interposes, between the eye chromate and the test liquid, a flat glass cell (of which the faces are about half an inch apart) containing a solution of potassium chromate of such strength as will neutralise the colour of the test liquid, which thus appears perfectly colourless, and in which the faintest appearance of red is readily visible The cell filled with other liquid may be similarly adopted in many other titrations

Kong (Proc Amer Phil Soc [18] 7, 29, 184, 208, 211) has devised a method for estimating metals by the intensity of the colour imparted by them to the borax bead He dissolves a known weight of the oxide in a known weight of borax, grinds the bead until its faces are flat, coats it with Canada balsam to render its rough faces transparent, and places it in an apparatus where it is viewed by a lens of small power, while, by means of a rack, a glass prism whose colour is complementary to that under examination, is moved before it until such a thickness is interposed that the colour of the bead is extinguished.

A photochemical process for estimating differences in the intensity of a colour has been described by E. J. Mills and Buchanan (J Soc. Chem Ind 1888, 309) It has been applied to the comparison of dyed goods. A number of discs of the tissues are photographed on one negative from which a number of positives on paper sensitised with silver, are copied are treated as usual, soaked for a considerable time in sodium thiosulphate to remove the whole of the unaltered silver salt, well washed, and dried. The disc photographs of each tissue are cut from a number of positives and each set is burned separately The silver in the residue is dissolved and estimated volumetrically relative amount of silver found in the different sets of discs directly represents the relative intensity of the colours.

The following colorimetric process for the estimation of minute quantities of sulphur in iron, mineral waters, black ash, slag, &c, is due to Wiborgh (Chem Zeit 10, 92, Chem News,

1886, 54, 158).

The divided metal, ore, &c, or the concentrated solution, is introduced into a small flask provided with an indiarubber cork, through which passes a stoppered funnel for introduction of acid, and a narrow-mouthed funnel ground at A disc of white calico, which has been previously saturated with a solution of 5 grams crystallised cadmium nitrate (or, preferably, cadmium acetate) in 100 c c of water and dried in a horizontal position on a cloth, is fixed between two indiarubber rings of the same interior diameters as the standard discs hereafter described, and the rings are firmly clamped over the funnel mouth Dilute sulphuric acid is poured into the flask and heat is applied from 30 to 45 minutes the whole of the sulphur which is capable of conversion into sulphuretted hydrogen has passed off in that form and has been wholly absorbed by the cadmium salt on The disc is removed and compared the calico with a set of standard discs, similarly prepared from iron containing a known amount of sul-The standard discs should not be exposed too freely to light Arsenic, carbon, silicon, and copper do not appear to affect the determination. This method is so delicate that a disc will show a tinge of the yellow colour due to the cadmium sulphide when so small a quantity as the 1000th of a milligram of sulphur is present per square centimetre

COLOUR AND CHEMICAL CONSTITUTION. The object of this article is to give as concise a description as possible of the various rules which have been established, and the theories which have been proposed, with regard to the relation between colour and chemical constitution, particularly to the colour of dyes, with special reference to those rules which have proved of value in the preparation of dyes and which have served as guides for modifying the

colour in a group of dyes

Outline -The first Historical synthetic dye (mauve) was produced by Sir W. H. Perkin in 1856. This branch of synthetic chemistry developed with great rapidity, and in the next twenty years the first members of many important groups of dyes had been prepared, eg. fuchsine (1859), rosaniline blue (1860), and alkylated triphenylmethane dyes (1863–1866);

Bismarck brown (1864), chrysoidine (1876), and naphthol orange (1876) in the azo- group, Martius yellow (1864) in the nitro- group, Magdala red (1868) in the azine series; alizarin (1869) of the anthraquinone group; fluorescein and cosin (1874), representing the phthaleins, and Lauth's violet (1876), foreshadowing the thiazines. By this time sufficient material had been accumulated to allow the formulation of the well-known Witt's Rule (1876), according to which substances attained the potentiality of colour when their molecules contained certain atomic arrangements or groups, which Witt termed chromophores The colour and dyeing properties were made manifest by the introduction of additional groups termed auxochromes
